These figures show that, particularly, in 1918-19, the cost of dry fodder was very high, owing to the high price of bought fodder.

By means of special researches, the *total work* devoted to hay-making and to the aftermaths was determined. The work thus utilised, calculated per quintal of dry fodder is given below :

	1916–1917		1917–1918		1918–1919	
	Hay-making	Aftermath	Hay-making	Aftermath	Hay-making	Aftermath
Hours worked by the men	1.06	0.72	1.23	0.45	0.96	0.28
Hours worked by the teams	0.79	0.95	0.98	0.30	0.54	0.23

(7) *Fruit-growing.* — Fruit-growing is not important at Neuhof, but all the same it gave very satisfactory results during the last two years. The net yield was :

	Total (fr.)	As % invested capital (fr.)
1916–1917	178.58	2.75
1917–1918	2 391.40	38.55
1918–1919	1 284.18	24.88

The production costs and market prices were as follows :

	1916-1917 Fr.	1917-1918 Fr.	1918-1919 Fr.
Production costs :			
Fruit for the household	35.06	5.16	13.29
Fruit for cider-making	19.28	2.58	7.59
Market prices :			
Fruit for the household	20.00	20.00	35.00
Fruit for cider-making	11.00	10.00	20.00

(8) *Forest crops.* — These occupy an area of 325 ares. The stand, partly made up of broad-leaved trees, is below the average. The profitable sale of a few high trees and of thinned-out wood gave a positive result in 1917-1918, but during the other 2 years, the expenses were not covered by the growth.

(9) *Draught horses.* — The appended statement shows the hours of work performed by the horses.

	1916-1917	1917-1918	1918-1919
Total	9 179	11 283	11 946
Per hectare	250	254	269
Per day fed.	7	8	8

The costs per hour worked by the horses were :

in 1916-1917	0.65 fr
in 1917-1918	0.74 fr
in 1918-1919	0.81 fr

Taking the duration of the work as 10 hours, the cost of a driver with a team of 2 horses was :

in 1916-1917	19.52 fr
in 1917-1918	21.32 fr
in 1918-1919	24.80 fr

The increased expense is mainly due to the heavier cost of feeding.

(10) *Draught oxen.* — The cost per hour worked by oxen was :

in 1916-1917,	0.469 fr
in 1917-1918,	0.255 fr
in 1918-1919,	0.372 fr

The oxen were not worked so intensively as the horses. During the 3 years, they yelded 91,44, and 30 hours of work per hectare and 3 1, and 1.7 hours of work for each days food.

(11) *Milking cattle.* — The number of cows was as follows :

in 1916-1917	17.9	head
in 1917-1918	15.1	head
in 1918-1919	16.6	head

The total cost of the dairy cattle was as follows :

in 1916-1917, :—	3,23	fr.	per	day	per aw and	1179	fr	per	annum.
in 1917-1918, :—	3,56	»	»	»	»	1300	»	»	»
in 1918-1919, :—	5,38	»	»	»	»	1965	»	»	»

The cost of feeding alone amounted :

in 1916-1917, to	2,19	fr.	i. e,	67.69 %	of the	total cost
in 1917-1918, to	2,13	»	»	59.52 %	»	» » »
in 1918-1919, to	3,59	»	»	66.77 %	»	» » »

The money value of the milk produced, the calves, manure, growth, and work is given below.

	Per day's food (fr.)	Per cow per annum (fr.)
1916–1917	2.66	9 71
1917–1918	2.13	7 77
1918–1919	4.14	15 11

The total yield from the dairy cattle was thus inferior to the expenses and the deficit per cow per year was 208 fr. in 1916-17, 523 fr. in 1917-18, and 454 fr. in 1918-19, with the following production which, being above the average, can be considered as sufficient :

Production	1916–1917	1917–1918	1918–1919
	litres	litres	litres
Total milk	54 646.4	46 363.4	47 071.6
Per cow per day	8.38	8.39	7.75
Per cow per year	3 059	3 063	2 829
Per 100 kg. of starch value	114.4	111.7	103.7

The milk was partly sold (6 429.6 litres in 1918) and partly consumed by the household (10 921 litres in 1918), partly separated for butter-making (14 540 litres in 1918), partly fed to calves (15 141 litres in 1918), and partly fed to pigs (40 litres in 1918).

The separated milk yielded :

in 1916-1917,	873.14	kg.	of	butter,	or	4.12	kg.	per	100	litres of milk
in 1917-1918,	488.32	»	»	»		3.89	»	»	»	» »
in 1918-1919,	606.11	»	»	»		4.17	»	»	»	» »

Assuming a price of 10 centimes for skim milk in 1916 and 1917, and 14 centimes in 1918, butter making increased the value of the milk to 25.94 centimes in 1916-17, 32.77 centimes in 1917-18, and 43.84 centimes in 1918-19. As the price of milk was 21, 26.7, and 32.5 centimes during the 3 years, and that of butter 4.35, 5.95, and 7.50 fr., butter making results appear more profitable than milk selling, assuming the milk to cost 25.52, 30.32, and 42.26 centimes at the shippon, for the 3 years under survey.

The cost of production is thus considerably above the sale price of the milk, but less than the yield from butter making.

Allowing for the cost of feeding and for the capital it represents, the capital invested in the exploitation of dairy cattle amounts, in round figures,

to 55 000 fr., or about 25 % of the total capital. This capital gave the following net yield :

	Total	%
1916-1917	275.43 fr	0.51
1917-1918	1 480.90 »	2.96
1918-1919	3.11 »	0.005

The chief cause of these unfavourable results is the increase in the cost of feeding and the decline in milk production.

(12) *Young stock.* — This account includes all the cattle from birth to the moment when they become cows, bulls, or draft oxen. The profit from some 14 head during the 3 years was, 1.11, 9.86, and 35. 0% respectively, Again the gain of 1 kg. in weight cost 2.33, 3.18 and 3.69 fr., respectively, for the 3 years. The increase in weight during the 3 years is given in the appended statement :

	1916-1917	1917-1918	1918-1919
Total gain . . . . . kg	3 374	2 637	3 371
Gain per day per head . . . . . »	0.63	0.51	0.67
Gain per 100 kg. starch value . . . . . »	23.6	13.0	23.2
Value of the gain . . . as a total . . fr.	7 442	9 517	11 699
Value of the gain . . . per kg. . . . »	2.25	3.61	3.47

(13) *Pigs.* — The yields from pigs consist of increase in weight, manure, and eventual profit from the use of the boar. The increase in weight during the 3 years is given below :

	1916-1917	1917-1918	1918-1919
Total . . . . . kg	3 816	3 304	1 759
Per day per head . . . . . »	0.233	0.193	0.128
Per 100 kg. starch value . . . . . »	15.1	18.9	15.3

It should be observed that, during the last 2 years, Neuhof has mainly gone in for rearing, not fattening, so that the increase in weight is very small. During the 3 years, the value of the gain in weight was 2.70, 5.92, and 8.54 fr., respectively, and the corresponding expenses 3.09, 3.63 and 6.97 fr. The profit per 100 fr. of capital invested was 12.10 fr. in 1916, 59.72 fr. in 1917 and 22.93 fr. in 1918.

(14) *Poultry.* — At Neuhof there are 30 fowls, on an average, to provide the household with eggs, which are only sold on exceptional occasions. The egg production was 90, 72, and 42 eggs per fowl per year for the three seasons. The results for 1918 were very moderate.

A few figures relating to the profit are appended :

	1916-1917	1917-1918	1918-1919
Cost of production . . . . . per egg	19 centimes	16 centimes	33 centimes
Market price. . . . . » »	20 »	30 »	36 »
Profit . . . . . » »	1 »	14 »	3 »
Net yield per 100 fr. of capital.	9.16 %	26.50 %	16.89 %

(II) *Final account.* — In this account are found the income, profit net yield, etc., for the whole farm. The net yield as a percentage of the, capital invested is given in Table V and is the only item that we quote.

TABLE V. — *Net yield of Neuhof as a percentage of the capital invested.*

	1916-1917	1917-1918	1918-1919
Winter rye	—	0.88 %	—
Winter wheat	7.12 %	19.78	25.74 %
Winter barley	7.53	—	—

Total for livestock:	**0.08 %**	**12.33 %**	**4.87 %**
Fruit crops	2.75	38.55	24.78
Forest crops	— 1.96	16.51	— 4.40
Total net yield:	**6.35 %**	**17.69 %**	**19.78 %**
Expressed in money, the net yield is :			
For the field crops . . . . . fr.	12 441.10	17 277.15	35 545.98
For the livestock . . . . . »	88.29	14 023.23	5 470.56
For the fruit crops. . . . . »	178.58	2 391.23	1 284.18
For the forest crops. . . . . »	— 68.55	768.54	— 222.39

Table V clearly shows the growing superiority of field crops, which are favoured at Neuhof by the work of the pupils. For details regarding

this work and its valuation, a report by the author (Part. 1 of the *Annuaire Agricole de la Suisse*, 1918, pp. 41-114) may be consulted.

Only in 1917-1918 did the livestock give an appreciable return.

The *conclusion* arrived at is that, at Neuhof, no restriction can be placed on field crops for the moment, as they ensure the revenue of the undertaking, whilst conserving the exploitation of livestock as far as possible. In time, the area occupied by natural meadows will be reduced to the proportion strictly necessary, and the artificial meadows and field crops will benefit from the largest possible area.

575 – **Cost Accounts on a Fruit Farm in Scotland.** — James Wyllie (*West of Scotland Agricultural College*) in *The Scottish Journal of Agriculture*, vol. I, nº 23, p. 301-306. Edinburgh, July 1918.

Arrangements were made in 1914 by the West of Scotland Agricultural College to keep a detailed record of costs on a fruit farm at Nemphaar, near Lanark, with a view of obtaining data as to the relative efficiency of various fruit farming rotations. This work is still in progress, but in view of the paucity of systematic accounts of this kind, the author has thought it useful to publish the first results :

Blank forms were distributed for : — *a*) manual labour, *b*) horse labour, *c*) general expenditure, *d*) receipts.

Duly completed they were sent back to the College, where the tabulation of results and preparation of accounts were done under the direction of the author.

By this means, records were kept for the following : strawberries, gooseberries, raspberries, and black currants. The last two crops were not handled to any large extent ; the data contained in this report refer then to the two first.

Example of cost account. — In the first place, the author gives as an example in Table I, the completed cost account to indicate the method pursued.

No charge is indicated concerning the cost of management. The omission is justified by the fact that the net profit shown may be considered as the farmer's " labour income."

Cost of planting strawberries in 3 successive seasons. — The data obtained with regard to this subject is summarised in Table II.

The low cost of planting in 1916. was due to :

1) the cost of the plants which was only 2s 6d. per 1 000 compared with 5/– and 7/– in 1915 and 1917 respectively ;

2) to the smaller expenditure on hoeing and weeding.

Cost of production and returns. — *Strawberries.* — Table III gives the average cost of production, yield, value of crop and net profit per acre, and the average sale price per lb. and per cent. for each of the three years.

It is necessary to state that in 1915, there were five fields involved (three under 1st crop, one under 2nd and one under 3rd), in 1916 also five

(one under 1st crop, three under 2nd and one under 3rd), and in 1917, only three fields (one under 2nd crop, and two under 3rd).

This partly explains why the cost per acre in 1917 had increased so little compared with 1915 ; in 1915 the total cost of £ 45 per acre had been divided as follows ; £ 20 for crop I, £ 15 for crop II, and £ 10 for crop III.

The most noticeable feature in Table III is the extraordinary fluctuations in yield. Independantly of the variety cultivated, and whether first, second, or third crop, the predominating factor seemed to have been the weather.

This table indicates also that the existing methods by which the fruit reaches the consumer are far from being economical.

TABLE I. — *Cost account.*

Field. — No. 3 (b). *Strawberries.* — Second crop.

P = Piecework

LABOUR REQUIREMENTS OF STRAWBERRIES. — Accurate records have been kept of the time spent (man and horse hours) on each field, and from these the following table has been constructed.

TABLE II. — *Cost of planting strawberries*

Year	Field	Acreage	Cost per acre
		Ac. ro. po. yds.	£ s d
1915	3 (b)	2 1 9 20	44 7 3
1916	1 (b)	2 0 0 0	31 15 4
1917	10 (a)	1 1 25 0	63 15 7

TABLE III. — *Cost of Production and Returns - Strawberries*

Year	Acreage	Average cost of production per acre	Average yield per acre	Average Sale Price		Average value of crop per acre	Average net profit per acre
				Per lbs	Per cwt		
	Ac. ro po yds	£. s. d.	lbs	d.	s. d.	£. s: d.	£. s. d.
1915.	7 1 23 14	38 2 9	5063	3.27	30 6	68 19 9	30. 17. 0
1916.	7 0 33 4	36 8 2	2166	3.07	34 3	33 2 1	3. 6. 1 (loss)
1917.	3 3 39 4	41 1 8	3739	5.62	52 6	87 10 8	44. 9. 0

TABLE IV.

Year	Hours. Man Labour		Hours. Horse Labour	
	Per acre	Per cwt.	Per acre	Per cwt.
1915	1134	25	21	.5
1916	1017	53	18	1.
1917	956	29	17	.5

The cost of manual labour, apart from the labour of planting, constituted about 43 % of the total cost of production. The average cost per hour being 3.4*d* per hour in 1915. 3.6*d* per hour in 1916, and 4.3*d* per hour in 1917.

The varietes grown were Ruskin, Lord Overtown, and Bedford Champion.

Gooseberries. — A single field extending to nearly 4 ½ acres was cultivated with gooseberries, variety "Whinham's Industry." The relative data in connection with the crop are shown in Table V.

The variations in yield are more noticeable than those associated with strawberry growing.

Whilst 1915 and 1916 showed handsome profits, they were lowered in 1917. As regards labour requirements, it requires about the same amount as strawberries, but in 1916 the proportion rose however to 5.1 % of the total cost of production.

These first results in the culture of small fruits on agricultural holdings on a industrial base, are certainly not sufficient to draw conclusions from.

The different elements of risk seem so considerable that they necessitate investigation as to the total yearly profit a loss over a period of years, in order to make it feasible to establish exact averages.

Furthermore, research work should be extended over a wide area in order to eliminate the effect of local conditions as much as possible.

TABLE V. — *Cost of Production and Returns* - Gooseberries.

Year	Average cost of production per acre	Average yeld per acre	Average sale price per cwt	Average value of crop per acre	Average net profit per acre	Man hours		Horse hours	
						per acre	per cwt	per acre	per cwt
	£. s. d.	cwts	s. d.	£. s. d.	£. s. d.

1916	38.11.6	74.7	20 0	75 13 10	37 2 4	1093	15	46	6
1917	11. 6.5	74	40 0	14 14 8	3 8 3	136	18	3	2

* Includes £ 15 for potatoes interplanted amongs young bushes.

AGRICULTURAL INDUSTRIES

INDUSTRIES DEPENDING ON ANIMAL PRODUCTS

576 – **The Production of Alcoholic Fermentation by Adding Pure Yeasts.** — CAUDA, A., in *Le Stazioni sperimentali agrarie italiane*, Vol. III Pt. 10-12, pp. 524-535. Modena, 1919.

The author has carried out several fermentation experiments with juice from Malaga raisins or from sterilised Nebbiolo di Barbaresco grapes. Except control samples which were fermented naturally without any addition, selected Barbera and Canaiolo ferments were added to the must, as well as some nutrient substance, such as monopotassium phosphate (0.05 gm. %), or ammonium carbonate (0.2 gm. %), asparagin (0.2 gm. %), or peptone (0.2 gm. %). Fermentation developed rapidly in the musts to which nitrogen had been added in the following order : — first to the must treated with ammonium carbonate, then to that containing asparagin, and finally to that containing peptone. Fermentation lasted much longer (over 105 days) in the control must to which nothing had been added and in that which contained phosphate. The phosphate also assisted the growth of the ferment, but the nitrogenous compounds, especially ammonium carbonate and asparagin, were more efficacious. It seemed as if the musts aged more rapidly owing to the addition of nitrogenous compounds ; in fact they had a yellowish colour (especially, those containing peptone), which shows rapid ageing. The author has arrived at the conclusion that the use of asparagin in wine making is advisable, particularly as it presents advantages from the economic point of view.

577 – **The Relationship of the Chief Acids in Wine.** — GARINO-CANINA, D. E. (R. Stazione enologica sperimentale di Asti), in *Le Stazioni sperimentali agrarie italiane*, Vol. I,II, Pt. 10-12, pp. 536-541. Modena, 1919.

In a previous paper (Studio sulla variazione degli acidi nel succo d'uva durante il processo di maturazione, *Annali della R. Accademia d'Agricol-*

tura di Torino, vol. LVII, 1915), the author has shown that, given the tartaric acid content of the wine expressed in cc. of normal solution per litre, a relation can be established between the total free and the combined acidity (by the alkalinity of the ash) also expressed in cc. of normal solution ; in this way a constant can be obtained for each wine-growing district and for each year of wine production. Once ascertained, this constant can be used to detect watering with the addition of cream of tartar and tartaric acid. The author stated that " A ratio of this kind, founded on the physiology of the ripening of the grape, like those proposed by GAUTIER and others, and conjointly with them, would be of great assistance to the chemical expert. If old or simply mature wines are in question, the malic acid that has disappeared will have to be calculated, and correction made for this and for other factors made necessary by the alterations and treatments.

The present paper is a corollary of the former, and attempts to show the actual percentage content of tartaric acid compared with the other organic acids of new wines.

As the author has shown, the organic acidity of wine is mainly due to acids that already exist in the grape (malic, tartaric, and citric acids) and to acids that form during alcoholic fermentation, the chief of which are lactic, succinic and acetic acids. These acids are present in determined proportions, which are altered by the addition of any one of the acids.

The author has made use of data from previous work carried out by him or in collaboration with M. MENSIO, and has drawn up two tables, in the first of which is given the ratio *total malic acid* × 100 : *titratable acidity* + *alkalinity of the ash*, and in the second the ratio *lactic acid* × 100 : *titratable acidity* + *alkalinity of the ash*. The figures given show that, for new wines, the content of malic acids is about 41 %, a value which decreases by one-half and more in old wines. The opposite occurs in the case of lactic acid, which may rise from an average of 10 % in new wines to 28-30 % in old wines.

Use was also made of previous analyses made by the author, of unpublished data from the Royal Oenological Station of Asti, and particularly of publications of the Italian Ministry of Agriculture relating to analyses of Italian wines made in the Ministry's Laboratories, and he has constructed, for some thousand wines from all the regions of Italy, the curves showing the variability of the ratio *total tartaric acid* × 100 : *total titratable acidity* + *alkalinity of the ash*. These graphs have led the author to conclude that, as the values of the suggested ratio vary with the region and the years, they must be applied with a certain latitude and discretion. Thus there are maximum values as high as 70 % for certain Tuscan wines and minimum limits of 7 % for certain wines from the province of Avellino, whereas the values vary between 15 and 45 % for Piedmontese, Emilian and Sicilian wines and are usually between 25 and 30 %.

In the presence of the continual complication of adulteration and of the means for detecting it, the author asks whether it would not be better to give the preference to the idea of legal commercial limits, rather than

to the too elastic one of purity. A proposal of this nature was made by prof. MARTINOTTI, Director of the Royal Oenological Station at Asti, at the Viticultural Congress held in Alba in 1908.

578 - **Determination of the Hydrogen-Ion Concentration of Wine.** — CASALE, L., in *Le Stazioni sperimentali agrarie italiane*, Vol. LII, Part. 7-9, pp. 375-388. Modena, 1919.

The author (Royal Laboratory for Agricultural Chemistry of Avellino) puts forward a new method for determining the hydrogen-ion concentration (either the actual acidity or the acid energy) of wines and for ascertaining the total quantity of bases combined with each acid. By studying the hydrogen-ion concentration of numerous wines by means of the saccharose-inversion method, it was found that the data obtained were not always in proportion to the acid concentration. The proportion is lacking, for example, in wines of high acidity, wines for which the value of the hydrogen-ion concentration loses its importance and cannot be used for calculating the acids-to-salts balance. The author suggests a formula deduced from the calculation which gives the acid energy, a value that corresponds to the ratio of acid-base combination. In normal wines, in which the value is that deduced from the inversion of saccharose, the proportions of the two acids, malic and succinic, can be deduced algebraically. On applying these calculations, the author obtained values generally little different from those obtained with the other methods now in use and which are also of a mathematical character, since the succinic acid is calculated from the weight of alcohol (0.17 cc. of normal succinic acid to 1 gm. of alcohol) and because the malic acid is calculated by difference. As the ratio of succinic acid to alcohol is not constant in wine, the determination of the two acids by the method described above does not always give accurate results, whereas the algebraic method proposed by the author is more accurate.

579 - **Electrochemical Methods for Investigating the Addition of Sulphuric Acid to Wine.** — CASALE, L., in *Le Stazioni sperimentali agrarie italiane*, Vol. LII, Pt. 10-12, pp. 549-568. Modena, 1919.

When wines with feeble coloration, or wines difficult to keep or even " diseased " are in question, the addition of a little sulphuric acid in such proportions as not to exceed the legal limits of the sulphates will obviate all these difficulties. This quite unhealthy practice is certainly illegal, but the chemist does not always discover the fraud because, with the uncertainty of analytical methods, the origin of the sulphates present in wine is hardly ever investigated when they occur in abnormal proportions.

The author states that none of the methods for investigating this type of adulteration discriminates with certainty between the addition of sulphuric acid and ordinary " plastering " (addition of gypsum). Since the chemical reactions showing the presence of sulphuric acid and the use of " plastering " are essentially the same, whilst the electrochemical reactions are different, the author investigated the question at the laboratory of agricultural chemistry at Avellino (Italy). The conclusions he arrived at are given below :

The addition of free sulphuric acid to wine produces an increase in the ash which does not correspond to the quantity of acid added. The alkalinity of the ash does not decrease in proportion to the acid added, but in a lesser proportion, and no neutral reaction is obtained even if the amount of sulphuric acid added is proportional to the alkalinity of the ash. The ash still remains alkaline even if more sulphuric acid is added than corresponds to the alkalinity of the ash itself.

The electrochemical determination of the ash in normal or plastered wines gives results that agree with those obtained gravimetrically, whereas, in wine to which sulphuric acid has been added, the figures obtained are higher than those obtained by the former method The addition of sulphuric acid to wine leads to the formation of both the neutral and acid potassium sulphate. The presence of these two salts can only be shown by electrochemical methods, the electrical conductivity of the wine being determined using the Wheatstone bridge.

580 – **The Behaviour of Artificial Colouring Matters in Wine.**— SCURTI, P. and RUATA, in *Le Stazioni sperimentali agrarie italiane*, Vol. LII, Pts. 10-12, pp. 497-520. Modena, 1919.

The authors report investigations which demonstrate that, in certain cases, wines shown by a first analysis to be coloured artificially have been proved (e. g.), by a control analysis made by law, not to contain any artificial colouring matter.

On account of the importance of these observations as regards the prevention of fraud in the preparation and sale of wine, the authors have examined the question, especially regarding the extent to which the various factors which, in time, may have an influence on the disappearance of artificial substances added to wine, can be taken into account in practice. To this end, a large number of basic and acid dyes were studied as to :

(1) The action on them of the ferments and extract of the must during the period of most active fermentation.

(2) The action on them of the volatile and extractive matter in wine, particularly during slow fermentation.

(3) The action on them of the corrective materials used in oenological practice.

(4) The action on them of pathogenic organisms.

The results, which are given in a series of tables, can be summarised as follows :

The disappearance of artificial colouring matters in wine depends chiefly on the protein content of the wine in question and on the eventual presence of pathogenic organisms. A reaction is also apparently due to the tannins, since the dyes tend to disappear more quickly in red than in white wines. In consequence, the dyes disappear more quickly from must than from wine, more quickly from incompletely fermented wine than from dry wines, and more quickly from altered wines than from healthy wines.

Living agents differ from organic agents by their wider scope and,

in fact, whereas proteins and tannins can only remove the acid dyes, pathogenic organisms can free a wine from all the dyes added, no matter what their nature.

As regards the practical application of these observations, it is obvious that if a wine shown by analysis to be coloured artificially is afterwards kept in such a way that it becomes altered by disease, the fact that a fresh analysis reveals the presence of no dyes does not constitute a valid argument for annulling the first analysis. If, however, the wine remains unaffected, two cases will have to be considered in the event of a second analysis :

(1) *An acid dye was used* (the nature of the dye is usually clearly shown by the tests used to identify it). — In this case, the second analysis, specially if made some time after the first, also has little value, because the artificial colouring matter has combined with the albuminoids and tannins in the wine and may no longer be identifiable by analytical methods.

(2) *A basic dye was used.* — In this case, the control analysis is fully reliable, because basic dyes remain practically unchanged in healthy wines.

581 - **Researches in Fluorine in Wine, in Italy.** — Zay, C., in *Le Stazioni sperimentali agrarie italiane*, Vol. LII, Pts. 10-12, pp. 485-489. Modena, 1919.

The author reviews the scanty literature dealing with the presence of fluorine in wine and in the grape, and draws the conclusion that, although fluorine is biologically a normal constituent of wine, natural wines must be considered from the commercial point of view as free from this element, as it only occurs in minimum and negligible quantities.

Studying the question from the standpoint of Italian wines, the author examined samples of undoubtedly natural wines from Piedmont, Lombardy, and the region around Venice. Some thirty wines were analysed, but only slight traces of fluorine were found.

To find out whether, in soils exceptionally rich in fluorides, the vines could assimilate large quantities of fluorine and thus yield grapes and, consequently, wines with a high fluoride content, the author carried out an experiment lasting two years in which he watered vines (in 10 different vineyards) with fluoride solutions of 0.25 per 1000 or 1 per 1000 strength. The wines made from the grapes produced by these wines were found to contain but traces of fluorine, as did the lees deposited in the fermentation tanks.

The conclusion was then drawn that fluorine is normally present in natural wines, but in such small amount that its quantitative estimation is not possible by means of ordinary methods, whence it follows that if commercial wines contain fairly large quantities of fluorine, it can be assumed that this element has been added artificially.

582 - **On the Plastering of Wine** (1). — Borntraeger, A., in *Le Stazione sperimentali agrarie italiane*, Vol. LII, Pt. 7-9, pp. 349-360. Modena, 1919.

An investigation of the influence on the reaction between cream of tartar and gypsum of : (1) Alcoholic fermentation ; (2) the duration of

(1) See also *R.*, Nov. 1917, No. 1063 and *R.*, July, 1918, No. 814. (*Ed.*)

the contact between gypsum and grape ; (3) the relative quantity of gypsum ; (4) the presence of whole marcs ; (5) the separation of the grapes from the bunch. The results obtained show that : (1) The total marc present has a considerable influence on the quantitative results of plastering ; (2) the stalks have little effect in this respect ; (3) the addition of 1 % of gypsum to the grapes was more than sufficient to obtain the highest possible plastering in the kinds of grape used (Catalanesca, Rosa, Befania, Sanginella, Isabella) ; (4) the degree of plastering increases up to a certain point with the rise in temperature ; (5) plastering takes place rather rapidly in small-scale tests made at 21.5-24.5° C., and in 48 hours if frequent agitation is applied ; (6) the alcohol that forms leads to a decrease in the initial content of sulphates, owing to the precipitation of the gypsum that had merely dissolved in the must.

583 – **On a Simplified Method of Sugar-making : the Production of Red Beet-Sugar with the Beet Taste.** — The Kestner process, described by M. LINDET before the Académie d'Agriculture ; remarks by M. E. PLUCHET, in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. VI, No. 11, pp. 291-293. Paris, March 17, 1920.

M. KESTNER, of Lille, wondered whether it was worth while for the French beet-sugar makers to produce a sugar as white as that ordinarily used ; provided such sugar would only be used for certain purposes, e. g., sweetening coffee, in chocolate, cakes, etc. For this reason he produced a red sugar by the direct evaporation of slightly purified beet juice.

At first, M. LINDET cast doubts upon the process, since beet sugar always retains something of the taste of the beet ; in fact, so much so, that makers of champagne wines no longer sweeten champagne wines with beet sugar, no matter how purified it may be ; the taste even reappears some years after the sugar was first added.

M. KESTNER found an elegant solution of the problem. In his process, the beet juice is heated to 125 or 130° C, a temperature which does not affect the juice, but causes the beet taste to disappear. The juice is prepared by the usual diffusion method and purified by adding an amount of lime equal to only half of that usually employed ; the juice is then passed through a filter-press and evaporated at 125 or 130° C. In this way, he obtains a slightly alkaline syrup which he saturates with phosphoric acid and evaporates (to a consistency almost like that of putty) at 130° C, at which temperature the beet taste disappears. The thick syrup sets and gives crystalline sugar.

It was M. KESTNER's idea that beet sugar could be made in this way in small sugar factories, particularly in regions such as the South-west, where the sugar-beet is not grown. M. LINDET thinks, however, that the small works he had in view were destined to become large factories, for a works always engenders has a certain outfit, the cost of which must be paid out of the general expenses ; he is of opinion that this process would have a chance of succeeding in the sugar factories in northern France, as they are gradually reconstructed. It requires less material and labour, since it does away with carbonatation, sulphitation, clarification, etc.,

and working up the by-products. The fiscal question still requires solution, as the Revenue authorities wish to tax this sugar at the same rate as pure sugar, i. e., on the net weight; but it only contains 86 % of saccharose, and this alone should be taxed.

M. KESTNER asks that the same rule as that applied in refineries, the rule of yield, should be applied to this sugar, and, in this case, there would be a deduction of 15 to 18 % on which no tax should be paid. The Revenue authorities ought to go into this question.

In any case, it appears that 3 sugar factories, one in the South-west, will be established to work next season's crop according to this method. It will be interesting to know the results obtained.

M. E. PLUCHET asked M. LINDET whether this process would not require a large amount of fuel, seeing that the evaporating temperature is 130° C, and whether the present high price of coal would not make the process very costly. With evaporation in a vacuum, evaporation is obtained at a much lower temperature than 100° C.

M. LINDET replied that he had no data which would enable him to answer the question, but he would go into the matter.

584 - **The Chemical Composition and Industrial Utility of « Ye Goma » Oil.** — *L'Agronomie Coloniale, Bulletin mensuel du Jardin Colonial*, New Series, Year IV, 1919-1920, No. 28, p. 122. Paris, January-February, 1920.

The Chemical Department of the Jardin Colonial (Nogent-sur-Marne, France) has examined a sample of the seed of the " Eno Abura " of Japan also known as " Ye Goma " and " Sudza " (*Perilla ocymoides* L.), which yields a drying oil in fair amount. The results of the examination were as follows :

Moisture	8.80 %
Fat	39.27 »
Nitrogenous matter	22.75 »
Ash	4.38 »
Not estimated	24.10 »

Ye Goma oil is used in Japan for warding off insects and for waterproofing clothes, parasols, and paper. When incorporated with lac it yields a brilliant and translucent yellow varnish.

585 - **Mangora Oil.** — See No. 525 of this *Review*.

586 - **The Preparation of Soya Sauce in Kwantung, China.** — GROFF, E. H., in *The Philippine Journal of Science*, Vol. XV, No. 3, pp. 307-316, 7 pl. Manilla, Sept., 1919.

The preparation of soya sauce in China does not constitute merely a home industry, but is often a true commercial industry, carried out in large factories. But it is always very difficult to obtain information as to the methods of manufacture and to obtain entry into the works. For this reason, the author, having been able to study the whole process followed in a factory in Canton, gives a description of the process, accompanied by photographs of the plant, etc., and the different stages of manufacture.

The process described comprises the following operations : The soya seeds are placed in a boiler, covered with water (14 parts by weight of the former to 11 parts of the latter), and boiled until soft, care being taken to prevent them getting crushed ; when boiled, the beans are drained in bamboo baskets, allowed to cool, then spread on a table and mixed with flour (12 of flour to 14 of beans), taking care not to break the seed coat and making sure that each bean is covered with flour ; the beans are now placed on racks to a depth of some 4 cm., and arranged with the fingers so as to allow free circulation of air ; the racks are made of bamboo, and are usually round, 90 cm. in diameter and with a side 4 cm. deep. The racks are piled one above the other in a dark " moulding " room ; in three days after being placed in this room, moulding begins and is complete in one or two weeks, according to the season. The flour-covered mouldy beans are placed in earthenware jars (46 cm. high and 47 cm. in diameter) which have been exposed to the sun for some months, and which are then filled up to the brim with a 27 % solution of common salt. The jars are left in the sunshine for from 2 to 6 months (the product is all the better the longer the exposure ; during the night or when it rains the jars are covered with bamboo mats). The exposure to the sunshine leads to the evaporation of the liquid with which the jars were filled ; for this reason, 3 days before some of the sauce is siphoned off, the jars are again filled with salt solution. The $^{6}/_{15}$ of the liquid in the jar is siphoned off ; the jar is allowed to stand, and more liquid is siphoned off until only $^{1}/_{3}$ of the content is left. The sauce first extracted is the best and most costly ; before being put on sale, it is again exposed to the sun for from 1 to 6 months, sometimes as much as 2 or 3 years. The addition of salt water, exposure to sunshine, filling up, and siphoning off the liquid are repeated 3 more times ; in this way, the quality of the sauces obtained deteriorates and these sauces are mixed together for sale. In some factories, instead of exposing the residue from the previous extraction to the sun, it is boiled to obtain the 2nd, 3nd and 4th extractions of sauce, but though this gives a product that sells very cheaply, it is of very poor quality.

The mould which gives the sauce its characteristic perfume and taste is yellow and is probably an *Aspergillus ;* a black, injurious mould, a *Mucor*, sometimes appears, but all the beans covered with this black mould are rejected.

INDUSTRIES DEPENDING ON ANIMAL PRODUCTS

58 / – **The Cost of Milk to Producer and Consumer in the U. S. A.** — PEARL, R., in *Hoard's Dairyman*, Vol. XVII, No. 4, p. 148. Fort Atkinson, Wis., Feb. 14, 1919.

The author gives the following information in tabular form : (1) The prices obtained by farmers who sold milk in 9 cities in the U. S. A. in each year from 1913 to 1918 (first half-year) ; for the extreme years, these were, in cents per quart on 3.5% milk, New York 35 and 66, Boston 36 and 74, Philadelphia 34 and 65, Chicago 38 and 56, Buffalo 41 and 66, Baltimore 41 and 70, Pittsburgh 30 and 60, Cleveland 32 and 58, Washington 42 and 79. Compared with the figures for 1913 there were the following percentage increases in respect of each town : 88.6, 105.5, 91.2, 47.4, 61.0, 70.0, 100,

81.3, 88.1 ; (2) the average prices obtained for 11 other farm products were, on the average for the U. S., as follows :

Products			Price in 1913	Price Jan.-June 1918	Increase %
Milk	per	*quart*	$ 0.037	0.066	78.4 %
Wheat	per	*bushel*	» 0.787	2.024	157.2
Maize	»	»	» 0.594	1.483	149 7
Potatoe	»	»	» 0.642	1.021	59.0
Butter	»	*pound*	» 0.269	0.416	54.6
Hogs	»	*dozen*	» 0.218	0.379	73.9
Pigs	»	*cwt.*	» 7.494	15.473	106.5
Cattle	»	»	» 5.892	9.373	59.1
Sheep	»	»	» 4.542	11.458	151.6
Lambs	»	»	» 6.050	14.570	140.8
Onions	»	*bushel*	» 0.957	1.528	59.7
Beans	»	»	» 2.221	6.822	207.1

In a third table, the prices paid to the producer and the retail price for milk in each of the above-mentioned towns during 1913, 1917, and the first 6 months of 1918 are compared.

Taking the average of these nine cities, it will be found that the farmer's share for milk during the first 6 months of 1918 are 78.4 % higher than those of 1913. This increase in price is greater than that of potatoes, butter, eggs, cattle, and onions, and is smaller than that of wheat, maize, hogs, sheep, lambs, and beans. The percentage increase in the price of milk during the first 6 months of 1918, compared with the same period of 1917, was greater than that of any other food product, three of which (potatoes, onions, and haricot beans) decreased in price. Except in Chicago and Buffalo, the producer received a higher percentage of the price paid by the consumer in 1918 than in 1913.

588 – **Milk Production in Southern China.** — See No. 558 of this *Review*.

589 – **The Fungoid Flora of Brie Cheese.** — LOUBIÈRE, A., in *Comptes rendus de l'Académie des Sciences*, Vol. CLXX, No. 6 pp. 336-339, 2 fig. Paris, Feb. 9, 1920.

Amongst the fungi which grow on the surface of Brie cheese, the only ones that have been recorded and studied as yet, are several species of *Penicillium*, which are supposed to play a part in the process of ripening.

When the curd is left alone, it undergoes a series of changes. The micro-organisms disseminated in the mass, attack the lactose and casein, and bring about various fermentations ; the milk sugar, in particular, undergoes a lactic fermentation and the nitrogenous matter, under the influence of proteolytic enzymes, is transformed to caseone. However, if these proteolytic ferments are to display their normal activity in the coagulum, this must be neutralised or even become alkaline. And it is owing to the intervention of the moulds that grow on the surface that the

organic acids, particularly lactic acid, undergo progressive combustion and are finally destroyed. On account of the important part thus played by these fungi in ripening, the author has investigated the question and now publishes his first results.

When samples from different ripening cellars were examined systematically, it was found that the fungoid flora of Brie cheese was much more complex than had previously been thought. During ripening, besides the well-known species of *Penicillium*, a whole fungoid flora develops; this flora includes, in order of frequency: *Fusarium sarcochroum* Desm. and *Geotrichum candidum* Link, which are almost constantly present; then, much less frequently, *Trichosporium* sp. and *Botryotrichum piluliferum* Sacc. and March; finally, on dried-up, ripe specimens, *Hormodendron cladosporioides* (Fresen.) Sacc., *Gymnoascus luteus* Zuck. and a species of *Lasiobotrys* are often found.

All these fungi develop solely their conidial form, with the exception of the last one, which develops perithecia in culture tubes. The author gives interesting new details about two species, *Trichosporium* sp. and *Hormodendron cladosporioides*.

590 – **The "Xarque" (Dried Meat) Industry in Brazil; Production and Exportation.** — *Bulletin commercial de la Section des Affaires économiques et commerciales du Ministère des Relations extérieures de la République des Etats-Unis du Brésil*, No. 8, p. 22; No. 9, pp. 6-5. Rio de Janeiro, 1919.

"Xarque" is dried, salted meat; its manufacture dates back over a century in Brazil and the methods used have been imitated in other South-American countries. Xarque is one of the products that helped most in developing Brazilian cattle, especially before the war, as the cold-storage industry has only been established in the country since then.

The xarque industry of Brazil is very advanced, whether on account of its plant or for the product itself and its derivatives, and large amounts are invested in it. The production of xarque in the different producing states is as follows:

Rio Grande do Sud	46 000	metric	tons
Minas	7 500	»	»
Matto Grosso	1 500	»	»
São Paulo	3 000	»	»
Goyaz	553	»	»
Rio de Janeiro	500	»	»

Prior to the war, trade in this product was limited to the states of Brazil, and recourse was necessitated to imports from other South-American countries to satisfy home demands. Since 1914, however, exportation has begun and developed rapidly. The exports from 1913 to 1918 were as follows: **1913,** 21 tons; **1914,** 138 t.; **1915,** 2 265 t.; **1916,** 7 122 t.; **1917,** 8 728 t.; 1918, 4 809 t.

591 – **A Native Method Used for Preserving Meat at Fez, Morocco.** — CARPENTIER, in the *Recueil de Médecine vétérinaire*, Vol. XCV, No. 5, pp. 149-156. Alfort, 1919.

Description of a native method used in Morocco for preserving meat, particularly beef. The meat is sterilised by the triple action of salt, drying,

and heating, whilst external contamination is avoided by covering with a layer of fat. The author observes that this method combines practically all the known methods for preserving meat.

592 – **Country Hides and Skins.** — WALIN, C. V., FREY, R. W., VEITCH, I. P. and HICKMAN, R. W., in *U. S. Department of Agriculture, Farmers' Bulletin* 1055, p. 64, figs. 46. Washington, August, 1919.

A joint contribution from the Bureaus of Markets, Chemistry and Animal Industry.

Country hides and skins make up more than one-third of all the hides and skins produced in the United States, and their condition on arrival at the tannery is of vital interest to all who use leather. Too often the value of "country" hides for leathermaking is less than that of "packer" hides, because less care and skill are shown in the "take off" and in curing and handling. In consequence the hide trade discriminates between "country" and "packer" hides and skins and pays less for the former.

This bulletin shows how farmers, ranchers and butchers may produce hides and skins of better quality. It gives detailed directions for skinning the animals and for salting, curing, and handling the hides and skins, with suggestions for more advantageous marketing, in order that that both the producer of hides and the user of leather may be benefited.

The market classes and grades of both packer and country hides and skins are also defined and the main defects of country hides and skins, and the waste resulting from faulty practices, are indicated. Statistical information in tabular and graph form as to market prices and price fluctuations is included in the appendix.

PLANT DISEASES

DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

593 - **Behaviour of Hybrid Direct Bearers as Regards Disease during the Drought in 1919 in Touraine, France.** — See No. 488 of this *Review*. RESISTANT PLANTS

594 - **The "Laorcas" Vine, Resistant to Oidium, in Cyprus.** — *The Cyprus Agricultural Journal*, Vol. XIX, Pt. 3 and 4 ; Vol. XV, Pt. 1, p. 146. Nicosia, July-Oct., 1919-January, 1920.

During 1919, a vine was found in the Heloan property, at Alethrico, which was completely immune to *Oidium Tuckeri*, whereas all the surrounding vines were severely attacked by the fungus. It was found that this vine came from Ayros Ambrosios (Kyrenia district), where it is known as "Laorcas." The Agricultural Department will carry out experiments to ascertain the persistency of the immunity enjoyed by this vine.

595 - **Action of Chloropicrin on Various Fungi.** — MATRUCHOT, L. and SÉE, P., in *Comptes rendus des Séances de la Société de Biologie*, Vol. LXXXIII, No. 7, p. 170-171. Paris, February 21, 1920. MEANS OF PREVENTION AND CONTROL

The toxic action of chloropicrin on animals (1) suggested to the authors the idea of trying its action on fungi. They used a closed area in which the air was saturated with toxic vapour. The fungi were left in this air for periods varying between 7 minutes and 8 hours, then withdrawn and immediately replanted to ascertain their vitality. The experiments showed that the most fragile fungi are : *Hypomyces ochracea* (conidia and chlamydospores), killed without fail after 30 minutes ; then *Mucor Mucedo* (sporangia), *Botrytis cinerea* (conidia), *Sclerotium echinatum* (sclerotia), killed after 3 ½ hours ; then *Nocardia* sp. (arthrospores), *Pènicillium* sp. (conidia), *Amblyosporium* sp. (arthrospores), and *Chaetomium bostrychodes* (perithecia), which die after period of contact longer than 5 hours 40 minutes and shorter than 8 hours.

In an atmosphere not saturated with chloropicrin, but containing 10 cgm. per litre of air, all the fungi except *Amblyosporium* sp., were killed in 48 hours, and double the strength killed even that fungus in 42 hours.

(1) See R., July-Sept., 1919, Nos. 1049 and 1050 ; *R.*, Jan., 1920, Nos. 6 and 148 ; *R.*, Feb., 1920, No. 274 ; *R.*, March, 1920, Nos. 374 and 378. (*Ed.*)

The fungi experimented on belonged to very different groups and represented the most varied vegetative or reproductive forms (mycelium, arthrospores, conidia, chlamydospores, sclerotia, perithecia) and it may be concluded from the results that chloropicrin will completely disinfect an enclosure, in respect of any fungi it contains. It suffices to employ the toxic vapour at saturation point for 8 hours, or at a smaller concentration during a longer time which, however, is apparently not more than a few days.

596 - **Patents for the Control of Diseases and Pests of Plants.** — See No. 572 of this *Review*.

DISEASES OF VARIOUS CROPS,

597 - **The Behaviour of Certain Varieties of Wheat as Regards Smut, in Emilia, Italy.** — PEGLION, V., in *Rendiconti delle sedute della Reale Accademia dei Lincei*, Classe di Scienze fisiche, matematiche e naturali, and, Half-year, 1919, Vol. XXVIII, Part 10, pp. 398-400. Rome, 1919.

Researches on 34 samples gathered in the field or taken succesively from parts of wheat recognised as smutted, by the Commission for the requisition of cereals in the province of Bologna, showed that 14 samples from various localities in that province were attacked by *Tilletia Caries* (= *T. Tritici*), while 20 samples from the lower Ferrara district and from various localities in the provinces of Bologna, Modena, and Ferrara, were attacked by *T. laevis*. A few samples were affected by both species. The samples belonged to the varieties Gentil rosso, Inversable, Rieti, Cologna, and one came from a field of Carlotta Strampelli.

Gentil rosso and Inversable suffered most, but a marked resistance was noted in fields sown with Cologna, and which could be considered as practically free from the disease, as, all things being equal, only occasional ears were smutted, whereas, in adjacent plots, the Gentil rosso and Inversable varieties were severely attacked.

The variable degree of resistance of the species and varieties of *Triticum* in respect of smut has been the subject of various researches, amongst which those of TUBEUF, KIRCHNER, and HECKE are particularly instructive. These investigations show that the practical value of a wheat variety as regards its behaviour towards smut is the result of 2 factors: the intrinsic resistance and the degree of germinating energy. Consequently, to judge the resistance of wheats to smut, it is sufficient to have recourse to the same criteria as those used in judging the resistance of wheats to rust.

The intrinsic resistance is independent of the degree of germinating energy, which influences the behaviour of wheat in respect of smut in a similar way as the earliness of the vegetative cycle does in respect of rust.

Early wheats like the Cologna variety escape attack; thus, varieties of wheat with considerable germinating power, like the Ohio wheat used by TUBEUF and APPEL, appear likely to escape smut. But KIRCHNER'S experiments, confirmed by HECKE, have shown that this estimate does not possess absolute value and, just as it should not be concluded that a variety with feeble germinating power is liable to smut, similarly a high

germinating power is not a sure sign of resistance to infection. It follows that, on lowering the germinating energy — which closely depends on the conditions of moisture and temperature under which germination takes place — it will be relatively easy to show the degree of resistance possessed by varieties of wheat.

The author has applied this theory to the study of 13 selected families of wheat grown on a large scale ; the sample grains were uniformly covered with spores of *T. laevis*. One part of the seeds was sown in large pots on November 21, 1918 ; the rest was sown in rows in the field on November 23. Germination was very slow and the first shoots began to show only on December 15.

The results obtained in July, 1919, are summarised in the appended table :

Families	No.	Total ears obtained	Healthy ears.	Infected ears.	Percentage of infected ears
Cologna	12	208	138	70	33.6 %
Zucchette	238	332	210	122	36.7 »
Cologna	29	184	101	83	45.1 »
Zucchetto	235	181	91	90	49.7 »
Carosello	112	229	99	130	56.7 »
Turgido	255	207	80	127	61.3 »
Gentil rosso . . .	48	200	76	124	62.0 »

Inversable	179	82	24	58	70.7 »
Rieti	39	198	56	142	71.7 »
Romanello	187	248	64	184	74.1 »

The extremes of this scale (Cologna No. 12 = 33.6 % ; Romanello No. 187 = 74.1 %) are much more distant than those found between *Triticum polonicum*, *T. polonicum* × *T. vulgare*, and *T. vulgare* in HECHE's experiments (23.5 % and 40 %). On confronting this result with the observation previously cited regarding the almost absolute immunity of Cologna, grown in soils where other wheats were decimated by the disease, it can be concluded that this variety, like Zucchetto, is endowed with considerable resistance to the attacks of *T. laevis*, a fact which the author thinks should be taken into account in the improvement of wheat by selection or crossing.

598 – ***Pythium Butleri* n. sp., a Peronosporaceous Parasite of Various Cultivated Plants in India.** — SUBRAMANIAN, L. S., in the *Memoirs of the Department of Agriculture in India*, Botanical Series, Vol. X, No. 4, pp. 181-194, 6 pl. Calcutta, 1919.

During the last few years, phenomena of withering and rotting to a fairly large extent have been observed in nurseries of young tobacco and pepper plants in Pusa and the surrounding district. These phenomena coincided with the presence of *Pythium*, which is now known to be the cause of these alterations.

The disease had already been found on pimento near Surat (Bombay) and at Rangpur (eastern Bengal), and on the papaw tree in Kathiavar (western India) at Dacca, and in Burma.

When the fungus, isolated from tobacco, ginger, and the papaw tree, was inoculated into these plants, as well as pimento, the potato and castor plant, the inoculation gave clearly positive results in most cases.

The species of *Pythium* in question is described by the author as new to science under the name of *P. Butleri*.

In the case of ginger, the disease is propagated chiefly by the use of infected rhizomes in new plantations, and, in rare cases, by the soil itself if water logged. To control the disease, the measures advised include the burning of all diseased ginger plants, the use of crop rotations and healthy seed, perfect draining, and careful destruction of all weeds.

The disease is very harmful to the papaw tree in damp seasons. The diseased portion of the tree should be completely removed as soon as signs of attack are shown, and the wound thus caused by cutting should be treated with liquid antiseptics.

As regards tobacco and pimento, treatment of the nurseries with chemical was not found efficacious. If the soil, however, is sterilised by burning the dry vegetation present in the nurseries, this acts as a preventive measure

599 – ***Catalpa bignoniodes* × *C. Kaempferi*, Resistant to Low Temperatures and to Attacks by *Macrosporium Catalpae*.** — See No. 517 of this *Review*.

INJURIOUS INSECTS AND OTHER LOWER ANIMALS.

GENERAL

600 – **Insects Injurious to Cultivated Plants in Morocco.** — VAYSSIÉRE P., in the *Bulletin de la Société entomologique de France*, No. 18, pp. 340-342. Paris, 1919.

Using specimens sent during recent years to the Entomological Station at Paris, and others collected during a visit in the spring of 1919, the author has drawn up a preliminary list of the insects injurious to cultivated plants in Morocco. The list includes the following species:

A) Orthoptera

(1) *Schistocerca tatarica* L., the most serious pest in Morocco.

(2) *Dociostaurus maroccanus* Thunb., of secondary importance of recent years to Moroccan crops, as it has not appeared in numbers for some time.

(3) *Gryllotalpa vulgaris* L., very common, particularly in the Fez region, where the town nurseries suffer considerably.

B) Coleoptera

(1) *Tropinota crinita* Charp., occurred in great numbers in 1919 in the Figuig and Bou-Denib oases, where the insect devoured the flowers of kitchen garden and ornamental plants, particularly beans, iris and roses.

(2) *Cassida viridis* L., collected at Taza on cultivated artichokes; it has probably been introduced recently, as it is not widely distributed.

(3) *Colaspidema atrum* Ol., indentified from larvae gathered in large

numbers in a lucerne field at Marrakech, where it caused serious damage in early spring, 1919 ; the natives have only noticed it since 1918.

(4) *Labidostomis hordei* F., in vine buds at Meknes (1).

(5) *Capnodis tenebricosa* Ol., common in nurseries at Fez, where its larva is very injurious to fruit trees (peach and cherry).

(6) *Laria pisorum* L., causes considerable damage to pea crops and in stores in the Meknes and Rabat regions.

(7) *Larinus afer* Gyll. and *L. flavescens* Germ., very harmful to artichokes (by mining the stems) on farms to the north-east of Casablanca.

(8) *Lixus scabricollis* Bohem., named from an imperfect specimen on beet in the Fez region.

(9) *Xyleborus dispar* F., has developed in large numbers on stone-fruit trees, especially at Fez and Rabat ; the trunks are literally riddled with the holes of this Scolytid.

C) Lepidoptera

(1) *Zeuzera pyrina* L., appeared at Fez and Rabat as a veritable pest of fruit trees ; the author found 6 larvae in one quince tree.

(2) *Leucania* (*Heliophila*) *unipuncta* Hw. ; a larva whose identification ought to be examined carefully is reported to have ravaged the fields in the Fez region from January to March of late years ; it is said to attack all crops, especially graminaceae.

(3) *Sesamia nonagrioides* Lef., very harmful to young sugar-cane plantations at Sidi Ali (Azemmon) and at Rabat.

(4) *Phthorimaea operculella* Zell., can be considered, after *S. tatarica*, as the insect most injurious to crops in Morocco ; it offers a serious hindrance to the extension of the potato crop in the country ; available information shows that this pest has been long present in the country (2).

(5) *Phycita diaphana* Stgr., said to have attacked the leaves of the castor plant in 1917 at Rabat.

(6) *Earias insulana* Gn., is the sole pest found by the author on cotton plants at the Fez Experimental Farm.

(7) *Lita ocellatella* Boyd., has increased to large numbers in the beet crops in the Fez region since 1917 (3).

601 – **New Studies on *Sorosporella uvella*, a Fungoid Parasite of Noctuidae in America** (4). SPEARE A. T., in *Journal of Agricultural Research* Vol. XVIII, No. 8. pp. 399-439. Washington D. C., Jan, 15, 1920. MEANS OF PREVENTION AND CONTROL

Observations mainly of a biological nature on *Sorosporella uvella* (Krass.) Gd., a fungus recorded from the eastern United States and from Canada

(1) See *R.*, Oct.-Dec., 1919, No. 1298. (*Ed.*)

(2) See *R.*, Jan., 1919, No. 140 and *R.*, March, 1919, No. 404. (*Ed.*)

(3) Besides the species listed here, the beetle *Cyrtognathus forficatus* L. and the Lepidopteron *Thaumetopea* (*Cnethocampa*) *processionea* L., have been reported as injurious to the vine and cork-oak respectively, in Morocco, as well as other insects. See *R.*, July-Sept., 1919, No. 1057, and *R.*, Oct.-Dec. 1919, No. 1305. (*Ed.*)

(4) See *R.*, June 1917, No. 611 and *R.*, April, 1918, No. 494. (*Ed.*)

as a parasite of various species of Noctuidae. The observations are based on the study of artificial cultures of the fungus, on inoculation experiments on various living hosts, and on the histological study of infected insects before and after death.

It is now admitted that the fungus in question should be classed not with the *Entomophthorales*, but with the verticillate Hyphomycetes until its perfect or ascigerous stage is discovered. In fact, the development and structure of the conidiophores of *S. uvella*, and the formation of the conidia are characteristic of the latter group of fungi.

The fructifications of the parasite in question consist of thick-walled resting spores or chlamydospores and thin-walled conidia ; the latter have now for the first time been definitely connected with the life cycle of the fungus.

It has been shown that the special, saccharomycetiform vegetative cells present in the blood of infected insects are ontogenetically connected with other phases in the cycle of the fungus. These cells are ingested by some of the white blood-corpuscles (phagocytosis) and this is apparently followed by the destruction of the phagocytes. This phenomenon has been overlooked by those who have studied the fungoid diseases of insects.

The fungus grows quickly on artificial media and shows two entirely different types of development when cultivated on the appropriate medium. In certain cases, whether the fungus is cultivated on artificial media, or whether the chlamydospores are put in damp cells, fruiting structures of the *Isaria* type are produced.

The disease caused by *S. uvella* is rapidly transmitted to healthy insects ; in laboratory experiments a mortality varying between 60 and 90 % can soon be obtained.

602 - ***Prospaltella berlesei*, a Hymenopterous Parasite of *Diaspis pentagona* in France.** FOUTIERS, S., in the *Bulletin de la Société entomologique de France*, No. 18, pp. 334-335. Paris, 1919.

As attention was drawn towards the end of 1918 to the appearance of *Diaspis pentagona* in France at various points on the Mediterranean shore (1), researches were begun with the aim of finding whether this scale insect was controlled by its natural parasite, *Prospaltella berlesei*.

The number of pierced scales of *D. pentagona* furnished an almost certain sign of the presence of the parasite. In fact, a number of microscopical preparations and rearing the adult insect in breeding bottles provided absolute confirmation of the forecast made.

INSECTS, ETC. INJURIOUS TO VARIOUS CROPS

603 - ***Bruchus rufimanus*, a Beetle Injurious to Beans in California.** — CAMPBELL. R. E., in the *U. S. Dept. of Agric., Bulletin* 807, pp. 1-22, 6 fig., 1 Pl. Washington, D. C., January 27, 1920.

Of late, bean growing, in California has been seriously affected by the presence of the bean weevil (*Bruchus rufimanus* Boh.).

Although this beetle was recorded for the first time in the United

(1) See *R.*, March, 1919, No. 408. (*Ed.*)

States in 1909, it has probably been present there since 1888. Wherever beans are grown in California, the beetle has been found ; it not only decreases the value of the product, but it has even led the farmers to reduce considerably the area devoted to the crop.

B. rufimanus has one generation a year and does not develop in dried beans. The egg stage lasts 9 to 18 days, the larval stage 10 to 15 weeks and the pupal stage 7 to 16 days ; the adult lives from 1 to 8 months. The eggs are laid on the green pods in the fields from the middle of March to the middle of May ; the larvae are full-grown by August and September and the adults can be found from August to the June of the following year.

The damage caused by the bean weevil is mainly due to the fact that the larva feeds and becomes the perfect insect inside the seeds Many imagines remain in the seeds for several months, thus rendering them unfit for food, but other imagines leave the seeds as soon as they have passed the pupal stage, leaving round holes in the seeds at the place where the larvae have fed on the tissues. The appearance of these seeds decreases their chance of sale and, moreover, the seeds are not only lighter but have a reduced germinating power. The germination power of infested beans is 20 to 40 % less than that of healthy ones. The germination of seeds one year old or more is only slightly less than that of new seed.

In America, there are no natural enemies of the beetle that provide an efficacious and sure control.

Exposure to a temperature of 77-82° C for over 90 minutes kills all the beetles present in the seeds. Fumigation with sulphur is not an efficient method of control. Carbon disulphide in the proportion of 112 gm. per cu. metre in a hermetically closed receptacle, causes the death of all the *B. rufimanus* in the seeds. It has been found that, in seeds kept for two years, all the beetles were dead. Seeds from late crops (after March 1) are much less attacked than those from early crops (Nov. to March).

604 – **Insect Pests of the Groundnut in Queensland.** — Jarvis E., in the *Queensland Agricultural Journal*, Vol. XII, Part 4, pp. 200-204, 1 pl. Brisbane, 1919.

The insects listed below were observed by the author at Meringa, near Nairns (Queensland), on groundnut plants belonging to the Spanish variety, grown for home use. Little or nothing has yet been published on insect pests of the groundnut in Australia, probably, on account of the small area of the crop in that country.

The following insects attack living plants :

(1) *Pseudococcus* sp., very similar to if not the same as *P. trifolii* Forbes recorded from South America, where it chiefly attacks clover ; about 30 % of the crop suffered in varying degree from attack by the scale ; various stages of the scale were on the roots and other subterranean parts of the plant and were present in such numbers on the fruit as to cover them completely ; in certain cases, most of the fruits on each plant were decayed and the foliage had faded; apparently, *P. trifolii* had not previously been recorded on the groundnut in Queensland.

(2) A Pyralid (*Glyphodes* sp., or another microlepidopteron closely

related to that genus) ; in March, the larvae join the leaves of the plant together with silken threads, and eat the young shoots and leaf buds in the shelter thus provided.

(3) *Laelia* sp. (fam. *Lymantridae*) ; adults of this Noctuid moth were reared in February from larvae found eating groundnut leaves.

(4) *Chloridea assulta* Gn. (= *Heliothis assulta*) ; the larvae of this Noctuid were fairly common and damaged the young leaves and tender shoots.

(5) *Chl. obsoleta* F. (= *H. armigera* Hb.) ; a few larvae attacked the young leaves to a slight extent.

(6) *Atractomorpha crenaticeps* Blanch. (fam. Acridiidae).

(7) *Cyrtacanthacris* sp. (fam. Acridiidae) ; this orthopteron, like the previous one causes slight damage to the leaves.

(8) *Isodon puncticolle* (fam. Scarabaeidae) ; the adults of this beetle were recorded from Sandgate in 1917 as damaging the plants by eating the stems just below the surface of the soil.

Insects that attack stored groundnuts :

(1) *Homoeosoma vagella* Zell. (fam. Pyralidae) ; the larvae of this Pyralid attacked some Giant Peanut groundnuts from Cairns ; they live on the seeds and, when full grown, they leave the pods and pupate in silken cocoons.

(2) *Tribolium ferrugineum* Fab. (fam. Tenebrionidae) ; common in stored groundnuts ; *T. confusum* Duv. has already been reported as injurious to groundnuts in America.

(3) *Carpophilus* sp. (fam. Nitidulidae) ; some adults of this beetle were attracted by dry groundnuts kept in a tin ; they probably fed on broken nuts, residues, etc.

605 – ***Coelaenomenodera elaeidis* n. sp., a Beetle harmful to the Oil Palm (*Elaeis guineensis*), in the Gold Coast, Africa.** — MAULIK, S., in the *Bulletin of Entomological Research*, Vol. X, Pt. 2, pp. 171-174, 3 fig. London, January, 1920.

The author describes, as a new species, a beetle named *Coelaenomenodera elaeidis* (sub-fam. Hispinae, fam. Chrysomelidae), which is reported to be injurious to the oil palm (*Elaeis guineensis*) in the Gold Coast, Upper Guinea.

From information supplied by Mr. W. H. PATTERSON, Government Entomologist in that British colony, the insect has suddenly become injurious and is said to have destroyed all the leaves already open of several thousand palms in a single district. A similar invasion occurred in 1909, but ceased as soon as the next rainy season came on ; after that period the insect was very rare. The total damage is apparently considerable when the beetle is numerous. Regarding the nature of the damage, the larvae bore galleries in the young buds and the adults destroyed the young leaves

606 – **An Unidentified Dipterous Pest of Celery in Cyprus.** — *The Cyprus Agricultural Journal*, Vol. XIV, Pt. 3-4, Vol. XV, Pts. 1, p. 152. Nicosia, July-Oct., 1919, Jan. 1920.

A dipteron belonging to the sub-family *Trypaneidae*, but not yet specifically identified, was recorded in 1919 on celery, which was attacked by

large numbers of the insect. The dipteron lays its eggs on the leaves, and the larvae mine in the leaf, eating the parenchyma.

The presence of the larvae is shown by patches of varying extent on the leaves. All attacked leaves should be cut off and burnt at once ; this prevents the appearance of a second generation of the dipteron and, consequently, a second attack.

607 - ***Neophyllaphis podocarpi*** **n. gen., n. sp., an Aphid Observed on *Podocarpus macrophylla* in Japan.** — TAKAHASHI R., in the *Canadian Entomologist*, Vol. LII, No. 1, pp. 19-20, 1 fig. London, January, 1920.

The author gives a systematic description of a new species and genus of aphis named *Neophyllaphis podocarpi*, and found on the leaves of *Podocarpus macrophylla* at Meguro (Tokyo). The winged and wingless forms both appear from May onwards in the second and following generations. The sexuparous forms are wingless, but it is interesting to note that the oviparous female and the male as well are winged ; these forms appear in September.

As is often found with species of *Siphonophorina*, the wingless viviparous females may produce either winged or wingless forms, but the winged females only produce apterous forms.

The new genus is closely related to *Phyllaphis* Koch., but differs from it in several characters.

608 - ***Cheimatobia brumata*****, a Macrolepidopteron Injurious to Cherry Trees in the Rhone Valley, France.** — BLANCHARD, E., in *La Vie agricole et rurale*, Year IX, Vol. XVI, No. 10, p. 169. Paris, March 6, 1920.

The winter moth, *Cheimatobia brumata*, has been a pest for some years in the Rhone valley, especially in the north of Ardeche and the Loire department. The invasion has gradually spread up the Rhone valley and has been found at certain places in the Roanne district.

Orchards of cherry trees have suffered most. In the Rhone valley, some were found whose foliage had been entirely scorched, and the crop was consequently much reduced.

The author has tried to find out a method of control, complementary to that which consists in the use of bird-lime. The transformation into the perfect insect takes place in the soil, but at a depth that it is difficult to estimate on account of the vegetable remains that cover the soil. In 1916, the author injected carbon disulphide into the ground around some isolated trees which had been heavily attacked by the pest during the previous year. The injection was at the rate of some 600 kg. per hectare and was used at distances 50 cm. apart in every direction. Satisfactory results were obtained, as the number of female moths caught on the bird-lime was much smaller than on trees around which no carbon disulphide had been injected. However, the moth attacked the treated trees in spring, which showed that the treatment was not sufficient. Therefore, some more efficacious method should be sought, and the injections of carbon disulphide should be made closer together than they were in 1916.

The pest climbs the tree when the first cold weather arrives, a period which varies from one year to another.

609 - **Insects Injurious to the Almond Tree in Palestine.**— BLAIR, K. G., in *The Entomologists' Monthly Magazine*, Series 3, Vol. VI (Vol. LVI), No. 61 (N. 668), p. 13. London, January, 1920.

Mr. G. GARB of New York, who has recently travelleed through Palestine, sent to the British Museum (Natural History), for identification, three species of insects which he stated caused serious damage to almonds growing in Palestine.

Two of the insects received were wood or bark-boring beetles: *Capnodis carbonaria* Klug (fam. Buprestidae) and *Eccoptogaster* (*Scolytus*) *amygdali* Guér. (fam. Scolytidae); the third is the aphid *Tuberodryobius persicae* Cholodk.

It appears that *Capnodis carbonaria* has not previously been recorded as injurious to the almond tree. The specimens in question were taken from trees in the Gderah colony, south of Jaffa (Palestine), on July 10, 1919. Fullgrown or nearly full grown larvae were found boring galleries between the bark and the wood in the subterranean part of the trunk and roots. The larvae pupate inside the galleries they have bored. The insect has also been found in other localities, particularly in the colonies of Ekron, Beer-Jacob, and Pishon, and it is assuming great economic importance in connection with almond growing in Palestine.

Capnodis cariosa and *C. tenebrionis* L. have been recorded in Dalmatia as injurious to plum and cherry trees, to which they cause harm similar to that done to the almond tree by *C. carbonaria*.

A note appended to the present paper states that Mr. J. J. WALKER has often found two or three species of *Capnodis* — amongst which *C. tenebrionis* is the commonest — on the trunks of old apricot and other fruit trees at Salonika, in Besica bay, and in other regions in the eastern Mediterranean. These species, with *Chalcophora stigmatica* Dalm., had evidently developed in the trees, which had already been attacked by their larvae.

610 - ***Phryneta spinator*, a Beetle Injurious to Fruit Trees and Other Plants in South Africa.** — GUNN, D., in *The Agricultural Journal of South Africa*, Vol. X, No. 58, pp. 11 25, 14 figs. Johannesburg, 1919.

Morphological and biological description of *Phryneta spinator* F., more or less common in the Union and also known in Rhodesia, British East Africa, Nyassaland, and the Belgian Congo.

The larva damages fig trees and willows most, by hollowing out, in the lower part of the trunk and sometimes in the roots, numerous galleries which hinder the growth of the tree, cause a decreased yield in the case of the fig tree, and make the plant less resistant to mechanical strain. When the attacks are repeated and serious the tree usually dies. It sometimes happens that the beetle lays its eggs in peach and pear trees situated near infested fig and willow trees.

The adult insect does considerable harm by eating the bark of many plants: — Willow, fig, apple, apricot, peach, nectarine, pear, plum, vine, *Melia Azederach*, *Cupressus lusitanica* and *C. horizontalis*.

Nothing is known concerning the existence of natural parasites of the

eggs and larvae of *Phr. spinator*. Imagines collected on fig and willow trees have been found to be attacked by *Isaria* sp., but it seems that this fungus is not to be counted on as an efficient means for controlling the perfect insect.

In the case of the fig tree, the larvae hidden in the easily recognisable galleries in the trunk can be killed with the drawn-out tip of a knife or a strong, flexible wire; if the larvae are hidden deep in the roots and thus out of reach of a wire, a little paraffin or carbon disulphide should be injected into the gallery, which should then be stopped up.

After the larvae in the galleries are destroyed in this way, it is advisable to prevent deposition of further eggs, to protect the trunk in October (the adults begin to appear in November) by means of close-meshed wire gauze, the two ends of which are tied close together with strong string, but taking care that the part where the gauze is tied is sufficiently far from the trunk to prevent the insect from laying its eggs on the bark through the meshes.

Bands made of paper covered with tar or carbolineum, as well as painting the trunk with these two substances are not to be recommended as they injure bark of the fig tree. Spraying the trunk with insecticides is also inefficacious.

The fig tree should be cultivated in such a way as to have a single trunk, so that the cluster shape or the presence of several stems on one tree should be avoided. The growth of weeds during summer should be prevented a they provide shelter for the beetle and make it difficult to see where the eggs have been laid on the bark. The growth of fig trees near willows should be avoided also, because the willow is the chief food of this cerambycid.

Fig and willow trees that are severely attacked by the beetle and, for this reason, of no further utility, should be removed and carefully and completely destroyed.

611 – **The Orange Fly (*Ceratitis capitata*), Injurious to Peaches in Madagascar.** — LEGENDRE, I., in the *Comptes rendus des séances de la Société de Biologie*, Vol. LXXXIII, No. 1, pp. 8-9. Paris, 1920.

As a complement to the information published in 1915 (1), the author now communicates the fact that, in December, 1917, and January-February, 1918, he has again observed the presence of *Ceratitis capitata*, widely distributed in the neighbourhood of Tananarive (Madagascar), where it injures peach trees.

Peaches produced by trees from the Cape, gathered towards the end of December, 1917, before completely ripe, apparently healthy, and kept, in the laboratory, showed after a few days the presence of *Ceratitis* larvae in their pulp, in which the pest produced the usual alterations.

GENERAL INFORMATION

612 – **Protein Requirement of Maintenance in Man and the Nutritive Efficiency of Bread Protein.** — SHERMAN, H. C., with the Co-operation of GILLET, L. H. and OSTERBERG, E. (Department of Chemistry, Columbia University, New York), in *The Journal of Biological Chemistry*, Vol. XLI, No. 1, pp. 97-109. Baltimore, M. D., Jan., 1920. RURAL HYGIENE

A report of the net results of earlier experiments upon the protein requirement in the maintenance metabolism of man which were suitable for direct quantitative comparison, together with the data of the authors' own experiments upon a dietary in which nearly all the nitrogen was taken in the form of wheat bread.

Probably the best indication of the normal protein or nitrogen requirement can be obtained by averaging the observed nitrogen output in all available experiments in which the intake appears to have been barely sufficient or not quite sufficient to balance intake with output. Since, however, the protein minimum thus determined is influenced by the action of carbohydrates in economising protein and fats (1), the results will be comparable and will bear directly upon the practical problems of protein requirement in food economics, but only in those cases in which the energy value of the experimental ration is at least approximately adjusted to the energy requirement of the subject. In order to minimise the personal equation in the interpretation of the work of others, the authors' uniformly excluded all experiments showing a loss of body nitrogen greater than 1 gm. per day. The general average of the 109 experiments that remained shows an indicated requirement of 0.635 gm. of protein per kg.

(1) See *R.* No. 1918, Nol 1195 and 1196; *R.* April, 1920, No. 380. (*Ed.*)

of body weight, or 44.4 gm. per " average man " of 70 kg. per day. The minor differences between the sexes are 0.633 gm. per kg. with men, and 0.637 gm. per kg., with women and therefore can be neglected. Although this represents a large amount of work from numerous sources, so that errors due to individual peculiarities etc., are minimised, the data of individual experiments, however, are rather divergent. If the extremes are rejected, and attention is paid only to 94 or 76 experiments out of 109, the protein requirement becomes respectively 43 or 41 gm. per man of 70 kg. per day, compared with. 45 gm. for the 109. The more critical the selection included in the average, the lower the indicated protein requirement becomes. As a general average, it can be estimated at about 0.6 gm. per kg., or 42 gm. per 70 kg. per day.

The authors have previously shown that the protein of rations consisting essentially of maize or oatmeal supplemented only by small amounts of milk (the latter furnishing but 10 to 20 % of the food protein), may be fully as efficient in the maintenance metabolism of man as the average protein or ordinary mixed diets.

The authors give the data of a series of experiments (1) in which ordinary (white) wheat bread furnished over 95 % of the protein consumed, and which demonstrated : 1) That practical equilibrium was maintained on an intake of a little less than 0.5 gm. of protein per kg. of body weight per day ; 2) that the protein of wheat bread showed as high an efficiency in maintenance as would be expected of the protein of mixed diet in general. This result is in accordance with the findings of HINDHEDE and of MORGAN and HINTZE and also of OSBORNE and MENDEL and of Mc COLLUM and his associates, that the wheat protein that suffices to maintain body weight in adult rats is about 5 to 6 % of the total calories of the food consumed. Thus, as there is an average requirement of about 0.6 gm. of protein per kg. of body weight per day, this corresponds to 2.4 protein calories, or 6 % of the 40 calories per kg. which is commonly accepted as a fair average energy requirement for moderately active people.

It appears that a standard allowance of 1 gm. of protein per kg. of body weight per day, supplemented by milk products, provides a margin of safety ; the latter should be more liberal in proportion for growing children and for pregnant or nursing mothers.

613 – **The Nutritive Value of Yeast Protein.** — OSBORNE, T. B. and MENDEL, L. B. with the Co-operation of FERRY, E. L. and WAKEMAN, A. J., in *The Journal of Biological Chemistry*, Vol. XXXVIII, No. 2, pp. 223-227 + 1 Chart. Baltimore M. D., June, 1919.

The idea of using yeast as a source of food protein for man and the higher animals is not new, although it has been given renewed emphasis through the war. It also presents the possibility of a synthetic production of protein from exceptionally simple compounds, and in addition, its use

(1) SHERMAN, H. C. and WINTERS, J. C., *Journal of Biological Chemistry*, Vol. XXXV, p. 307, 1918 ; SHERMAN H. C., WINTERS J. C. and PHILLIPS V., *Ibid.*, Vol. XXXIX, No. 1, p. 53, 1919.

in supplying water-soluble vitamine was recently demonstrated (*Journal of Biological Chemistry*, Vol. XXXI, p. 149, 1917; *American Journal of Physiology*, Vol. XLV, p. 431, 1918). Although the statements on this point are not in uniform agreement, it has repeatedly been found that in the case of both adult men and animals, the utilisation of the nitrogenous components of yeast, as judged by the coefficient of digestibility and by the nitrogen balance is good. Feeding experiments with growing animals with the most exacting requirements for physiologically adequate protein are particularly useful for determining the utility nitrogenous nutrients. Apparently, there are no records of prolonged growth when yeast was the sole source of protein. Owing to this the authors kept rats for more than a year upon a diet in which yeast was the sole source of nitrogen as well as water-soluble vitamine. The results showed a nitrogen utilisation in several cases of 74 to 83 %. The fact that animals can tolerate such large quantities of a food product so unique as yeast, obviously indicates that toxic substances must be excluded. In other experiments in which yeast was used solely as a source of water-soluble vitamine, the animals grew vigorously to adult size, but were sterile, with a very few exceptions, as the testes showed an absence of germ cells.

Other investigators have described similar conditions among animals fed on diets deficient in water-soluble vitamine.

614 – **Maintenance and Production Value of some Protein Mixtures.** — Hart, E. B. and Steenbock, H. with the Co-operation of Letcher, F. in *The Journal of Biological Chemistry*, Vol. XXXVIII, No. 2, pp. 267-285 + Charts 3. Baltimore, M. D., June, 1919.

The efficiency for growth of a protein mixture depends upon the qualitative and quantitative composition of its amino-acid content. The supplementing effect of specific amino-acids for certain definite proteins has been especially studied by Osborne and Mendel, but up to the present time very little data have been accumulated on the efficiency for growth of practical protein mixtures in common use, both in human and in animal nutrition. McCollum has shown the relatively low efficiency for growth of the cereal grain proteins when fed alone or in mixtures, and a much higher utilisation of casein and milk proteins. Hart and Humphrey demonstrated that there is considerable variation in the utilisation of protein mixtures from plant sources for milk production. These studies have a decided practical bearing, as they show how a greater utilisation of a poor protein mixture can be obtained by adding some single protein, or a mixture of several with the proper supplementing qualities.

At the present time definite knowledge is needed as to what products and in what amounts efficient supplementary effects be secured to obtain the maximum utilisation of the cereal proteins. Bearing this in mind, the authors carried out experiments with pigs. The results, which are shown in charts, contain the following facts of practical importance :—

Cereal grain proteins of low production value are not appreciably increased in efficiency by supplementing with a maize kernel protein concentrate, such as gluten feed, or by a legume roughage, such as alfalfa ; even the

proteins of flaxseed meal (oilmeal) when constituting 50 % of the ration did not increase the efficiency of those of the maize kernel, but when they constituted 20 to 25 % of the ration, there was an evident increase.

The effective supplementing of cereal proteins, cereal proteins + alfalfa proteins, or cereal proteins + cabbage and potato proteins, was accomplished by additions of either milk or whey, or meat or fish proteins. The two former were the most effective. With but 16 % of nitrogen coming from the whey proteins, the efficiency of a maize + alfalfa + whey mixture was made nearly equal to that of a similar mixture in which 27 % of nitrogen came from skim-milk proteins in place of whey proteins.

The tankage proteins were not quite so effective in their supplementary relations as were those of milk ar whey.

The 18 % of nitrogen in a maize alfalfa tankage ration was practically as efficient as when 35 % nitrogen was supplied. It is to be expected that variations in the efficiency of the proteins of such commercial products as tankage, fish meal, meat scraps, etc., will occur, dependent upon what proportion of their total proteins is derived from the less active and incomplete albuminoid group, such as elastin, collagen, keratin, etc.

Meat crisps or fish meal fed with starch and serving as the sole source of nitrogen showed efficiencies of only 40 %, whilst milk proteins used under similar conditions showed a value of 60 %.

The protein mixture of maize and milk, or oats and milk, showed production values of 60 to 65 %, with approximately 25 % of the nitrogen derived from skim milk, whilst the efficiency of a maize and tankage protein mixture, or a barley tankage mixture was about 40 %. In the latter case approximately 30 % of the nitrogen was derived from tankage. It appears fairly certain that either milk or meat will supplement the proteins of the various cereal grains to approximately the same degree, i. e., tankage when used to supplement barley, oats, or maize, will yield a protein mixture of similar production value. In the same way, milk will supplement the various cereal grains, but in every case with more efficiency than tankage. This being granted, the choice of cereal grains for feeding animals depends entirely on their price when tankage or skim milk is added as a supplement.

Further experiments, which touch human as well as animal nutrition, indicated that a protein mixture drawn from 5 common sources, viz., rice, wheat, maize, potatoes, and cabbage showed a low value for growth when the protein level was brought to a basis comparable with the other experiments, i.e., 13.3 %, by the use of a protein concentrate such as wheat gluten. The production value of this mixture was 19.4 %. When the nitrogen of the wheat gluten was displaced by an equal amount of meat crisps nitrogen, the efficiency rose to 32.7 %, and when replaced by an equivalent in milk nitrogen it rose to 47 %. The efficiency of the latter mixture was not so high as a maize-grain-milk protein, mixture, due largely to the greater faecal losses involved in the mixed ration containing cabbage.

615 – **The Distribution of Water-Soluble Vitamine.** — OSBORNE, T. B. and MENDEL, L. B with the Co-operative of FERRY, E. L. and WAREMAN, A. J., in *The Journal of Biological Chemistry*, Vol. XXXIX. No. 1, pp. 29-34 + 2 Diagr. Baltimore, M D., August, 1919.

The water-soluble vitamine is widely distributed in ordinary food products and it is also present in cottonseed, millet seed, flaxseed, Kafir corn, hempseed, cabbage, alfalfa, clover, timothy, spinach, potato, carrot, and coconut meal. To this list the authors added the onion bulb, turnip root, the leaves, stem and roots of the beet, and the tomato fruit.

It is also important to know the comparative value of the different natural foods with regard to water-soluble vitamine and nutrition, and the authors have conducted experiments with this in view.

To permit more accurate comparisons of the water-soluble vitamine content of natural foods, the procedure adopted consisted in feeding each day small, known quantities of the vegetable product under investigation, apart from the basal ration which was fed *ad lib.* In this way the effects of the different food substances could be compared, based on the water-soluble vitamine content. It was found that the samples of clover, alfalfa, and timothy hays used to furnish the water-soluble vitamine were much less efficient than the dried immature specimens. The fact that this difference exists, may have importance in feeding young animals and dairy cows. Consequently the authors advise that hay made from immature clover or alfalfa be used to replace a part at least of the milk fed to young stock, whilst the hay ordinarily given to dairy cattle should be replaced by that from less mature plants.

616 – **Probable Relation between the Fat-soluble Vitamine and the Yellow Plant Pigment.** — I. STEENBOCK, G., White Corn versus Yellow Corn and a Probable Relation between the Fat-soluble Vitamine and Yellow Plant Pigment, in *Science*, Vol. I,, No. 1293, pp. 352-353. Philadelphia, Oct. 10, 1919. — II. STEENBOCK, H. and BOUTWELL, P. W., with the Co-operation of GROSS, E. G., and SELL, M. T., Fat-soluble Vitamine, the Comparative Nutritive Value of White and Yellow Maize, in *The Journal of Biological Chemistry*, Vol. XLI, No. 1, pp. 81-96. Diagr. 7, Figs. 2. Baltimore, M. D., Jan., 1920.

The distribution of fat-soluble vitamine in various roots was investigated by STEENBOCK, at the University of Wisconsin, Madison who concluded that, whilst coloured roots (carrots and sweet potatoes) are rich in this vitamine, the white roots (sugar-beets, mangels, dasheens and Irish potatoes) contain a negligible quantity or none at all. It is the same with the maize. The yellow maize has, all things being equal, a much higher efficiency in assisting in the development of young stock thus fed, than the white grain. Red maize, with a white endosperm free from yellow pigment, gave, in experiments with rats, the same result as white maize, although somewhat inferior. A variegated maize with white, yellow, red and blue grain resulting from the predominance of yellow and red) gave results intermediate between those obtained with yellow and white maize.

There have also been other cases of possible correlation between the simultaneous occurrence of yellow pigment and fat-soluble vitamine. OSBORNE and MENDEL found that whilst the yellow petroleum oils contain

this vitamine, it is lacking in beef suet. Further, butter fat may be divided into 2 parts : One without colour and without vitamine, and one a yellow liquid containing vitamine. STEENBOCK and his collaborators have verified the fact that in the series of petroleum oils, the vitamine content is rather greater when the yellow pigment is more intense. Consequently, the vitamine ought to be found where the yellow pigment itself, or a compound in close relationship with it, is present. If heated, butter loses the vitamine, and at the same time, becomes decolorised.

617 – **Behaviour of *Bacterium coli* in Milk.** — GORINI, C., in *Atti della Reale Accademia dei Lincei* Serie Quinta, Rendiconti, classe di Scienze fisiche, matematiche e naturali, Vol. XXIX, Pt. 3, pp. 114-118. Rome, Feb. 1, 1920.

The biochemestry of *Bacterium coli* is a subject of much discussion, and one of the most debated points is its behaviour in milk. The author studied this question in the Bacteriological Laboratory of the Royal School of Agriculture, Milan, and has obtained results which led him to the following conclusions :

Bacillus coli develops differently in milk cultures according to its acidifying power. That is why it is possible to classify them into two types ; 1) Power ful acidifiers which cause coagulation even when the milk has undergone, owing to sterilisation such changes as to acquire a brownish tint ; 2) weaker acidifiers, which by means of its rennet enzyme, only cause coagulation when the milk has been so treated during sterilisation as to preserve its white colour. The best way would be, if possible, to have milk produced antiseptically, so that any far-reaching process of sterilisation would not be necessary.

The distribution of the two types of coli in the various media show the vigorous type more frequently in forage and the weaker type in the excrements of man and cattle. In milk, the proportion varies owing to the double means of contamination through excrement and forage.

The general conclusion from these observations is that the diagnostic value of the coagulating power of coli becomes augmented, and several differences of opinion on this subject, especially with regard to the hygiene of water, can be smoothed over.

CROPS AND CULTIVATION

AGRICULTURAL METEOROLOGY

618 – **Effect of Frost on Maize on the Tablelands in New South Wales, Australia.** — WENHOLZ, H., in *The Agricultural Gazette of New South Wales*, Vol. XXX, No. 7, pp. 509-511. Sydney, July, 1919.

On the tablelands in New South Wales, frost is one of the meteorological factors most harmful to maize, and considerably shortens the growing season, exposing late varieties which have not yet reached maturity, to injury from heavy frosts.

The season without frost is limited by the late spring frosts on the one hand, and by the early autumn frosts on the other. The latter have the more marked influence for the following reasons :

(1) The plant in the first stages of development is much less sensitive to the affect of low temperatures than in the cobbing stage when the turgid tissues contain a large percentage of water (very diluted cell sap).

(2) In the spring some varieties are comparatively resistant to cold, whilst in the autumn, during the stages of earing and cobbing, all the varieties, without exception, are unable to withstand very low temperatures.

(3) Several varieties of maize, even if injured by the spring frosts, are capable of developing fresh suckers, which grow normally and replace the dead main stem.

(4) If total permanent injury is caused, replanting is always possible.

For these reasons, the following recommendations may be made:

(1) Very early varieties should be chosen, such as Early Canada and Gehu (flint varieties,) Minnesota 23, Golden Glow, North-Western Dent and Silver King (dent varieties).

(2) Acclimatised seed should be used and rigorous selection for early maturity varieties should be carried out.

(3) Sow as early as possible.

(4) Sow thinly to encourage stooling.

(5) Hasten maturity by applying superphosphate at sowing time (an advance of 15 days is obtained.)

(6) Avoid the use of very large amounts of soluble nitrogenous fertilisers (ammonium sulphate and sodium nitrate) which tend to delay maturity.

619 – **Relation of the Moisture Equivalent of Soils to the Moisture Properties under Field Conditions of Irrigation.** — Harding, S. T., (Irrigation and Hydraulic Engineer, Berkeley, California) in *Soil Science*, Vol. VIII, No. 4, pp. 303-312, Figs 5. Baltimore, 1919.

SOIL PHYSICS, CHEMISTRY AND MICROBIOLOGY

In studies of the water requirement of soils under irrigation, or to be irrigated, some criterion which will furnish an index of the soil moisture properties is needed. This index can be expressed in a moisture equivalent (1); the comparison of this equivalent with other soil properties has usually only been made under laboratory conditions. The author reports on investigations dealing with the critical moisture points of soils, under the actual field conditions of irrigation practice.

The data given were secured from a wide range of soils, and include more than 9150 individual moisture determinations. The results discussed covered a total of 136 determinations of moisture equivalents varying in numerical value from 4.1 to 37.6, and made in various parts of the Eastern United States from 1913 to 1918. Comparisons of moisture conditions were made both for the surface foot of soil and for the average of the upper 5 feet, between the maximum field capacity applied to soils shortly after irrigation, the normal field capacity at from 1 to 3 days after irrigation, and the usual moisture before irrigation and the wilting of the crop.

(1) See *R.*, 1919, No. 422, Note. (*Ed.*)

This comparison shows that there is a fairly constant, relationship between the moisture equivalent and the various moisture properties of soils, which appears to offer promise of utility in determining moisture properties and probable irrigation practice of soils, where irrigation is contemplated, particularly as regards the depth of water retained after irrigation, with its effect on the depth to be applied and the necessary frequency of application. However, although the data presented indicate the nature of the relationship between the different properties studied, they are not sufficient to fix the numerical values except in a very general way. It appears that the relationship is not a linear one, that is, measured in one dimension only, except in the case of the wilting coefficient (1); under normal field conditions, this last relationship would have been lower compared with that based on experiments with limited volumes of soil.

The maximum depth of water per foot depth of soil, retained for the upper 5 feet of soil was about 1.25 inches, which indicated that depths of single irrigation in excess of 6 to 8 inches, even under favourable soil conditions, will not be retained in the upper 5 or 6 ft. of soil. This conclusion is in accord with the results of general field observations from many sources (2).

620 – **Cause of the Unproductivity of "Raw" Subsoils in Humid Regions.** — McMiller, P. R. (Agricultural Experiment Station, University of Minnesota), in *Soil Science*, Vol. VII, No. 3, pp. 233-236, bibliogr. of 4 works. Baltimore, March, 1919.

Harmer has previously shown that certain subsoils, even when inoculated, are less productive than others with regard to alfalfa (3).

The results of vegetative experiments carried out by the author with soils similar to those employed by Harmer, show that an application of potassium sulphate and disodium phosphate, removes the "rawness" of the above-mentioned subsoils, and renders them equally productive towards alfalfa as the corresponding surface soils. This proves that "rawness" in these cases is due to lack of readily available mineral nutrients.

621 – **Potassium-Bearing Minerals as a Source of Potassium for Plant Growth.** — De Turk, E. (University of Illinois), in *Soil Science*, Vol. VIII, No. 4, pp. 269-301, Tables 12, Bibliogr. of 69 works. Baltimore, Oct., 1919.

The earth's crust, to a depth of 10 miles has been estimated to contain an average of 2.32 % of potassium; more recent calculations place the estimate at 2.46 %, which indicates that the problem of potassium for agriculture is one of liberation rather than of supply for normal agricultural soils and the common farm crops.

After a review of previous investigations connected with this subject, the author passes on to his own researches which included 4 experiments carried out for the purpose of obtaining information on the following questions; *a*) Will applications of primary potassic minerals to peat soil affect

(1) See *R.* 1912, No. 903. (*Ed.*)

(2) See Mosier J. G. and Gustavson, A. F., *Soil Physics and Management*. Philadelphia, 1917. (*Ed.*)

(3) See *R.*, 1919, No. 162. (*Ed.*)

the yield of crops grown therein ? *b*) To what extent can crops utilise the potassium in those minerals ? *c*) Is the availability of the mineral potassium for plants affected by the presence of actively decomposing organic matter or of magnesium or sodium chlorides ? *d*) What are the effects of the above-mentioned decomposing matter upon the amount of potassium which can be extracted by water from these minerals under soil conditions ? *e*) What effect does decomposing organic matter have upon the solubility of the mineral potash in the absence of soil ? *f*) What is the explanation of the low availability of the potassium of dune sand ?

The author employed in these researches minerals containing the following amounts of total potassiun : Orthoclase 11 %, microcline 11.23 %, leucite 9.49 %, alunite 8.32 %, ignited alunite 13,72 %, lepidolite (1) 8.99 %, limestone 0.21 %, and calcium carbonate 92 % (approximately). The organic materials used were : Clean, finely ground, alfalfa hay, and prairie hay, fresh cow manure without litter, dried at low temperature and ground ; and the same without drying ; pure chemicals were also used. Buckwheat was employed for the pot cultures.

Results showed that finely ground potassic minerals increased the yield of buckwheat in peat soil by 21 to 34.8 % ; but lepidolite was detrimental, expecially if present in large amounts. These results should, however, be confirmed by further experiments and with other cultivated plants. The addition of crop residues, manure, soluble sodium or magnesium salts to peat soil together with the minerals used in this experiment, did not increase the crop yield or the availability of the mineral potash. The so-called " feeding power " of the plant itself, through the activities of the roots system, is an important factor in the utilisation of relatively insoluble potash.

The solubility of the minerals used, as determined by extraction with water, was very low, except in the case of lepidolite, but this was increased by ammonium chloride, and by decomposing alfalfa. The result in the latter case may be due to ammonification of the nitrogenous compounds in the alfalfa. All the minerals used can absorb considerable amounts of potash in solution ; this absorption is probably physical to a large extent.

The low availability of the potash of dunesand was due to the fact that most of the potash was contained in the larger particles, whose relatively small surface is sufficient to explain the low solubility of the potash, however, the increase in solubility of the potash in such sands was not sufficient to be of practical value.

622 – **The Relation between Certain Acidic and Basic Constituents of the Soil as affected by Ammonium Sulphate and Nitrate of Soda.** — Howard, L. P. (Rhode Island Agricultural Experiment Station), in *Soil Science.* Vol. VIII, No. 4, pp. 313-321, bibliogr. of 12 works. Baltimore, Oct., 1919.

From investigations made with soils manured with ammonium sulphate and nitrate of soda, respectively, during the past 25 years, the author draws certain conclusions concerning the well-known fact that the former

(4) A mica containing lithium and potassium. (*Ed.*)

produces an acid condition in the soil, whereas the latter tends to produce an alkaline reaction. He believes that soil acidity is comparable to the condition of acidosis in the animal organism, and reflects a change in the position of equilibrium between acids and bases, the soil being considered as a mixture in part, of more or less inactive basic and acid constituents.

In the soils under observation, the lime requirement, the exchange of bases by extraction with a normal solution of potassium chloride, the extraction with 2/N hydrochloric acid, the ammonia extract, an the hydrogen-ion concentration were determined The results of the whole series of observations indicated that soil acidity caused by long-continued use of ammonium sulphate is due to a change in the ratio of bases to acids. The position normally occupied by the stronger bases such as calcium and magnesium is taken by weaker bases such as iron and alumium. The neutrality of the soil solution can no longer be maintained, since salts of these weak bases dissociate, and the resulting free acid is accompanied by a definite concentration of hydrogen ions.

623 – **Influence of Mines upon Land and Livestock in Cardiganshire, Wales.** — Griffith, J. J. (Agricultural Department, University College Aberystwith), in *The Journal of Agricultural Science*, Vol IX, Pt. 4, pp. 366-395, pl. 16. Cambridge, 1919.

In North Cardiganshire there is an area of 3000 acres of good land that has become unproductive and deleterious to stock owing to contamination from lead mines in the neighbourhood, caused either by surface drainage water from the débris, by sand blown from the heaps by the dry east winds., by the use of mine waste for making and repairing roadways, by contaminated water running out of mine levels, or by actual contact with the animals themselves. Whatever the exact cause, the unproductiveness of the affected land is due to the presence in the soil of toxic substances mainly lead and zinc, and, in some cases, copper, iron pyrites and marcasite. The list of minerals classified according to relative abundance causing injurious effects is given as follows : Galena, cerussite, pyromorphite (lead minerals); blende, hemimorphite or Smithsonite, calamine (zinc minerals) ; iron pyrites and marcasite (iron sulphides) ; copper pyrites, malachite, azurite (copper minerals); manganite (hydrated oxide of manganese) ; and siderite (carbonate of iron). Unfavourable changes may arise in the mechanical composition of the soil, leading to deterioration of its physical properties such as its capacity to retain water.

The deleterious effects are much more pronounced upon some crops than others. Leguminous plants, for example, appear to be the most susceptible. Lead and zinc are carried on to the soil in the form of galena and blende respectively, *i. e.*, as sulphides that are soon acted upon in the soil, and converted into other compounds. It appears probable that the lead is in some measure retained by the humic or other colloidal substances of the soil, and enters into the composition of the plant, but only in very minute quantities. The poisoning of animals may be attributed more to the lead deposited on the exterior of the plants rather than to that contained internally.

The application of sodium silicate to the soil tends to mitigate the undesirable influences of mine refuse upon plant growth; but the most effective remedial measure is the application of a heavy dressing of lime considerably greater than the lime requirement, as determined by the absorption of lime from calcium bicarbonate solution. Apart from liming it is by preventive rather than remedial measures that the losses of both land and livestock may best be minimised and this should involve: Careful management of active mines, to reduce as far as possible the amount of injurious ingredients allowed to flow into rivers; the guarding against pollution from disused levels; the protection of mine slime and sand heaps at both active and disused mines so as to prevent the material from being washed into the water courses; due attention paid to the construction and care of river and leat embankments; selection of stock the least susceptible to lead poisoning for grazing affected pastures which should be worked alternately with unaffected land; allowing the washing of pastures by rain after floods before further grazing; fencing off the very worst of the poisoned land; threshing contaminated hay before it is supplied to the animals; the strict avoidance of utilising mine wastes for any purpose whatever that may lead to injury to land or stock.

The effects on oats, clover and mustard were determined by experiments in pots, and these were confirmed by limited additional experiments carried out in the field.

PERMANENT IMPROVEMENTS, DRAINAGE AND IRRIGATION

24 – **The Use of Alkali Water for Irrigation.** — HARRIS, F. S. and BUTT, N. I., in *Utah Agricultural College Experiment Station, Bulletin* No. 169, pp. 1-41, Bibliogr. of 54 works. Logan, Utah, July., 1919.

A survey of the literature dealing with this subject demonstrates that although some observations have been made on the action of water containing alkali on the soil and plants, i. e., water with excessive quantities of soluble salts, practically no systematic experiments have been conducted to determine plant tolerance of such water. Most of the field observations admit error in interpreting the effect, owing to complicating factors, such as the original salt content of the soil, the accumulation of salts in the upper strata and the action of various non-alkaline salts. To study the effect of the alkali salts when present alone in the water, an experiment was begun at the Utah Experiment Station in 1915, to determine the concentration of various salts necessary to make water unsuitable for irrigation in loam and sandy soils. Pots containing an equivalent of 7.24 kg., of dry loam soil and others with 7.69 kg., of dry sand, were used. Throughout the experiment, moisture was maintained at 20 % of the dry weight of soil, by the addition of adequate solutions. In each pot, 30 kernels of New Zealand wheat were planted with a final reduction to 20. The pots were then sealed with paraffined paper to minimise evaporation and, consequently, the concentration of the salts at the surface. The following solutions were used: Sodium chloride and sodium carbonate, ranging from 500 to 4000 parts per million; sodium sulphate from 1000 to 14 000 parts per million, and equal quantities of each of these salts from 1 000 to

10 000 parts per million. The soil in the pots was moved and mixed each year, the experiment covering a period of 4 years, until 1918.

So many factors enter into the toxicity of alkali (the nature of the soil, drainage, amount of water necessary for irrigation, soil moisture, methods of handling the soil, etc.), that it is impossible to give definit limits of salinity in irrigation water. However, in the experiments reported, the dry matter produced, the height of plants, the number and weight of leaves, the number and length of culms, the number of ears and spikelets, the turgidity of the plants, and the general appearance of the crops, were all found useful indications of the effect of alkali water.

Results in different soils, showed that wheat cannot be irrigated with water containing 1000 parts per million of sodium carbonate, and that even 500 parts per million will, in a short time reduce the growth of the crop. On the other hand, more than 1000 parts per million of sodium chloride, and more than 4000 parts per million of sodium sulphate proved to be harmful after 2 or 3 years. A mixture of the three salts, although not so toxic as the most injurious of the salts, was more harmful than the less toxic ones. More than 4000 parts per million should be considered as dangerous. The authors also conducted laboratory experiments during the winter of 1918-1919 with 20 groups of loam soil, each of which contained 66 tumblers ; to each group, combination solutions of sodium chloride, sodium carbonate and sodium sulphate were applied in proportions varying from 1 to 9. The concentration of the different solutions ranged from 0.062 to 1.25 gram-molecules per litre.

In this experiment, the first definite toxic effect was with a molecular strength of 0.3125 and became more marked with a molecular strength of 0.5.

MANURES AND MANURING

625 - **The Carbonification of Burnt Lime in Soils.** — MacIntire, W. H. (University of Tennessee Agricultural Experiment Station) in *Soil Science*, Vol. VII, No. 5, pp. 325-44. Fig. 1, Pl. 4, Bibliogr. of 73 works. Baltimore, May, 1919.

The practical and economic importance of liming is more and more evident, and the development of modern crushing machinery has favoured the use of ground limestone as well as of burnt lime. The following question has therefore to be considered: — Which of these two types is scientifically and economically most advantageous? The application of either burnt, air-slaked or water-slaked lime is followed by the phenomena of absorption and carbonification, changes whose order depends on existing soil moisture conditions and the manner of application. If the application is in excess of the immediate absorption coefficient, calcium carbonate will be formed from the unabsorbed lime, followed by the slow decomposition of the carbonate and, finally, an absorption of lime by the soil which differs from the initial rapid absorption and may continue over a period of years. A quantitative comparison between the activity of burnt lime and natural limestone in soils can, therefore, be based upon periodic determinations of the calcium carbonate, which shows the need for a careful study of the carbonification of lime in soil. The author has examined this question both in the field and in the laboratory.

Neither dry calcium oxide, nor dry calcium hydrate react with carbon dioxide, but a slight film of moisture is sufficient to initiate the carbonate reaction. Small amounts of calcium oxide exposed to normal humidity reverted to the carbonate more rapidly than if obtained by slaking.

The formation of carbonate from calcium hydrate is controlled by the amount of free water available to convert the hydrate from solid to solution phase. The carbonification of the burnt lime must be preceded by hydration and dissolving, but, when moist carbon dioxide is present, the reactions, are so rapid as to be practically simultaneous. A protecting film, of calcium carbonate around the nuclei of hydrate is liable to be formed, which retards further carbonification due to exposure to the air.

Pot and field experiments showed that the lime carbonated more rapidly when applied on the surface of the soil, than when dug in either as dry mulch or in damp soil; a sandy compost applied to the surface soil tends to retard carbonification. After the application of 2 tons per acre of burnt lime and the admixture with the upper 6 inches of a soil 8 in., deep, the maximum carbonification ensued within 5 days, and complete absorption occurred within 10 days. The time taken to attain this maximum was not influenced by the 90 tons of supplementary dry manure.

When the applications were larger (8 tons per acre) the maximum carbonification (96 % theoretically) of the unabsorbed residues was completed after 19-38 days. The supplementary dry manure treatment caused no determinable change during thus period. Whilst carbonification was more rapid with light or medium application of lime, with heavy applications of 32 tons per acre, however, it took place more gradually; it reached about 80 % of the theoretical amount for the lighter quantity and 50 % for the heavier at the end of the second year of exposure, after which there was but little change.

The losses of total calcium salts from the several carbonate checks were practically independent of the extent of treatment; whereas the losses from the burnt lime increased according to the amount of treatment. In the case of soil *in situ*, the subsoil considerably obviates these losses.

The comparison between a clay loam and a silt loam showed that the addition of water to the former caused more rapid and greater carbonification either with surface application or with lime dug in but this was not the case with the silt loam.

The result of practical experiments under different conditions demonstrates that although the carbon dioxide utilised in carbonification is partly due to the soil atmosphere, it is derived in the main from that furnished by the aerial atmosphere. The open sandy types effected a more extensive carbonification than the heavier types even if these were rich in organic matter. This was probably due to a smaller absorption of lime by the sandy types of soil.

Finally, the following facts are interesting from a practical standpoint: The burnt or slaked lime in 2-4 ton application per acre, reverts to the carbonate more rapidly when left on the soil surface than when mixed with a dry mulch or the moist soil; carbonification is much more

rapid in humid atmospheric conditions. If the oxide or hydrate application is left on the surface for several days prior to working in, the treatment is, in effect, an application of finely divided calcium carbonate. If, on the contrary, the oxide or hydrate is incorporated within the upper zone of the soil, prior to a more thorough distribution, the concentration thus effected will bring about in the treated zone, a temporary and partial sterilisation which may have beneficial results. The first action of burnt lime applied to soil is to fix atmospheric or soil moisture, and once this is accomplished, there is no tendency to effect any chemical disintegration of soil organic matter. Neither the burnt lime nor the slaked lime, in the quantities ordinarily employed can be considered as chemically destructive of soil organic matter when used in the manner considered advisable in ordinary applications either on the surface or worked into the soil.

626 – **Carbonication or Manuring with Carbon Dioxide.** — I. GERLACH (Landw. Institute der Kaiser Wilhelm-Gesellschaft in Bromberg), Kohlensäuredüngung, in *Mitteilungen der Deutschen Landwirtschafts-Gesellschaft*, Year XXXIV, No. 6, pp. 77-82. Berlin, 1919. — II. RIEDEL, F., Die Anwendung der Kohlensäuredüngung in grossen. *Ibid.*, Nos. 32-34-35, pp. 429, 451-455, 467-469, Figs. 6. — III. IBID, in *Tonindustrie Zeitung*, Year XLIII pp. 607-619. Berlin, 1919. — IV. IBID, Die Ausnutzung der Kochofenabgase zur Kohlensäuredüngung, in *Stahl und Eisen*, Year XXXIX, pp. 1497-1506. Essen a. d. Ruhr, 1919. — V. IBID, Verfahren und Einrichtung zur Ausnutzung Kohlensäurehaltiger, unreiner Gase oder Abgase. (D. R. P. 316637, Kl. 80b), in *Chemisches Zentralblatt*, Vol. I-II, No. 8, Techn. Teil., p. 334. Berlin, 1920. — VI. GEHRING, A., Düngung mit Kohlensäure, in *Umschau*, Year XXXIII, pp. 809-813, Berlin, 1919. — VII. BLOCK, B., Die Verwendung der Kalkofengase zur Kohlensäuredüngung, in *Deutsche Zuckerindustrie*, Year XCIV, pp. 399-401. Berlin, 1919.

I. — FISCHER R. (*Gartenflora* pp. 298-1912) and others have previously demonstrated the possibility of increasing the yelds of crops by augmenting the amount of carbon dioxide in the air. GERLACH, resuming these experiments at the Agricultural Institute at Bromberg, obtained on an average, in 1918 the following results (p. 697, Table I), comparing crops in open field with crops in glass cases in small greenhouses with or without the introduction of carbon dioxide.

The extra yield in the open field may be attributed to cloudy weather, but the data for the lettuce are not reliable, as there was only a single plant in each pot. Nevertheless, according to these experiments, a positive action of carbonication cannot be denied, but GERLACH asks if the results are sufficiently important to justify practical use without first waiting for further confirmation by later experiments.

II-VII. — Besides this, RIEDEL observed that out of 100 parts of organic plant tissue one-half is composed of carbon, in this way :

Although up till 1860, it was believed *ab antiquo* that plants were able to feed themselves organically, that is to say on carbon from the soil humus, LIEBIGS' theory of carbon dioxide assimilation from the atmosphere was accepted, without however attributing any importance to the fact that the air contains barely 0.3 % of carbon dioxide and that the marked development of vegetation in the carboniferous period, which led to the

Percentage of dry matter of crops grown in open and also from plants grown under cover with addition of carbon dioxide.

Crops	In open field	Under cover + CO^2
Oats	+ 8 %	+ 15 a 20 %
White Mustard	+ 11	+ 18
Carrots	+ 25	— 4
Runner Beans	+ 60	+ 6
Blue Lupin	+ 35	+ 14
Tagetes	+ 19	+ 31
Phlox	+ 41	+ 47
Heliotrope	+ 8	+ 37
Lettuce	+ 50	— 31

	Water	Mineral content	Nitrogen	Hydrogen and oxygen	Carbon
Potato tubers	75 %	1 %	0,3 %	12 %	11,7 %
Rye, seed	13,4	2	1,8	41,8	41

formation of the coal measures now utilised by man, may be attributed to the larger quantity of carbon dioxide then present in the atmosphere. Taking this into consideration, RIEDEL worked out a method of applying carbon dioxide by utilising gases produced by combustion rich in this compound. These gases are available in large quantities, especially in the metallurgical industry. With this in view the DEUTSCH-LUXEMBURGISCHE BERGEWERKS UND HUTTEN A. G. of Dortmund took up the author's proposition, and made an experimental apparatus. Thus, in the spring of 1917, 3 glass houses 19.68 ft wide by 81 ft. long were constructed, and 2 of these were used for comparative experiments. Burnt and purified blast-furnace gas was introduced through a double set of perforated pipes running round one of the glass-houses.

The other, on the contrary, better exposed, received no carbon dioxide. The following table shows some of the quantitative results obtained :

Crops	Under glass with gas	Under glass no gas
	kg.	kg.
Tomatoes	29.5	138
Cucumbers	87.3	235

Thus, the addition of carbon dioxide apparently produced a surplus yield equal to 2 ½ times the control in the case of tomatoes, and to 1.7 times in the case of cucumbers. RIEDEL also arranged a scheme for the

treatment of plants in the open field with carbon dioxide. For this purpose, he set out square plots surrounded by perforated cement pipes, through which the residual blast-furnace gas was passed; at the same time an untreated field with a similar sandy loam soil served as a control. The results obtained with crops treated with carbon dioxide were as follows:

Spinach	2.5 times the yield of the control plot
Beets	1.5 » » » » »
Potatoes	2.8 » » » » »
Lupins green	2.74 » » » » »
Lupins dry	2.9 » » » » »
Barley	2.0 » » » » »

In 1918, the work was extended and the same interesting results were obtained; the surplus yield due to the carbon dioxide treatment was 2-3 times for the tomatoes under glass; in the open field, potatoes treated in a similar manner gave a yield 4 times as high and beets gave the following results:

	With CO_2	Without CO_2	Ratio
	kg	kg	
Plot of 1 sq. metre area + manure + fertiliser, one application	2.8	3.9	1 : 1.40
Plot of 1 sq. m. area + manure + fertiliser, double application	3.3	5.1	1 : 1.54
Ratio	1 : 1.18	1 : 1.30	—

It appears from this that the addition of carbon dioxide would prove useful also to the other manuring of the soil.

To complete these experiments, the treated air was analysed in order to determine the amount of carbon dioxide absorbed in glass houses containing tomatoes and in others that were not cultivated. In the first case, after stopping the inflow of carbon dioxide, the content fell to 0.1 to 0.2 %, and in the second case, 0.42 to 0.65 %, compared with 1 % at the start.

According to RIEDEL, these tests give a positive answer to the question raised by GERLACH namely that the addition of carbon dioxide contributes to a marked extent towards plant development, because the ordinary content of carbon dioxide in the atmosphere does not constitute an optimum. The unsuccessful results should be attributed to unfavourable experimental conditions or to other exceptional causes.

Another question must be asked: Can sufficient quantities of carbon dioxide at a reasonable price be obtained for fertilising purposes? With the hope that this problem may be successfully solved, the future of agriculture assumes a bright aspect. It is obvious that compressed carbon dioxide can not be employed as in previous experiments for this purpose except in case of absolute necessity, as such a method is both too expensive and inadvisable. Quite apart from the possibility of considerably reducing

the consumption of carbon dioxide, there are sufficient sources from whence the gas can be obtained cheaply.

Without taking into account the many combustion gases which require special treatment for the elimination of harmful ingredients, blast-furnaces gases constitute a convenient source of carbon dioxide. These gases contain, it is true, carbon monoxide, but, at normal concentration, it is not injurous to plants, and it is in the interests of heating economy to reduce the content as much as possible.

Other harmful constituents of blast-furnace gases are usually eliminated in most plants, in order to avoid injury to the apparatus. In several cases, the gases still contain sufficient heat to warm glass-houses to a large extent. The exhaust gas from gas engines should be especially useful, as it is under pressure, and therefore does not require machinery to distribute it, particularly if it has to travel several kilometres; a network of piping will be sufficient. As regard the amount of blast furnace gas available, it must be remembered that a furnace charged with 100 tons of coke burns 85 tons of carbon, capable of producing 320 tons of vegetable matter such as potatoes. In Germany, before the war, the siderurgical works used 4000 tons of coke daily in the blast-furnaces, and produced 35 million cub. metres of gas with 20 % of carbon dioxide per day. The lime kilns, as well as sugar refineries could also supply carbon dioxide.

The time will come, according to RIEDEL, when there will be special installations for supplying carbon dioxide for agricultural purposes, just as there are now special plants for the distribution of electric power. This possibility depends on a question of development which cannot be settled in a moment, but which will no doubt be cleared up when conditions are more favourable. Although it is possible that Germany may be able to obtain sufficient industrial carbon dioxide to give increased yields capable of covering the deficit in agricultural crops, until the time when this can be realised, great importance should be attached to organic manures as a source of carbon dioxide for plants. Considering that an increase in the foliar surface necessitates a greater absorption of carbon dioxide, all organic residue matter available should be collected in order to help in the formation of mould.

In conclusion, RIEDEL quotes the opinion of a German Horticultural Inspector, to the effect that the use of carbon dioxde as manure can hardly be neglected, as it constitutes, like nitrogen, phosphates and potash, an important factor in plant nourishment (1).

---

(1) In the United States, CUMMINGS, M. B. and JONES, C. H. (*Journal of the Chemical Society*, Vols. 117-118, No. 689, Pt. I, p. 267. March, 1920), in carrying out experiments with a current of carbon dioxide under glass (boxes or frames), have obtained favourable results with peas, potatoes, strawberries, and lettuce, but not with radishes, which, however, matured early. In most cases, the plants grown with carbon dioxide showed a higher carbohydrate content and a lower protein content. Lettuce benefited the most when given 300 litres of carbon dioxide per day in boxes 130 × 70 × 30 cm. (*Ed.*)

627 – **Influence of Fertilisers on the Combustibility of Tobacco; Researches in Cuba.** — Moreno (Chief of the Department of Chemistry at the Agricultural Experiment Station, Cuba,) in the *Revista de Agricultura, Comercio y Trabajo*, Year II, No. 4, pp. 169-170; No. 8, pp. 377-379. Havana, 1913.

The author has attempted to show the influence of different fertilisers on the combustibility of tobacco, and states the conclusion drawn from practical experiments in Connecticut, Wisconsin and North Carolina, (United States), all of which support the idea that an excess of chlorides is harmful to combustibility, but that the deleterious effects of a known quantity of chlorides is annulled, provided that the soil contains a certain quantity of potash. The experiments made by the author were of a physical and chemical nature, and combustion trials were made with manufactured and leaf tobacco burnt in an automatic apparatus. Several chemical analyses of the stem were made at the same time to show the effect of various fertilisers on its percentage composition. Botanical studies were carried out on leaves which had shown a high coefficient of combustibility, in order to bring out the correlation of characters between the chemical properties and the botanical characteristics of a good leaf, in order to furnish certain data of use in the industrial selection of tobacco.

The experiments were carried out with tobacco from the 1914-15, 1915-16, and 1916-17 crops, grown on the best system available in the fields of the Agricultural Station at Cuba. The land reserved for these trials was divided into 50 small plots 16½ feet long, making 10 series of 5 plots, and these were manured with mixtures of the following fertilisers : — Double surperphosphate ; sulphate of ammonia or sodium nitrate or calcium cyanamide ; potassium sulphate or carbonate. When the plants were full grown, the harvest began, and the dried and prepared leaves were grouped in 3 classes : — Crown (extremity of the leaf), centre (median part), and base. A selection was made of leaves suitable for use in manufactured tobacco with leaves of the same thickness ; the coefficient of combustibility was in each case determined. The results obtained are indicated in Table I.

The author also carried out combustibility trials, with detached leaves by burning the extremity, the centre and the base of each leaf.

The results obtained are shown in Table II.

The author shows the influence of each fertiliser and the nature of the leaves on combustibility and draws the following conclusions :

(1) Double superphosphate, sulphate of ammonia and potassium sulphate increase the combustibility of tobacco.

(2) Calcium cyanimide should only be used in small amounts, because larger proportions produce toxic effects.

(3) Sulphate is the best potassic fertiliser ; the proportion can be increased with advantage to combustibility.

(4) Manufactured tobaccos which burn the best are those of homogeneous composition, those with a small bulk and light colour being preferable.

TABLE I. — *Influence of Fertiliser on Tobacco.*

Fertiliser	Duration of combustion in minutes	Colour of ash	Consistency of ash	Appearance of the combustion rings	Manner of burning	Classification
Double superphosphate, Sulphate of ammonia or calcium cyanamide, potassium sulphate or carbonate	60	Pale grey	Very consistent	Very fine	Very even	Good
None (control), . . .	10	Dark grey	Soft-ridged	Slightly large	Uneven	Bad

AGRICULTURAL BOTANY. CHEMISTRY AND PHYSIOLOGY OF PLANTS

628 – **Oxidising Enzymes of Plants.** — ONSLOW, M. W. (Biochemical Laboratory, Cambridge), in *The Biochemical Journal*, Vol. XIII, No. 1, pp. 1-9. Cambridge, May, 1919.

The dual nature of an oxidase, *i. e.* peroxide-peroxidase, and the fact that one component, the peroxidase, is an enzyme, has been established by previous workers. The resolution of the system into its component parts has also been effected to some extent.

The present investigations, carried out with pears and potato tubers, indicated that the oxidation of an aromatic compound, giving the reaction characteristic of the catechol group, gives rise to the peroxide, and that it is the peroxidase itself which activates this oxidation. The aromatic compound can be separated from the peroxidase by a chemical process, and the two components can afterwards be recombined anew. The peroxidase thus separated turns guaiacum blue only when hydrogen peroxide is added. If the peroxide-peroxidase system is synthesised afterwards by combining the separated substances, it will then turn guaiacum blue. The peroxidase activates the oxidation of the aromatic substance giving rise to peroxides and this system peroxide-peroxidase will then act on guaiacum. In plant

tissues which turn brown on injury or exposure to chlorophorm vapour the peroxidase is associated with the aromatic compound : tissues which do not turn brown on injury, do not contain a substance with the catechol grouping, and their enzymes do not catalyse the oxidation of substances grouped thus.

629 – **The Effect of Potassium Salts on the Anatomy of *Dactylis glomerata*** — PURVIS O.N. (Royal Holloway College, University of London, and Rothamsted Experimental Station) in *The Journal of Agricultural Science*, Vol. IX, Pt. 4, pp. 338-365, Figs. 23, Bibliogr. of 9 works. Cambridge, Oct., 1919.

Potassium compounds play an important part in the metabolism and growth of plants. Amongst these effects are some which have received little attention from investigators, such as the effect on the strength of the stems of herbaceous plants, which may be due to strengthening of the mechanical tissues, or to some other influence on the chemical composition of the walls, or on the physiological condition of the plants.

During the summer of 1917, the author investigated the effect of potassium salts on the anatomy of *Dactylis glomerata*. Plants were collected both from field plots which had received potassic fertilisers, and from those which had not. The yield of hay from these plots was in close agreement with the average, which shows that the season during which the work was done was not abnormal. The thickness of the wall, the diameter of the lumina and the ratio of the lumen to the wall, were measured both in the sclerenchyma and metaxylem.

It was found that in the early stages of the sclerenchyma the walls were thinner where potash had been supplied, but this effect was lost as the season progressed. The lumina were larger in plants which had received potash but no nitrogenous fertilisers whilst in the presence of ammonium salts, this effect was reversed. In the xylem, the thickness of the walls was unaltered whether potassic fertilisers were used or not. When no nitrogenous fertilisers were added, the diameter of the lumen decreased when potash was present, but when ammoniun salts had been applied as well, the diameter was increased. The addition of potassium salts, however, produced an increase in the ratio between the lumen and the walls of the vessels, but this effect gradually passed off. Presumably, therefore, potassic fertilisers reduced the strength of the mechanical cells during the early stages of development.

From these results, it is concluded that the rigidity of plants supplied with potassium salts, is not due to anatomical strengthening, but must be attributed to other causes, such as the influence of the salts on the physiological condition of the plant, or on its chemical composition.

630 – **Observations on the Stimulative Effect of Copper Sulphate on Plants.** — MONTEMARTINI, L., in the *Rivista di Patologia vegetale*, Year X. No. 3, pp. 36-40. Pavia, Feb., 1920.

The author has previously demonstrated (1) that copper sulphate absorbed in very dilute solutions (0.005 to 0.02 %) and in small amounts, can exercise a stimulative effect both on the respiration and chlorophyll

(1) See *R.*, Nov.-Dec., 1911, No. 3110. (*Ed.*)

assimilation of plants. Can this same salt exert the same effect when spread on the outer surface of the leaves ? This question has been discussed, but that it is probable is suggested by the fact that anticryptogamic sprays compounded of the copper salts almost always result in vigorous growth which cannot be entirely explained by the absence of parasites, This action proceeding from the exterior, varies according to the species, more than the action exerted in the interior by the absorption through water channels: it varies especially according to the structure and nature of the cuticle, which is more or less resistant to the passage of moisture. The author has therefore re-opened the question by employing glycine, a plant whose leaves are very sensitive to the action of copper sulphate. It was found sufficient to stimulate these by sprinkling a few drops of a 0.04 % solution of copper sulphate on the upper surface, which caused a greater formation of dry matter. From the results obtained, the author concluded that copper sulphate, sprinkled in dilute solution on the outer surface of leaves of certain plants, exerts a double beneficial action: on the one hand it stimulates chlorophyll assimilation by causing more abundant formation of organic matter ; on the other hand, it also stimulates the circulation and assists the passage of organic substances from the leaf blade to the stem. As a result, special effects ensue in connection with the circulation of the mineral substances contained in the leaf ash.

631 – **On the Supposed Parthocarpy of the Hazel.** — TROTTER A., in *Atti della R. Accademia dei Lincei*, Rendiconti, Serie V, Classi di Scienze fisiche. matematiche e naturali, Vol. XXIX, Pts. 1-2, pp. 72-76, Figs 10. Rome, Jan. 8, 1920.

It has been stated that hazel shows the phenomenon of vegetative parthocarpy and this has been suggested as the explanation of the fall of the young fruit.

The question has been studied experimentally by the author, who enclosed the bushes under movable glass frames and endeavoured to provoke fructification without preliminary pollination. An entirely negative result was obtained.

The presumption that the fall of young fruits is due to parthocarpy can therefore be excluded, and the author considers that it is, on the contrary, due to a form of degeneration of the reproductive system, that is to say, a true abortion, (both ovular and embryonic) comparable to that of animals.

632 – **Plant Breeding and Tropical Crops.** — BATESON, W., in *The Agricultural Journal of India*. Vol. XV, No. 1, pp. 55-62. Calcutta, Jan., 1920. PLANT BREEDING

The crops in temperate countries, for many centuries and in largely populated areas, were put through several genetic stages in the process of improvement and thus tended to differ increasingly from the original types and to be gradually improved.

But, in spite of the considerable improvement aleady obtained, it is evident that the plant breeder, by the selection of valuable types and still more by hybridisation, still succeeds in obtaining immense improvements.

This being granted, it will now be easy to imagine the splendid results which could be obtained by the selection of tropical crops, until now not attempted.

For instance, the coconut is always the same in all the points of the immense area through which it is distributed, and the few local races which exist are very imperfectly differentiated. Taking their geographical distribution as a whole, the coconuts represent a population composed of several type varieties ; but within one individual plantation, it is possible after a simple superficial examination to distinguish distinct differences in respect of the mode of growth, the shape of the leaves, the quality and quantity of the produce. Nothing has yet been done to select the best types and to isolate and propagate them. When choosing and sorting nuts for planting, the planter always gives preference to the best developed and the most prolific plants. This, however, is not sufficient to guarantee success. The monœcious coconut is in reality essentially dichogamous, which accounts for the fact that fine palms can be fertilised with the pollen from very defective males and still produce nuts that are well developed, but incapable of producing plants of superior quality. The author considers it possible adequately to control fertilisation by means of artificial pollination, which will give first-class seed for sowing.

There remains a great deal to be done in thus direction even from a purely physiological point of view. The mechanism of pollination and fertilisation is not yet perfectly understood, and the possibility of self-fertilisation cannot be excluded *a priori*. Vegetative reproduction (as practised with the date) has, according to the author, not yet given positive results. Similarly, *Hevea brasiliensis* shows variation to an enormous extent Among a group of 29 trees of uniform age, grown under similar conditions, the highest and lowest average yields were respectively 166 and 8 cc. and the circumference of these two trees was 52 and 32 inches respectively. With regard to the selection and hybridisation of *Hevea*, nothing has yet been accomplished ; good results have, however, been obtained by propagation of the better strains by vegetative reproduction.

In Java, the Dutch have obtained very encouraging results by applying methods of seed selection to *Cinchona*, thereby nearly doubling the yield of alkaloid.

In India, America and Egypt, a considerable measure of success has been attained with cotton selection, whist Burkill and Finlow have made a beginning with jute, which at present consists of a mixture of most divergent forms.

633 - **Studies in the Pollination of Indian Crops, and the Possibility of Improvement by Selection.** — Howard, A., Howard, G. and Abdur Rahman Khan, in *Memoirs of the Department of Agriculture in India*, Vol. X, No. 5, pp. 195-220. Calcutta, Dec., 1919

The methods of pollination and the frequency of cross fertilisation are two questions of the first importance as regards the improvement of crops in India by selection. On these subjects, in fact, depends the method to be adopted, the choice of material, and the distribution thereof. In the

present paper, the authors present the results obtained in a series of trials conducted at Pusa with a view to studying the pollination mechanism of the following crops : San hemp (*Crotalaria juncea* L.) pigeon pea (*Cajanus indicus* L.), Java indigo (*Indigofera arrecta* Hochst.), Sumatran indigo (*Indigofera Sumatrana* Gaert.), linseed (*Linum usitatissimum* L.), taramira (*Eruca sativa* Lam.), til (*Sesamum indicum* L.), niger (*Guizotia abyssinica* Cass.), jute (*Corcherus capsularis* L. and *C. olitorius* L.), and roselle (*Hibiscus Sabdariffa* L.).

Some of the results obtained and described, especially those dealing with *Cajanus, Indigofera* and *Crotolaria,* are the most important from the point of view of applied pure line selection.

With *Cajanus* the question of yield holds the foremost place. The problem before the breeder, therefore, is to secure the heaviest crop possible before considering the quality. Now, the research on pollination and fertilisation shows that other factors, besides potential yielding power are involved, in particular, atmospheric conditions. Practically no setting takes place in damp and dull weather. This adverse condition can be avoided by increasing the range of the flowering period, and thus distributing the risk over a longer interval.

The author advises the use of a mixture of individuals differing considerably in time of flowering. This method, however, involves the necessary rejection of pure-line selection and the adoption in its place of mass selection.

With *Indigofera arrecta,* the case is still more interesting. The crop consists of a mass of heterozygotes with a wide range of general habit, root development, extent of leaf surface, and time of flowering. Cross-fertilisation is a normal process, but practically no setting takes place if insects are excluded. There as been so much crossing in the part, and the gametic constitution of each individual is so complex, that many years work would be necessary for the isolation of the unit species which underlie the existing fabric of heterozygotes . But, even if such a result were obtained, a new drawback would probably arise, namely a lowering of vitality that would render the pure lines finally obtained, worthless for any agricultural purposes.

Methods of continuous mass selection which were successfully adopted by the Dutch planters in Java are far more promising. Crossing cannot be prevented but if it is to be regulated, defective cultures should be eliminated so that crossing is only permitted between those cultures which are agriculturally desirable.

The authors then summarise the results obtained with the best crops.

San-hemp (*Crotolaria juncea* L.). — If flowering takes place in muslin bags, the pollen is liberated and forced on to the stigma, but no subsequent setting takes places ; the flower itself even, gradually fades after a few days. This does not prevent the possibility of self-fertilisation, which, however, cannot take place unless the stigma is first stimulated by contact with insects. One consequence, therefore, of insect visitation is self-pollination. Stimulation of the stigmatic surface does not appear

necessary, however, for cross-pollination. The frequency and the facility of natural crossings obtained with cultures of very different habit grown side by side, *e. g.* the local Pusa variety and the Jubbulpore variety from the Central Provinces within a few years only, gave an indistinguishable variety showing elimination of the marked differences of habit of these two varieties. For these reasons, it may be concluded that improvement of crops by selection is not an advantageous proceeding. It is doubtful if the enormous amount of work necessary to combat the continued counter-activity by vicinism to any extent, would repay the cost and trouble involved.

Pigeon Pea (*Cajanus indicus* Spreng.). — The numerous marked characteristics noticeable with the progeny of one parent plant indicated the frequency of natural cross-fertilisation. To determine the precise extent of natural crossing, some observations were made in 1912-13 on a pure culture of " arhar " (var. *bicolor*), characterised by pale yellow flowers and white seed, which made the detection of heterozygotes an easy matter. Of this pure culture, 140 single plants were selected and sown separately the following year. Natural crossing was found to have occurred in 91 of the cultures, that is, in 65 %. The characters which best lend themselves to the detection of heterozygotes and which show the kind of splitting which takes place are : the general colour of the standard, the colour of the pods, and the character of the seed coat The flowers may be either pale yellow, deep yellow, or orange, with or without reddish lines,etc., on the back of the standard, and each of these types gives rise to progeny with the most extraordinarily varied characteristics. The pods may be green or variously marked with red or black, the latter markings being sometimes present to such an extent that the pod appears to be entirely covered. The seed coat may be white, grey, brown, reddish-brown, purple, smoky or black, and usually in addition to this ground colour, brown, black, violet or red spots.

There appears to be no obvious connection between the colour of the seeds and that of the flowers, and in any case the peculiarities after splitting showed the heterozygous complexity of the plant in question.

The difficulties that attend pure line selection are evident. In addition to this, the flowering period of the local crop was much greater that than of the pure culture. The effect of adverse weather conditions is therefore in the former case less harmful, as only a part of the plants in flower can be attacked or damaged.

In 1911-12, at Pusa, one of the most promising of the pure lines (characterised by pure white sed and a pale yellow standard) was compared with the local mixed crop, and gave a yield inferior to the latter, in the ratio 1 : 2.5. The local crop thus showed an output twice as high as the pure culture.

The sets in the pure culture were distinguishable with regard to productivity according to the behaviour of the homozygotes and the heterozygotes ; the latter gave nearly three times the yield of the former.

These results lead to negative conclusions concerning the advantages

of pure line selection. The shortening of the flowering period and the lack of stimulation due to heretosis are liable in every case to decrease the yield considerably. Continuous mass selection, then, is more advisable.

JAVA INDIGO (*Indigofera arrecta* Hochst.) and SUMATRA INDIGO (*I. sumatrana* Gaertn.). — With *I. arrecta* self-fertilisation is a very difficult matter, the visits of bees being necessary for seed formation. With *I. sumatrana* no setting takes place if cross pollination is hindered by artificial means. However, even with flowers thus isolated, setting can be produced (not always, it is true) if the flowers are artificially made to explode (" heterosis "). The attempts to cross these two species have so far failed.

LINSEED (*Linum usitatissimum* L.) — The linseed cultivated in India as an oil-seed, is very different from the European form grown for its fibre ; it is a short, much branched plant with thick stems and numerous capsules.

For some years, a large collection of pure lines of Indian linseed obtained from the black soil areas of Peninsular India, and also from the Plains (N. India) have been under investigation. From the observations and experiments made with the anthers and pollination, it was concluded that self-pollination is a practical certainty, in such a way that even if bags are employed, this does not interfere with setting and there is no apparent falling off in vigour in the progeny produced in this way.

TARAMIRA or DUAN (*Eruca sativa* Lam.). — (See Table I.)

Flowers bagged and afterwards left untouched		Flowers pollinated				Cross-pollinated from other plants	
		from flowers of the same inflorescence		from flowers of another inflorescence on the same plant			
Flowers treated	Pods formed	Flowers treated	Pods formed	Flowers treated	Pods formed	Flowers treated	Pods formed
79	0	18	1	42	6	24	24
		24	1	13	0	30	30
				20	0	13	13
				19	0	14	14
				16	0	18	17
				36	6	10	10
				22	4	10	10
				43	0	12	10
						34	34
79	0	42	2	211	16	165	162
		These 18 pods as a rule contained only one seed each.				Pods well filled with seed.	

Cross fertilisation, however, is, possible. In 1916, the seed of 340 bagged plants was sown and 334 bred true, whilst splitting took place in 6 cultures only. In 1917, the seed of 233 plants were sown under similar conditions and all bred true except one which split as regards habit and flower colour. It thus seems that cross-fertilisation is more frequent than would be suspected from a study of the flowers; hence the necessity for isolation in accurate work on the genetics of the crop.

Self-fertilisation is exceedingly rare; setting is consequently the result of cross-fertilisation. The crop is therefore a mixture of freely-crossing heterozygotes.

Til (*Sesamum indicum* L.). — Self-fertilised. In 1910 the seeds of a large number of single plants were sown separately at Pusa and the progeny examined. There was no doubt that many of these were heterozygotes, which signified the possibility of natural crossing. A study of the homozygotes and the heterozygotes made it possible to determine the characters of the various Indian types of til.

Rough and Smooth seeds. — As a rule, the surface of the seed is smooth, and with homozygotes this is always the case; in the cultures raised from some heterozygotic smooth parents, some plants with rough seeds were produced.

Colour of corolla. — Almost pure white to deep violet.

Branching. — Those types with one flower in the axil are generally much branched while those with 3 flowers have few or no branches.

Number of flowers. — As a rule, only one flower is produced in each leaf axil, the other two bud-like bodies developing into extra floral nectaries. Sometimes on the contrary, 3 flowers are developed and without any branching.

Other distinctive characters may be observed in the form of the leaves, and in the hairiness of corolla and capsule.

Niger (*Guizotia abyssinica* Cass.). — Cross-fertilisation is common in this crop and, consequently, the cultures containing heterozgotes are prevalent. Splitting took place in the following characters: — Time of maturity, colour of the stem (green, red or intermediate tints), habit (branching or erect), size and margin of the leaves, colour of the seeds, and height of the plant.

Round-podded Jute (*Corcherus capsularis* L.). — The prevalence of self-pollination and the comparative ease with which heterozygotes can be detected and removed before flowering takes place, render improvement of this crop possible by means of pure-line selection.

Long-podded Jute (*Corcherus olitorius* L.). — The rarity of natural crossing, and the fact that each plant pruduces a large quantity of seed should render improvement by selection certainly possible.

Roselle (*Hibiscus Sabdariffa* L.). — Self-pollination is the general rule. A few cases of natural crossing were observed duè to the visits of humming birds.

34 – **Criticism on the "Crossing Over" Theory, according to the Calculation of Probabilities.** — NACHSTHEIN HANS, in *Zeitschrift für induktive Abstammungs und Vererbungslehre*, Vol. XXII, Pt. 2, pp. 127-141, figs. 4. Leipzig, Jan. 1920.

The author, arguing from a mathematical standpoint, sets out to refute the objections raised by TROW with regard to the "crossing over" theory (1) formulated by MORGAN.

Suppose that there are 6 factors for each chromosome :—

A B C D E F
a b c d e f } homologous chromosomes.

On varying the point of exchange or crossing according to the law of probabilities, 5 possible forms of crossing (see fig. 1) will be obtained :

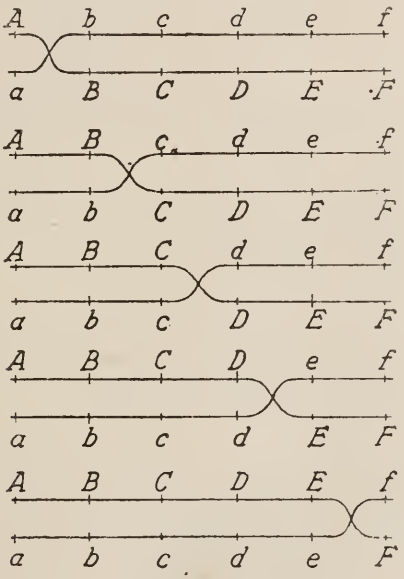

Fig. 1.

With these 5 forms of crossing, the following new combination of factors occurs :—

1 Ab	2 Ac	3 Ad	4 Ae	5 Af
	1 Bc	2 Bd	3 Be	4 Bf
		1 Cd	2 Ce	3 Cf
			1 De	2 Df
				1 Ef

The number of crossing possible between two factors (in 2 homologous chromosomes) increases proportionately to the distance between the two factors. Factor **F** for example, is placed 5 units from **A, D** 3 units and B

(1) See *R.*, Jan., 1918, No. 29, pp. 52-54, note (1). (*Ed.*)

one unit. Therefore, the combination **Af** is reproduced 5 times, **Ad** 3 times, etc. The percentage between 2 of these 6 factors results from the following combinations :—

Ab / AB	1/4	= 20%;	Bc / BC	1/4	= 20%;	Cd / CD	1/4	= 20%;	De / DE	1/4	= 20%;
									Ef / EF	1/4	= 20%; cross-overs
Ac / AC	2/3	= 40%;	Bd / BD	2/3	= 40%;	Ce / CE	2/3	= 40%;	Df / DF	2/3	= 40%; cross-overs
			Ad / AD	3/2	= 60%;	Be / BE	3/2	= 60%;	Cf / CF	3/2	= 60%; cross-overs
						Ae / AE	4/1	= 80%;	Bf / BF	4/1	= 80%; cross-overs
									Af / AF	0/5	= 100%; cross-overs

If 1 chromosome contains on the contrary, 26 factors, **A, B, C, Z...** the following would be the result :—

$$\frac{Ab}{AB}\ \frac{1}{24} = 4\%\ \text{cross-overs};$$

. . . . . .

$$\frac{Az}{AZ}\ \frac{25}{0} = 100\%\ \text{cross-overs}.$$

If 1 chromosome contains n factors ; the following general formula will be obtained (to determine the percentage) :—

$$\frac{1}{n-2},\ \frac{2}{n-3},\ \frac{3}{n-4},\ \ldots\ldots\ldots\ldots\ \frac{n-1}{n-n}$$

Application of these formula shows that :—

$$\frac{Ab \times 100}{AB - Ab},\quad \frac{Ac \times 100}{AC - Ac},\quad \text{etc.}$$

The percentages of " cross overs " constitute an arithmetical progression :—

$$\frac{1 \times 100}{n-1},\ \frac{2 \times 100}{n-1},\ \frac{3 \times 100}{n-1},\ \text{etc.}\ \ldots\ldots\ \frac{(n-1)\ 100}{n-1}.$$

Whilst the number of cross-overs increases with the distance of the factors, the number of " non cross-overs " decreases, up to this point, and mathematical analysis does not in any way contradict MORGAN's theory.

What will happen now, if, instead of only one, 2 or more cross-overs are observed ? Figure 2 (p. 712) illustrates this case of double crossing

ver, the 6 factors remaining invariabile, as in the preceding case. The ollowing combinations are possible :—

1.	4 Ab	3 Ac	2 Ad	1 Ae
2.		3 Ac	2 Ad	1 Ae
3.			2 Ad	1 Ae
4.				1 Ae
—	4 Ab	6 Ac	6 Ad	4 Ae

The percentages of cross-overs are :—

$$\frac{Ab}{AB} = \frac{4}{6} = 40\%. \quad \frac{Ac}{AC} = \frac{6}{4} = 60\%, \quad \frac{Ad}{AD} = \frac{6}{4} = 60\%;$$

$$\frac{Ae}{AE} = \frac{4}{6} = 40\% \text{ cross-overs.}$$

Supposing that there are 26 factors, A. . . . Z, the following com inations will be obtained :—

1.	24 Ab	23 Ac	22 Ad	21 Ae	20 Af	19 Ag	—	1 Ay		
2.		23 Ac	22 Ad	21 Ae	20 Af	19 Ag	—	1 Ay		
3.			22 Ad	21 Ae	20 Af	19 Ag	—	1 Ay		
4.				21 Ae	20 Af	19 Ag	—	1 Ay		
5.					20 Af	19 Ag	—	1 Ay		
6.						19 Ag	—	1 Ay		
...								...		
...								...		
...								...		
24.								1 Ay		
	24 Ab	46 Ac	66 Ad	84 Ae	100 Af	114 Ag	...	84 Av	66 Aw	46 Ax 24 Ay.

Therefore, in the case of double crossing-over, the percentages of cross- vers do not form a series in arithmetical progression, but occur in the orm of a symmetrical curve. In other words, the number of cross-overs s not proportional to the distance between the factors.

Whilst, in reality, for series A . .Z, in the case of one single crossing- ver, the following percentages of cross-overs occurs :—

$$\frac{Ab}{AB} = \frac{1}{24} = 4.0\% \ldots \frac{Af}{AF} = \frac{5}{20} = 20.0\% \ldots \frac{Am}{AM} = \frac{12}{14} = 48.0\%,$$

$$\frac{An}{AN} = \frac{13}{12} = 52.0\% \ldots \frac{Au}{AU} = \frac{20}{5} = 80.0\% \ldots \frac{Ay}{AY} = \frac{24}{1} = 96.0\% \ldots \frac{Az}{AZ} = \frac{25}{0} = 100\%;$$

n the case of a double crossing-over these are :—

$$\frac{Ab}{AB} = \frac{24}{276} = 8.0\% \ldots \frac{Af}{AF} = \frac{100}{200} = 33.3\% \ldots \frac{Am}{AM} = \frac{156}{144} = 52.0\% \ldots \frac{An}{AN} = \frac{150}{144} = 52.0\%;$$

$$\frac{Au}{AU} = \frac{100}{200} = 33.3\% \ldots \frac{Ay}{AY} = \frac{24}{276} = 8.0\% \ldots \frac{Az}{AZ} = \frac{0}{300} = 0\%.$$

Fig. 2.

Therefore in the case of a double cross-over, the maximum number of cross-overs should be between A and M and between A and N.

Now, the distance between M and A (between N and A) is obviously less than the distance between A and X (A and Y). Although Y may be 24 times further from A than from B, the two combinations Ab and Ay are equal.

(An equal percentage of cross-overs, in the case of a simple as well as of a double cross-over, only occurs with A—N, being always 52 %).

The percentage of cross-overs increases from extremity up to median point in the chromosome, and then decreases, gradually, till the other extremity is reached.

According to the MORGAN method, the determination of the *locus* of the chromosome factors is based on the percentage of cross-overs, allowing that the higher this is, the greater should be the distance between the two factors in question. Then, after what has been shown above, the principle applies only in the case of a simple cross-over, but loses all its validity, in the case of a double cross over. Things become even more complicated if, instead of 2, there are 3, 4, 5 and anything up to 25 crossing-overs (given that the number of points where crossing is possible is equal to the total number of factors minus 1).

In this last case, the two homologous chromosomes should resemble a double spiral with numerous compact convolutions (see Fig. 3).

$$\frac{Ab}{AB} = \frac{Ad}{AD} = \frac{Af}{AF} = \ldots\ldots = \frac{Az}{AZ} = \frac{1}{0} = 100\ \%\ \text{cross-overs}$$

$$\frac{Ac}{AC} = \frac{Ae}{AE} = \frac{Ag}{AG} = \ldots\ldots = \frac{Ay}{AY} = \frac{0}{1} = 100\ \%\ \text{non cross-overs}$$

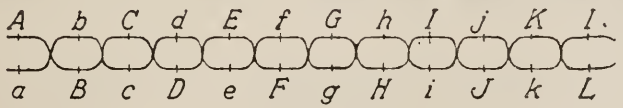

Fig. 3.

As regards a simple exchange between factors, no objection can be raised to TROW's arguments. On the other hand, the results are evidently in accordance with MORGAN'S conclusions, obtained by a process of induction; the percentage of exchanges increases proportionately with the distance between the two factors.

But the ratio differs when two or more cross-overs are under consideration. If it is true that the phenomenon of the double, triple, etc., cross-over was so frequent, as TROW admits, the localisation of the factor in the chromosome, based on the percentage of cross-overs, would be impossible.

But, to admit the frequency of double, triple, etc., crossing-over, constitutes the weak point in TROW's argument; these cross-overs are in reality very rare.

Therefore, in the determinations made by MORGAN on the behaviour

of 3 factors in chromosome *I* (=sexual chromosome), out of 10 495 cases, 3514 gave simple cross-overs and 9 gave double cross-overs, and 6972 neither one nor the other.

Experiments conducted by SARTEVANT are equally interesting:— In one experiment, dealing with 3 factors in Group I, out of 308 cases, 113 gave simple cross-overs, 1 a double cross-over, and 194 none. In a second experiment, out of 439 cases, there were 161 simple, no double, and 278 none. In a third experiment, dealing with 4 factors, also in Group I, out of 635 cases, there were 228 simple, 4 double and 393 none.

M. MÜLLER gives an analysis of 12 factors of chromosome I and 10 of chromosome II.

Chromosome I. — There was scarcely any change in 54.4 %, of the cases, whilst simple crossing-over gave 41.6 %, and double crossing-over only 4 %.

Chromosome II. — No cross in 32.5 % cases, simple in 51.1 % cases, double in 15.2 %, and triple in 1.3 % cases.

It can at least be concluded from the results at present obtained, that double, triple, etc., cross-overs are very rare compared with simple cross-overs, and the error that they may cause in the localisation of the factor in the chromosome is practically negligible.

The scheme for simple exchange constitutes therefore the mathematical basis of the crossing-over theory, in which the percentage of cross-overs gives a series in arithmetical progression. The result obtained by TROW by deduction agrees entirely with those obtained by MORGAN by the induction method.

635 – **"Pusa No. 4", Indian Wheat Variety imported into France because of its Early Maturity and Resistance to Scorching.** — SÉVERIN, R., in *Comptes rendus des séances de l'Académie d'Agriculture de France*, Vol. VI, No. 12, pp. 313 and 324-325. Paris March, 1920.

The author presented to the Academy some ears of the Pusa No. 4 wheat variety, selected by Prof. HOWARD of the Cereal Station of the University of Pusa. This wheat has the characteristics of rapid growth and of carrying its grain normally until mature, even if sown very late after the last rains, or if there is no rainfall from sowing time until harvest. This was proved at Vaucluse by M. BRULAT, in spite of a persistant north west wind after the sowing at the end of March., followed by an exceptional drought during the summer of 1919; also at Toulouse by Prof. RIVES, at the University Agricultural Institute, and at Bagnols sur-Garonne, by M. ROUART (sown on April 5), and also on the author's own trial plots at Clos-l'Arat, Fontet, near Réole (Gironde). The ears taken from these cultures were ripe in 90 days.

Several other varieties of Indian wheat with a rather less fine grain sown in the spring of 1919, escaped the rust which ruined the autumn sown varieties in 1918, and gave results which the author hopes to confirm this year. The author is also testing further samples from the Experimental Stations in Australia and the United States, bearing in mind the fact that the Indian wheats are particularly resistant to drought, and excess of moist

ure, and are thus valuable for improving wheats in countries that suffer rom excessive heat and dryness.

36 - **The Traumatic Production of a New Form of Maize: *Zea Mays*, var. *polysperma*.** — BLARINGHEM, L. in *Comptes rendus de l'Académie des Sciences*, Vol. CLXX, No. 11, pp. 677-679. Paris, March 15, 1920.

From *Family* II of a teratologic type of maize descended from the eeds of a type *B* obtained in 1907 after sectioning the main stem (1), the uthor isolated a line of maize with " shrunken leaves ", described in 911 and since then the line *Zea mays* var. *polysperma* with fruits composed f 2 and occasionally 3 closely-packed caryopses. The double caryopses re united on their homologous surfaces and the embryos are at the extremity of the diameter perpendicular to the point of contact. The general ymmetry is more easily observed in the very rare fruits consisting of ; carpels and 3 embryos.

In 1911, an interesting correlation was observed between the male nflorescences and the ears of aberrant varieties. All the plants with ars containing double seeds, produced panicles which though exclusively nale, showed fusions and repetitions of the floral parts :— glumes and ales either 3 or 4 in number, glumes with large parallel nervures in twos r threes, and supernumary or forked pales, stamens, 4, 5 and up to 7 in he same flower, authers fused or forked.

The male inflorescences opened before the appearance of the stigmas, nd all those not showing the anomaly could therefore be suppressed beore pollination. Since 1911, the author has reserved for pollination purposes solely the panicles showing a large proportion of abnormal ears; he pollen was supplied both by normal and abnormal blossoms. In ddition, to avoid the sterility to which entirely self-pollinated strains of naize are liable, the author introduced in 1913 as accessory male parents, lants derived from another tetralogical strain of maize " à grains acajou " btained from *Family* I. In the choice of ears destined for propagation y breeding, the author has always attributed more importance to those with double grains rather than to the actual number of these double grains n the ear selected.

Thanks to these precautions, the author has been able to propagate a new type in which the characters are transmitted with great regularity.

An ear in 1911, bearing 9 double grains gave :—

	Plants with double grains	Plants with single grains
In 1912	48	17
In 1913	71	54
In 1914	not noted	not noted
In 1918	46	62
In 1919	57	71

(1) L. BLARINGHEM, *Mutations et traumatismes*, p. 42. Paris, 1907 ; Foot note A. (*Author's note*)

At the same time the proportion of multiple caryopses on the more striking ears, rose from 5 % (1911) to 95 % (1919).

In conclusion, the author may be said to have obtained, amongst the strains from grain developed on a terminal inflorescence (consequently fasciated), a new strain of maize showing fasciation, even to the reproductive organs.

637 – **Pedigree Selection Applied to the Rice Variety, "Nang-Meo" in Indo-China.** — CARLE, E. (Agricultural Inspector, attached to the Plant Breeding Laboratory at the Scientific Institute, Indo-China), in *Bulletin agricole de l'Institut Scientifique de Saïgon*, Year 2, No. 3, pp. 73-75. Saïgon, March, 1920.

The author gives the characteristics of the "Nang-Méo" variety so as to allow comparison to be made, with the results obtained later by pedigree selection :—

Origin	Bacliêu
Date of receipt by author	1912
Colour of outer coat	brown golden yellow, several brown bristles.
Shape	fairly long
Weight of 1 000 grains	28.5 gm.
Percentage of red grain	8 %
Percentage of kernels	51.09 %
Percentage of husks	18.91 %
Average yield per hectare	1500 to 2000 kg.
Vegetation period at Saïgon	160 to 170 days.

This variety possesses all the characters of a group containing numerous types, and pure line selection would no doubt give excellent practical results and lead to the isolation of the better varieties.

The following Table gives a summary of the results of the first trial carried out at the Phu-my Experiment Station.

	Number of line	Number of ears per 100 tufts	Weight of ears in kg.	Average weight per ear in gm.
	Group	800	1.210	1.51
F_1	N° 1 060	1 775	2.916	1.65
	» 1 032	1 101	1.880	1.70
	» 1 069	753	1.362	1.89
	» 1 044	920	1.820	1.97
F_2	» 1 060	749	1.716	2.32
	» 1 032	905	1.384	1.53
	» 1 069	646	1.387	2.14
	» 1 044	729	1.345	1.84
F_3	» 1 060	677	1.700	2.51
	» 1 032	835	1.940	2.32
	» 1 069	1 027	2.497	2.40
	» 1 044	1 100	2.011	1.85

This Table shows that the highest yield is obtained in the F_1, but that two lines of the F_2 show a much higher yield than those in the F_3. These should be worth observation, especially as the divergence lies with the plants selected in one culture, whilst the yield given in the table for the 3 generations is an average yield for the total number of tufts belonging to these lines.

The low quantity of seeds obtained as yet by purely biological selection does not yet allow more than small-scale trials. The author is limited therefore to making cultures, on the one hand with selected pedigree seed and on the other, with ordinary seed sorted with the MAROT sorter or CERTANI table.

Although ordinary seed gave an average yield of only 2000 kg. on several plots, the pedigree mixture gave 4019 kg. per hectare at the Phu-My Experimental Station.

From the results so far obtained, the author has found :—

1) A distinct similarity in vigour, height, inflorescence, and maturity.

2) That the difference in the dates of flowering of one line and another is from 10 to 15 days.

3) That the weight of the ear obviously increases in the third generation.

638 – **Sugar-cane Breeding in North India.** — VENKATRAMAN, T. S., in *Agricultural Research Institute, Pusa, Bulletin* No. 94, pp. 1-17, pl. VI. Calcutta, 1920.

The steady increase in the quantity of white sugar imported into India, combined with its low prices, has had such a depressing effect on the native " Gur " (crude sugar) industry that the attention of the Government has been directed to this industry with a view to putting it on a satisfactory basis.

The measures adopted are of two kinds : 1) The improvement of sugar canes and manufacturing methods ; and 2) the improvement of local varieties.

The work of breeding a better cane for North India, was entrusted to the breeding Station at Coimbatore, Madras under C. A. BARBER (1912).

The sole disadvantage of the selected site at Coimbatore lies in the fact that it is in a portion of India subject to meteorological conditions very different from those in the northern regions, the final destination of seedlings produced at the Station. On the other hand, however, the sugar cane rarely flowers in North India, and even if it does, the seed does not usually set. As this is a necessity in plant-breeding work, the Station was therefore chosen further south.

During the early years, the varieties that flowered were mostly thick canes : the seedlings produced were consequently also thick, and therefore unsuitable for introduction into North India. Later on, however, it was found possible to induce many of the thin canes also to flower, and in February, 1918, the first batch of seedlings was ready for distribution for trial purposes.

Crossing of the sugar cane presents peculiar difficulties. Fortunately

certain varieties exist which are male sterile in different degrees. If this sterility is absolute, by enclosing such flowers with a muslin bag and introducing into it some known pollen, a cross can be obtained of known parentage, such as Co. 205. If, on the contrary, it is only a case of partial sterility, the seedlings will either be selfed or cross-pollinated.

Both these are referred to as " bagged crosses ". It was found that bagging an arrow frequently exerted an adverse influence on its seed setting, and therefore, in later years, crossing was done by merely marking the another arrows and keeping them constantly dusted with some known pollen till the stigmas were found to wither. These are called " unbagged crosses ".

The resultant seedlings are still more uncertain and may be :—

a) Selfed.

b) Crossed with paternal pollen.

c) Crossed with some unknown parent through some stray windborne pollen.

Such is the constitution of Cos. 214, 215 and 216.

To systematise the work as far as possible, and to guarantee that each character gets its due recognition in the final estimate, a system of marking was introduced. To each character was allotted a maximum of 10 marks. Marks were given for the following field characters :— 1) Stand or germinating capacity ; 2) vigour or weight of yield ; 3) habit (straightness of canes — an important point) ; 4) tillering, *i. e.*, number of canes per stool.

A Table gives the marks obtained for the above four characters by each distributed seedling.

The sucrose contents in the different farms were estimated, but the figures are not yet strictly comparable, because of : 1) The smallness of the samples analysed ; 2) the unequal state of maturity of the samples ; 3) differences in the methods of analyses adopted.

The distribution of the selected material for trial purposes include the following localities : — Bangalore, Manjri, Tharsa, Pusa, Sepaya, Shajahanpore, Gurdaspur, Cawnpore, and Gwalior.

639 - **Studies and Observations on the Hybrids of the *Genus Citrus*.** — Trabut, L., in *Bulletin de la Société d'Histoire Naturelle de l'Afrique du Nord*, Vol. X, No. 5, p. 89. Algiers, May 15, 1919.

For 20 years, the author has endeavoured to draw attention to a *Citrus* hybrid of the mandarin orange, which he named " Clementine ". The seeds from Clementine have produced Seville orange trees with very narrow leaves, mandarin orange trees with acid and bitter fruits, and orange trees of good quality. No precaution having been taken to avoid pollination from external sources, some of the these trees have originated from new crosses. At present, two of these hybrids can be preserved : the orange, good quality with highly coloured peel, juicy and with an agreeable smell ; and a small mandarin which the author proposes to call " Mandarinette. " The latter has a very pleasant smell, and is especially

suitable for confectionary, for which it may take rank with the "Chinese" and "Kumquat" varieties.

The seeds of "pomelo" have also given rise to a very varied progeny thus indicating that the pomelo is a hybrid of *Citrus grandis*; the author has obtained both *Citrus grandis* and orange trees from this hybrid. One of these orange trees resembled the American variety Pineapple. Another series consists of stock, bearing fruit similar in form and appearance to the Jaffa orange, but with very different leaves, many of which have a petiole with a big sheath like the pomelo.

These observations have shown that the seeds from these original hybrids can give rise to many new forms, some of which may be worth inclusion in orange plantations. In any case methodical crossing between the species of the genus *Citrus* will give new and interesting fruits in less time.

640 – **A New and Improved Variety of Plum obtained from a Bud Variation of the French "Petite Prune d'Agen", in California.** — SHAMEL, A. D., in *The Journal of Heredity*, Vol. X, No. 8, pp. 339-343; figs. 4. Washington, D. C., Nov. 1919.

The French plum (*Prunus domestica*) commonly called the "petite prune d'Agen" and cultivated on a vast scale in California, is noteworthy as a heavy bearer and for the excellent quality of the fruit, which however has the disadvantage of being somewhat small.

The production of a variety which, while retaining all the good points of the "petite prune d'Agen" can produce larger fruits, is consequently of considerable importance.

Good results have been obtained by a fruit grower, Mr. L. COATES, of Morganhill, California, who has succeeded in isolating some more or less distinct strains. In this paper the author describes one of these strains which originated from a bud variation and which promises to be the larger fruited variety so much sought after by plum producers. In 1904, in an orchard near Saratoga, Cal,. on a normal plum tree, COATES noticed one branch bearing very large fruits. The grafts secured from this branch gave plants which conserved the improvement in size, and at the same time possessed all of the desirable characteristics of the ordinary French plum. The new strain was called No. 1418.

In 1914, the No. 1418 (large fruited) and the ordinary plums (small fruited) were budded in alternate rows on about 1000 peach trees. The results furnish the basis for a fair comparison, as the yield of No. 1418 was more than double that of the parent variety; the fruit averaging about 25-30 to the pound, compared with 50-60 to the pound for the latter.

This new variety is not only remarkable for the size of the fruits, but also for the uniform distribution throughout the trees, which appear to be more vigorous growers and to develop larger leaves.

In studying the individual trees of No. 1418, several branches were occasionally found bearing fruits unmistakeably of the ordinary French type, which is additional evidence as to the origin of this bud variation.

At the present, in several localities, numerous experiments are in pro-

gress with a view to discovering the adaptability and possible area of distribution for this new variety of plum which should play an important part in fruit growing in California.

CEREALS AND PULSE CROPS

641 – **Spring Wheat on Southern Italy.** — CAMPBELL, C., in *Il Coltivatore*, Year LXVI No. 2, pp. 38-40. Casale Monferrato, Jan. 20, 1920.

The meteorological conditions in Southern Italy, always rainy in autumn, usually do not permit late sowings of wheat to be made, especially as the cold weather is not associated with snow and invariably includes a more or less lengthy period of frosts during which the plant not only stops growing, but also suffers from the direct action of the frost. These facts induced the author to attempt to cultivate spring wheat in the region in question, as the crop, towards the end of January and the beginning of February, can profit by the autumn cultivation of lupins or other leguminous plants as green manure, or used partly as forage and partly as green manure. There is thus the combined advantages of forage, green manure, and perhaps even compost, and also of avoiding the dangers associated with winter.

Following this system, successive wheat crops can be cultivated on the same land without danger, provided that between the two crops, comes the leguminous crop. The summer cultivation, even if only superficial, immediately after the harvest is sufficient to prepare the land for the leguminosae, when the first autumn rains begin.

The author's experiments lasted from 1905 to 1908. The trial with spring wheat in Northern Italy met with no success ; on the contrary, very encouraging results were obtained with Manitoba wheat (1).

In connection with the sowings made with Manitoba wheat, it should not be forgotten that for commercial purposes the Americans have classified this variety according to quality. Thus, Manitoba No. 1, has almost without exception an exposed ear possessing the ordinary qualities met with in spring wheat ; the other numbers are more or less a mixture of heterogeneous varieties amongst which those with exposed ear only constitute a small proportion.

This accounts for the unsuccessful results that Manitoba wheat has given and for the criticisms of its cultural qualities.

It had been hoped to discover a Red Fife in the Manitoba wheat. After due investigation the author has been led to believe that Manitoba No. I is no other than the Banatka wheat of Roumania and Ukraine, where it is cultivated as spring wheat The variety has probably been transported to America and cultivated there in a more or less pure state, gradually taking the place of the commercial product known under the name of Manitoba.

(1) With reference to Manitoba wheat in Canada and trials with this wheat in Italy, France and North Africa, see original article by M. L. H. NEWMANN, " Wheat production in Canada " in *R.*, July, 1917, pp. 961-967 and *R.*, April, 1917, No. 326 ; *R.*, Nov., 1917, No. 1017 ; *R.*, Jan., 1918, No. 34 ; *R.*, Sept., 1918, Nos. 978 and 1051 ; *R.*, Nov., 1918, No. 1230 ; *R.*, Dec., 1918, No. 1349 ; *R.*, Jan., 1919, No. 39 ; *R.*, Mar., 1919, No. 311 ; *R.*, May, 1919, No. 590. (*Ed.*)

After giving up work with the spring wheat varieties of the north, and having demonstrated that in actual practice, these cannot be adapted to southern climatical conditions, the author studied Manitoba comparatively with Apulian spring wheat („ Marzuolo di Puglia,„ "Marzulli") and the "Triminia„ from Sicily. These three varieties have proved themselves of good quality, but, although the productivity of the two first has not declined, the wheat from Apulia has given an inferior yield. During the author's experiments, the yield from spring wheats has kept fairly regular, and scarcely any noticeable difference has been found between this and the yield from the local autumn-sown wheats.

The question is whether it is advisable to extend the cultivation of spring wheat in Southern Italy in preference to the present uncertain production of maize. The author considers that this may be answered in the affimative, provided that the summer work on the stubble is not overlooked.

642 – **Mechanical Cultivation of Rice; The Gray Tractor with One Driving Wheel of The American Tractor Co.** — See No. 686 of this *Review*.

643 – **Preliminary Report on the Acclimatisation of Alfalfa in the Philippines.** — ELAYDA, I., in *The Philippine Agriculturist*, Vol. VIII, No. 3, pp. 10-76, pl. 1. Los Baños, Oct. 1919. FORAGE CROPS MEADOWS AND PASTURES

As alfalfa is reported to be under cultivation in Hawai, a tropical country it seems probable that suitable conditions may be found also for its growth in the Philippines, and several trials have been made in different localities.

The results as a whole indicate that the seed germinates well, and the plants cover the ground well, 2 or 3 cuttings may be expected, after which the plants will wither and die off. Where the land is limed and inoculation secured, the plants will grow during the dry season, but die out in the rainy season. The College of Agriculture, University of the Philippines, Los Baños, conducted several tests in 1917, on the cultivation of alfalfa varieties from seeds received from Minnesota, New York State, California, Arizona and India (Poona). The most encouraging results were obtained with the Indian variety. Seeds sown on December 12, 1918, germinated 2 days after. The flowering period began on February 5, 1919, and pods began to form on February 20. Mature pods were first harvested on April 8, and by May 28, flowers and fruits were still in developing. At the beginning of April, the lowest plants measured from 43 to 52 cm., and the highest from 100 to 118 cm. The fact that this variety produced, in the Philippines, seeds that were plump and bright yellow in colour (two main characteristics of good alfalfa seeds), encourages the hope that this forage crop may be acclimatised and improved with profit to the Philippines.

644 – **An Experiment on Thinning out Old Hevea Trees, in Java.** — CRAMER, P. J. S., in *The Tropical Agriculturist, Journal of the Ceylon Agricultural Society*, Vol. LIII, No. 5, pp. 299-304. Peradeniya, Ceylon, Nov., 1919. RUBBER GUM AND RESIN PLANTS

In the Government Experiment Garden for coffee at Bangelan (East Java), a field of coffee was planted with Hevea in 1901, to try this plant as a shade tree; the coffee was planted 7 × 7 feet, the rubber at 21 × 21 feet.

From natural causes, a few trees died out and, when the author examined the trees for the first time in 1915, 57 trees were left. These were 14 years old and had developed into high thick trees ; the growth was quite satisfactory, taking into account that the field was situated 1 800 feet above sea level. Up till then they had never been tapped.

Table I gives an idea of the distribution of the trees on the field.

TABLE I. — *Plan of the trees.* *

	51	**52**	53	**54**	55	56	**57**

	7	**6**	5	**4**	3	**2**	**1**

* The numbers in thick type were kept on thinning out. Distance between the trees is 21 × 21 feet.

1) PRODUCTION IN 1918. — In 1918 tapping was begun. From January till May, the trees were tapped with two cuts on ¼ of the girth, left side ; at first on alternate days, then, after April 15, every day. The total number of tapping per tree was 59.

TABLE II. — *Production of Rubber in* 1918.

1	1962	20	650	39	1485
2	2005	21	1172	40	1786
3	512	22	1240	41	1078
4	2036	23	1177	42	744
5	874	24	1700	43	2983
6	1750	25	645	44	551
7	515	26	567	45	1992
8	690	27	1587	46	1929
9	2652	28	2413	47	862
10	895	29	760	48	613
11	520	30	830	49	1570
12	2235	31	543	50	705
13	1279	32	717	51	1495
14	754	33	860	52	1940
15	2894	34	1874	53	617
16	1380	35	1585	54	1390
17	1185	36	1602	55	868
18	1160	37	1432	56	2185
19	1323	38	552	57	2471

The total production of 57 trees was 75,791 kg.

The rubber was cured by the Brazilian process, coagulating the latex on a stick by smoke. By this means, it was possible to ascertain the individual production of each of the 57 trees numbered; the stick serving every day of the tapping process for the same tree, one ball of coagulated rubber being obtained for each tree.

The production is shown in Table II.

2) THE PROPORTION CONTRIBUTED BY GOOD AND POOR PRODUCERS TO THE TOTAL CROP (1918). — The poorest tree (No. 3) amongst the 57 Heveas in 1918, gave 512 grams of dry rubber, and the best one (No. 43), 2983 grams. The average production of each tree was 1328 grams.

In Table III the trees are arranged in groups according to their individual production in lots of 300 grams, and these groups are divided into 2 parts by a line at about the average production (1328 gm).

TABLE III. — *Grouping of trees according to production.*

Individual production of dry rubber	No. of trees in the group		Total production of the group	
0 — 300 kg	—		—	
301 — 600 »	7 trees		3 760 kg	
601 — 900 »	16 »	28	12 084 »	21.616 kg
901 — 1200 »	5 »		5 772 »	
1201 — 1500 »	8 trees		11 024 »	
1501 — 1800 »	7 »		11 580 »	
1801 — 2100 »	7 »		13 738 »	
2101 — 2400 »	2 »	29	4 420 »	54.175 kg
2401 — 2700 »	3 »		7 536 »	
2701 — 3000 »	2 »		5 877 »	

It is evident, then, that the 28 poorest trees gave production of 300-1200 gm., that is to say, 49 % of the trees gave 28.5 % of the total crop, and that the 29 best trees, *i. e.*, the remaining 51 %, gave 71.5 %. If the trees are divided into two equal groups, the poor group will contribute only 30 % to the total crop, and the good group 70 %.

By proper thinning out, the soil, air, moisture, and plant food that was previously wasted on poor trees can be used to better advantage for the good trees. The results of such thinning will be considered later.

3) INFLUENCE OF EXTERNAL CONDITIONS (PARTICULARLY THE SPACE OCCUPIED). — The author divided the trees into 4 groups according to the space occupied : *a*) Closed in ; *b*) one side free ; *c*) two sides free ; *d*) three sides free (see Table I). Comparison between the total production of each group led the author to conclude that the differences observed with the individual productions are chiefly caused by the initial character of the trees, and only to a small extent by the external conditions, the production

in general being somewhat higher, if the trees have more space at their disposal (1).

4) PRODUCTION AFTER THINNING OUT. — In July, 1918, half of the trees was cut out (see Table I) ; only the best producers were kept, regardless of the question of spacing ; one good tree was cut by mistake, and tree No. 4, which suffered from bark disease was not tapped in 1919. The remaining trees, 23 in number, and all with high yields, underwent 59 tappings, just as in 1918 ; but, whilst in 1918 they were tapped almost all the time on alternate days, in 1919 it was a case of every day tapping. It is well-known that with alternate days, tapping with the same number of taps gives a higher yield than with every day tapping : in spite of this, in 1919 the production was superior to that of 1918, as shown in Table IV. In this Table, the signs + and — are employed to signify the trees above or below the average production.

The increase of total yield for trees after thinning is remarkable, the average production per tree rose from 1830 gm. in 1918 to 2403 gm. in 1919, and this, as previously mentioned, in spite of the less advantageous method of tapping.

Comparing the trees individually in 1918 and 1919, it is obvious that, as general rule, the trees kept their position well ; an exception is tree No. 27, but here again the differences from the averages are only small. For example, No. 2 is in both cases a little above the average ; Nos. 15 and 43, both high producers in 1918 (about $^8/_2$ of the average) remained the best producers in 1919, with about the same proportion ; the poorest tree before the thinning out, No. 30, was also the poorest afterwards.

These figures show that the relative production of the trees remains constant ; it is a further argument showing that the special character of the tree is more responsible for its individual production than the external factors such as spacing etc. By dividing the trees into two groups : 1) those with space slightly widened by thinning : 2) Those with space much widened (see Table I), the author still further strengthens the force of the argument.

5) CONCLUSIONS. — The number of trees experimented with was not sufficient to allow further investigation, but the experiment demonstrates that production can be stimulated by thinning out, which is certainly one of the most important problems in rubber growing at present. But the most marked influence on production is the initial character of the trees (2).

(1) As regards the spacing of trees and influence on crop, see M. GIRARD'S work on this subject ; see *R.*, Febr., 1919, No. 205, VI. (*Ed.*)

(2) Hence the considerable interest aroused in connection with the question of seed selection and new studies on grafting : see *R.*, Febr., 1920, No 194, and No. 645 of this *R.* (*Ed.*)

45 – **The Grafting of Rubber.** — *The Tropical Agriculturist, Journal of the Ceylon Agricultural Society.* Vol. LIII, No. 5, pp. 297-298, Peradeniya, Ceylon, Nov., 1919.

The attention of most rubber growers has been directed to the possibility of securing increased yields per acre. The possibility of seed selection has been considered, and on many estates seeds from selected trees have been sown in the young clearings (1).

Similarly, the Ceylon Department of Agriculture has made special plantings from the No. 2 Heneratgota tree, and will in 1920 have areas ready for tapping.

With a knowledge of the differences in yields of individual trees, and to avoid cross pollination between good and poor trees (2), certain estates have made use of this information when thinning operations have been undertaken. The poorer trees have as far as possible been removed, and the better one allowed to remain.

A brief survey is made of experiments conducted in the Federated Malay States and in Java in connection with seed selection, budding and

(1) and (2) See *R.*, Feb., 1920, No. 194. I and II. (*Ed.*)

grafting (1), with a view to securing increased yields. Sufficient evidence has been secured to warrant the trial of these methods in Ceylon, where the rubber industry may yet see extensive areas of plants thus treated, set out. The experimental stage has, however, not yet been passed, and it has yet to be demonstrated that these systems can be generally adopted.

Trials should, however, be made with a view to securing definite information. Not only should the trials be made on young stumps, but the question might also be investigated as to whether grafts cannot be made on the old stumps of the poorer yielders, which for certain reasons it may not be desirable to remove. It is intended to make some trials on rubber estates in Peradeniya, Ceylon, in order to gain experience in regard to the methods best suited to local conditions, and it is possible that grafts could be supplied from No. 2 tree, if required.

646 – **Italian Camphor** (2). — CAVARA, F., in *Rivista italiana delle Essenze e Profumi*, Year II, No. 2, pp. 13-17, Figs. 2. Milan, Feb. 1920.

Prof. F. CAVARA, Director of the Royal Botanic Gardens, Naples, points out the importance af camphor production, especially with regard to Italy, and demonstrates the possibility and advantage of obtaining native supplies, laying special stress on the work by Prof. Italo GIGLIOLI, *La Canfora Italiana* (Rome, 1908). This work is amply provided with data bearing on matters connected with the history, industry, trade, geographical distribution, cultivation and acclimatisation of camphor (*Laurus Camphora* = *Cinnamomum Camphora*). Original work by Prof. GIGLIOLI himself is also included, dealing with the productivity of camphor and camphor oil of plants grown in various parts of Italy.

In Italy, examples of complete acclimatisation of *Laurus Camphora* are frequent ; for example in Naples (Botanic Gardens) and its environs (Capodimonte, Portici), at Caserta (Royal Park), and Rome, Pisa, Florence, on the Riviera, on Lake Maggiore (Isola Bella), etc. Formerly camphor was almost exclusively employed in pharmacy, but now, the pharmaceutical applications absorb only ¼ of the total production, whilst the remaining ¾ are utilised in various industries, 70 % of the total production being employed in the celluloid industry and in the manufacture of miscellaneous disinfectants, insecticides and gun-cotton. The wood on the other hand, is much sought after for sculpture and cabinet work.

Prof. GIGLIOLI recommends the use of the leaves, either green or dried, which fall off the trees when the new foliage pushes forward, for the extraction of camphor.

The utilisation of the small branches and leaves has introduced an innovation into the ordinary method of cultivation, and has been adopted in the United States and in Ceylon where the bushes are planted 6 ½ ft. apart, making 2500 bushes per hectare, which bear leaves only after some

(1) See R. Feb., 1920 No. 194. I and II (*Ed*).

(2) With regard to the actual state of camphor production in the world and the trial tests with camphor trees, see *R.*, May, 1920. No. 528. (*Ed.*)

ears. The leaves and branches on plants 10 years old have also been utised on new camphor plantations in Japan. Also in Jamaica, East and Vest Indies, and Malay Archipelago, and in British E. Africa, the green r dry leaves on young camphor plantations have been used.

The analytical investigations made by Prof. GIGLIOLI show that the ield from Italian camphor leaves is higher than that obtained elsewhere. This fact has been confirmed by GILDEMEISTER in *Les huiles essentielles* French translation, 1914), and the following data are given :—

Percentage of Camphor furnished by Leaves and Branches in Various Countries.

Country	Analyst	Material analysed	Camphor %
Ceylon	Willis and Bamber	Leaves and branches .	1
East Indies	Hooper	Leaves and branches .	1
West Indies	Watts and Tempany	Green leaves	1.2 to 1.5
Jamaica	Emerson and Weidlein	Dry leaves	1.57
East Africa	Lommel	Dry leaves	1.55
Malay Archipelago	Eaton	Green leaves	1.17 to 1.2
Malay Archipelago	Eaton	Air dried leaves . . .	1.10 to 1.16
United States	Hood and True	Dry leaves.	2
Italy	Giglioli	Green leaves	1.2 to 1.5
Italy	Giglioli	Dry leaves	2.4 to 3

On the other hand, the yield from the other portions of the plant branches, trunk, roots), is much less than that from Japanese camphor. Prof. GIGLIOLI obtained only 10 % from the trunk of the Italian trees compared with 1 % obtained from trunk slivers in Japan.

The large proportion of camphor in the dry Italian leaves may perhaps be due not only to the low water content in the leaves, but also to the accelerated oxidation of the oil of camphor during the later stages of growth. This is consistent with the investigations made by YOSHIDA in 1885 on oil of camphor and on camphor formation.

The lower camphor content in the trunk of the Italian tree compared with the Japanese, may perhaps be attributed to the different elaboration that takes place in the cells of young plants compared with fully developed or old plants, rather than to the difference in climate. In the first case there is a bigger formation of camphor oil ; in the second, there is more camphor. The relative amounts vary according to the organs of the plant, and with the changing seasons ; thus, in winter, there is a larger proportion of camphor, and in summer, the production of camphor oil, is greater. Out of 100 parts extracted by distillation of leaves of the Italian camphor plant, about ⅓ is camphor oil.

It has been stated that if, owing to the low seed production from the big trees acclimatised in Europe, the Japanese seed is sought after, there is a distinct risk of very feeble germination, either because the germinating

power, does not cover a long period and does not last out over the long voyage, or because when sent, they are neither fresh nor good.

Prof. CAVARA hopes to be able to confirm these statements, having received seed from Japan (from the Yokohama Nursery) on several occasions, that germinated well, gave vigorous seedlings, and developed extraordinarily well in a few years' time.

From sowings made in the Royal Botanic Gardens at Naples 3 years ago, a plantation of camphor plants was established to test the value of *Laurus Camphora* grown in a copse, with the idea of carefully using the leaves and branches for the extraction of camphor and camphor oil.

STIMULANT, AROMATIC, NARCOTIC AND MEDICINAL PLANTS

647 – **The Cacao Industry in the Gold Coast and in the French Colonies and the Former German Colonies in Equatorial Africa.** — Report by Mr. TUDHOPE (Director of Agriculture, Gold Coast), followed by a note by M. LUC (Director of Agriculture in the French Colonies) ; Translation, preface, and conclusion by M. G. CAPUS, in the *Union Coloniale Française*, Publication du Comité d'Action Agricole Coloniale, Pt. I, pp. 37. Paris, 1919.

Mr. W. S. D. TUDHOPE presented his report to the third International Congress of Tropical Agriculture held in London in 1914. A complete translation together with notes by MM. LUC and CAPUS, is given in the publication under review and these two writers extract the points of interest to the French colonies and the former German colonies in Equatorial Africa. The chief conclusions are given below :—

(1) The production of cacao in the Gold Coast is an absolutely native industry and owes nothing to the European planter. Cacao was first exported from the Gold Coast in 1891, when, according to official statistics, the export was 80 lb., valued at £4. In 1913, the export amounted to 113 239 980 lb., valued at £2 489 218. The appended figures, quoted from official statistics, shew the development of the industry :—

Years	Quantities		Values		Quinquennal increase	
	Lb.	Kg.	£.	Fr.	£.	Fr.
1891	80	36	4	100	—	—
1896	86 745	39 839	2 276	56 900	2 272	56 80
1901	2 195 571	985 692	42 837	1 070 925	40 561	1 014 02
1906	20 104 504	9 117 393	336 269	8 406 725	293 432	7 335 80
1911	88 987 324	40 355 752	1 613 468	40 336 700	1 277 199	31 939 95
1913	113 239 980	51 354 331	2 489 218	62 230 450	875 750 in 2 years	21 893 75

Since 1913, the cacao production in the Gold Coast shows a progressiv increase. In 1915, the export was 77 378 tons worth 91 302 250 fr., an in 1916, 72 128 t., worth 96 152 250 fr. Owing to the war and the scarcit of freight, part of the 1916 crop had to be stored by the traders and, a the end of the season, no business was done in the interior regions. I his report for 1916 the Director of Agriculture of the Gold Coast attribute a beneficial influence to this lack of a market, which, though due to tempo

ry causes, none the less shows the danger of developing cacao as the le crop in the region, as both natives and Europeans neglect spontaneous oducts such as rubber and palm nuts, and even food products for local nsumption.

At present the Gold Coast is the largest producer of cacao in the orld, the whole output being due to the natives.

(2) The soil and climatic conditions are much the same as those of ie French colonies of Gabon, Dahomey, and especially, the Ivory Coast.

(3) The British administration has developed cacao growing by aking use of the favourable disposition of the educated natives and their sire for better conditions of life, and by buyng the crops at good prices hen they were not at a stage of interest to traders.

(4) The British administration then concentrated its efforts on ie increase of the native plantations, the improvement in the quality f the fermented and dried product, and on the diffusion of practical agri-ultural education amongst the natives.

(5) After this the traders began to buy and the product became a industrial commodity.

Thanks to the methods used, the export of cacao from the British old Coast increased from 39 000 to 51 000 tons, between 1896 and 1913 (1), hereas in the case of the French colonies of Gabon and the Ivory Coast, ie former only exported 155 tons in 1913 and the latter 47 tons. It is herefore important to ascertain how far the example given by the English an be followed elsewhere. The natural production from the Gabon entirely due to European cultivation, but the capital invested was xtremely small and the exports, in spite of their steady increase, have ot attained a large figure. The work done by the Germans in the Ca-eroons will thus be of interest in enabling an opinion to be formed as o whether a greater financial effort would give results comparable with ose obtained by the natives in the Gold Coast ; this is shown in the ppended table.

Comparative export (in tons) from the Gold Coast, Gabon, Cameroons, and the Ivory Coast.

Years	Gold Coast	Gabon	Cameroons	Ivory Coast	
				Years	Tons
896.	39	5	133	1900. . . .	—
901.	985	44	528	1905. . . .	2
906.	9 117	89	1 247	1910. . . .	7
911.	40 335	108	3 431	1913. . . .	47
918.	81 354	155	—	1915. . . .	114

(1) The exports amounted to 92 000 tons in 1917, according to the *Agricultural New* f April, 1919. (*Note by* M. Luc.)

These figures show that the progress in the German exports does not show a proportionately higher rate than that for the Gabon. Yet, the agricultural enterprises in the Cameroons cannot be reproached with lack of interprise, as capital, concessions, technical assistance from the official organisation of the local Government, labour (unscrupulous methods of recruiting black labour), none of these were wanting. Considering all the advantages that they had, it must be admitted that the German results were unsatisfactory : heavy expenses and low yields, and slow progress in the export trade.

Whilst the English, however, increased their production at little expense in 10 years from 985 to 40 335 tons, that of the Cameroons, during the same 10 years and in spite of a considerable financial effort, rose from 528 to 3431 tons only. The obvious reflection is whether the English method is not the best for Africa.

It is true that the example of San Thomé can be quoted in favour of European cultivation, but the cacao question there is not the same as in the coastal colonies on the Gulf of Guinea. According to M. A. CHEVALIER (1), the island of San Thomé is of volcanic origin and all the soils, almost exclusively formed by eruptions, consist of basalts, trachites and phonoliths, rocks which have weathered down to form the fertile soils of the island. These formations are extremely rare on the continent, practically all the soils in the Gabon and Ivory Coast being derived from the decomposition of crystalline rocks, such as granites, mica schists and metamorphic rocks ; they are far from being as fertile as those of San Thomé. It thus follows that the methods of cultivation — of decidedly special nature — in use in the Portuguese colony could not be applied in entirety on the continent, where similar soils are not to be found.

As the example of San Thomé is not applicable, the conditions of cacao cultivation by natives and Europeans must be examined comparatively. Mr. TUDHOPE gives valuable information regarding the Gold Coast, and states that the method of cultivation, as developed by the natives represents the *minimum of effort and expense.* The forest is only partly cleared, all the big trees being left standing, and the seed-beds are confined to nurseries situated in damp alluvial soils by watercourses, replanting generally taking place in competition with food plants such as the banana (*Musa*) and taro (*Colocasia*). In this way, the young plants enjoy good conditions for rooting, as the necessary shade is provided. The cultivation given to these crops, usually consisting in cutting the weeds with a bellhook or hoe, is of equal benefit to the cacao trees and helps them to come on well for the first 3 or 4 years. The cacao trees are usually planted very closely, and the natives prefer dense, straight trees forming a crown at a height of 7 ft., 6 in or. more. The area planted by each family is very small and does not produce more than 2 tons of cacao each year on an average. Thus, the whole production of the Gold Coast is the sum

(1) *Le Cacaoyer dans l'Ouest Africain*, by A. CHEVALIER, p. 245. Published by Challamel, Paris, 1908. (*Note by M.* LUC.)

of the output of a multiplicity of small village plantations, of small family crops, disseminated in a belt of plantations covering nearly 61 000 sq.km. These are special conditions, that cannot be duplicated in European plantations, requiring as they do the cultivation of vast surfaces within a limited radius. The natives pay but little attention to their plantations.

Mr. TUDHOPE is obviously forced to regard the native methods of cultivation as defective, as they are evidently the chief cause of the inferiority of the product :— Small capsules, atrophied seeds, bad fermentation ; but he has no need to worry about the extension of the crop, as the natives have become accustomed to grow it. His task at present consists chiefly in improving the quality of the product and, consequently, the primitive methods of cultivation, harvest, and fermentation. He sees all the disadvantages of the native methods, without ascertaining whether they have any compensatory advantages.

Mr. LUC differs from Mr. TUDHOPE on this point. The same stage has not been arrived at on the French coast, there is no production to improve, there is even no production. A large quantity must be produced above all, even if not first-class quality. Under these conditions, the simple native method will be seen to have the following advantages :

(1) Cultivated on small areas, near and around the villages, the young cacao plant benefits from the shade plants grown for food and from the manuring provided by household refuse.

(2) The native method carries out the principle of close planting and much can be said for this ; it is a point that must be insisted on. Whoever has visited abandoned cacao plantations will know that the old nurseries have persisted, *natural selection* having taken place, the weak yielding to the strong, which become more and more interlaced and seem to obtain through their common effort the faculty of resistance to disease and the invasion of the brush.

The native plantations are much on the same plan. Planted at 8 ft., 6 ½ ft., apart and even less, the trees rapidly cover the soil, the foliage interlaces and, when one tree dies, the vacant space is immediately occupied by adjacent trees. At Fernando-Po M. LUC has counted as many as 2500 or 3000 trees per hectare in native plantations, with an annual production amounting to 2 tons of prepared cocoa. This kind of plantation is probably very similar to that found in the Gold Coast.

(3) By their distribution through a vast forest region, the multitudes of small plantations are isolated one from another; they benefit from the shelter of the surrounding forest, from the constant humidity of the air, and the risk of the spread of fungoid disease, which has caused so many failures in extensive cultivation, is considerably reduced.

(4) The high cost of digging holes, planting, and replacing dead trees, estimated by M. LUC, at least 30 % in Gabon (1) during the

(1) At San Thomé, replacing is estimated at 30 % for the first year, 15 % for the second, 6 % for the third, and 2 % for the fourth (CHEVALIER). In Gabon, the losses are highest between the third and fourth years. (*Note by* M. LUC.)

first six years on European plantations, is quite insignificant for the native crop.

(5) Finally, the difficult problem of providing the fixed labour necessary for large plantations has not to be considered. It is partly solved by cultivation by families, chiefly by the women and children.

The principles of European cultivation are very different. So as to restrict the European staff required for management and supervision as much as possible, the plantations have to be grouped together, so that a considerable area of forest has to be cleared. The cacao plant does not do well in mediocre soils, in vast denuded surfaces. The nurseries are established in land carefully prepared and frequently manured; the seeds are selected and, from germination onwards, the plants are watched and cared for, and as weakly plants differ little from strong ones, the selection is artificial.

The plants, after being transplanted and placed at distances usually 11.4 to 13 ft., apart, are often growing in a less fertile soil than that of the nursery. They have to live under these conditions for 5 to 6 years or more, before their foliage touches, which is necessary in practice to ensure the success of a plantation, and to which the planters rightly attach great importance.

These disadvantages do not occur in close plantations and it is possible that where cacao is grown like a replanted forest with successive thinnings, better financial results might be obtained in French Equatorial Africa.

M. Luc does not condemn European planting such as it is, but merely points out that the expenditure it requires in mediocre soils is not compensated for in most cases by the returns. He thinks it would be advisable to procede in the direction of the plantation that costs less, is planted more closely and contains varieties that quickly produce high yields.

The cacao grown in the Gold Coast is exclusively of the oval "forastero" type of the Amelonado variety, and its beans require a longer fermentation that those of almost any other variety. As this variety is both robust and prolific, M. Tudhope concludes that it is particularly well suited to the conditions prevailing in the Gold Coast, and that it was fortunate that this variety should have been the first to be introduced. Other types or varieties are being tested at the Government experimental stations but, with one exception (a hybrid of spontaneous origin), none of them appears to be as prolific or profitable as the ordinary type. The new variety, called Cundeamor by M. Tudhope, on account of its superficial resemblance to the Ceylonese type of the same name, is apparently prolific and produces much larger beans which are of superior quality. The natives appreciate this variety which, in time, will be planted over considerable areas. The slowness of its fermentation is of slight importance, as the natives prefer slow tasks.

Mr. Tudhope states that, in the Gold Coast, the cacao plant yields a fine crop 3 or 4 years after planting and quotes, as an average yield at Aburi, the extraordinarily high figure of nearly 8 lb. of dry cacao per tree, a yield which is equalled if not surpassed on certain native plantations in

ertile districts. A yield of 4.42 lb., per tree can be obtained in the Gabon n close plantations; in 1914, the ARMOR plantation included 15 000 adult rees and produced 34.5 tons.

Some of the South American varieties introduced into Africa fruit bundantly in their fourth year. The yield of seeds may also vary in number nd weight (1). The search for varieties that quickly produce high yields, n spite of their rapid exhaustion, becomes indispensable when they are ot required as the main subject of a plantation.

It seems that the soil and labour conditions in the French colonies n Equatorial Africa are not sufficient to ensure the success of vast agricultural enterprises whose sole aim is to produce cacao. The crop, however, would be both interesting and profitable considered as a complementary rop on the farm, provided that the best soils, and only these, vere reserved for it, and if the principle of close plantation were ollowed.

The conditions required for obtaining a large production in a short ime are apparently present in the Ivory Coast, and it would thus be ossible to make, with some chance of success, an effort similar to that vhich has given such convincing results in the Gold Coast. This, however, as been in progress since 1908, thanks to the initiative taken by the Governor, M. ANGOULVANT, but by different methods, the chief of which is he obligation to plant.

The east coast of Madagascar seems equally well placed for a similar ttempt, with the advantage that the natives would be less refractory o French pressure.

But if these attempts are to be really useful and to lead rapidly to mportant productions, a considerable change will be required in the rench native policy. M. LUC does not say if this could be done without anger, but any method has its disadvantages and M. BAILLAUD, in his ook on *La politique indigène de l'Angleterre en Afrique occidentale*, points ut some of them. In this connection, the conclusions drawn by this uthor from a book by N. CASELY HAYFORD, a native lawyer of the Cape-Coast, will be of interest.

Mr. TUDHOPE does not seem very sure of the stability and security f this monoculture which has been taken up by the natives with such nthusiasm that they have completely neglected important sources of evenue such as rubber and the oil palm. In any case, it is evident that he policy followed in the Gold Coast has been the chief element in the uccess obtained in the production of cacao. It remains to be ascertained whether the principle can be applied to one or more of the French colonies, and if so, whether the possibility of providing the French chocolate ndustry with its requirements would compensate for the disadvantages f the method under discussion.

648 – **The Wild Tea Plant of Phou-Sang, Tranninh Region, Upper Laos, Indo-China** (1). — MIÉVILLE, R., in the *Bulletin agricole de l'Institut Scientifique de Saïgon*, Year II, No. 3, pp. 87-90. Saïgon, March, 1920.

This tea plant occurs wild in the wooded massif of Phou-Sang, Noung-Pek region. Phou-Sang is a large mountain group situated 60 km. in a straight line from Kiêng-Khouang ; it is 2300 m. high, and the wild tea plants only occur above an altitude of 1900 metres. There are two varieties of tea plant at Laos, one which is very common and gives rise to a certain amount of native trade, and one, a wild plant which is gradually disappearing and which is dealt with in the present article.

There are 280 plants of this species at the Tranninh Station, and, in 1917, 45 000 seeds were gathered from them, but none germinated. This was due to the fact that the native attendant gathered the first floral buds and used them after drying ; the last flowers left alone by the native were surprised by the first frosts and aborted.

In 1918 the 9000 seeds gathered were sown on October 30, and as the floral buds had been left untouched, these seeds were ripe on October 15. Germination began on October 20, 1919, and, by June 20, over 2000 plants had sprung up. The branches bore flowers only in the second year. It is estimated that, in normal seasons, the station could produce from 10 000 to 20 000 seeds of this tea plant each year. The station contains a plot of 400 sq. metres containing 148 Phou-Sang tea plants. The bushes, which were 3 or 4 m. high in 1919, were cut down to 1 m. above the ground ; numerous buds were produced and a first crop was obtained since 1918. Only young buds with slightly developed leaves were gathered. The harvest begun on April 10, 1918, ended on December 4 and produced a total of 23.565 kg. of dry tea, or an average of 160 gm. per plant. This yield is certainly smaller than that actually realised, for the coolies dishonestly retained part for themselves. Supposing 1 hectare were planted with Phou-Sang tea at 1.5 m. distance every way (distance necessary for the growth of the plants), there would be 5675 plants per hectare, and the corresponding crop would be 900 kg., of fine, prepared tea.

The following figures give, according to M. AUFRAY, the chemical analysis of samples provided by the author.

In 1903, the author had already tasted Phou-Sang tea, as a Chinese named AMOCK, who had become a French subject, had given him several samples, saying that it had come from the Imperial Chinese Court. M. AMOCK had informed him that the tea cost $20 to 24 (50 to 60 fr. at par) a Chinese pound (700 gm.), and the author learnt that Chinese preparers went each year to gather and prepare the buds of the precious species at the Phou-Sang mountain. When the Chinese arrived, the Meos showed them the trees they had found in the forest ; the Chinese then cut down the trees and gathered the young shoots which they prepared in their own way. The process consists in letting the shoots fade, then rolling the

(1) For information on the wild tea plants in India and China, see *R.*, April, 1920. No. 413. (*Ed.*)

	Fermented tea	Unfermented tea
Moisture	10.00 %	9.70 %
Nitrogenous matter	23.37	23.37
Fats	1.98	1.74
Tannin	13.25	13.75
Total ash	5.10	5.12
Soluble ash	2.02	2.14
Thein	2.35	3.70
Nitrogen	3.74	3.14
Matter soluble in boiling water	41.25	44.50

buds by hand and drying them in a large iron pot. The average crop each year from Phou-Sang was not more than 10-15 kg. of fine tea. The adult leaves were pressed while still green in large hollow bamboos and warmed over a flame, when the leaves were removed from the bamboo, dried in the pot and taken to China. If the Chinese went so far for such a small crop for the Emperor of China, it is because they valued it.

The Phou-Sang tea trees have almost disappeared and now the forest contains only scattered trunks cut down to 1 metre above the soil. The trunks send up new shoots every year, but they die for lack of air and light. It is fortunate for the preservation of this species that small plantations have been established at two stations. In fact, seed-bearing trees exist at the Na-Hoi station ; bought from a woman Pon-Ting who got them from Phou-Sang, they were planted in 1905 at 1 m. apart and have never been pruned. The author found them to be well grown, 5 to 6 m. high ; dug up in September, 1919, they were planted 5 m. apart, so as to form a new plantation of seed-bearers. The station now possesses 142 tea plants which, if cared for, could produce an abundant fructification by 1922. In addition, the 400 sq. m. plantation mentioned above was started by the native attendant who went with coolies to Phou-Sang to obtain young plants ; he brought back about 300, of which 148 are still living at the station.

649 – **The Effect of Fertilisers on the Combustibility of Tobacco.** — See No. 627 of this *Review*.

650 – **Coca Production and Trade in Java.** — De Wildeman, E., in *Bulletin Agricole de l'Institut Scientifique de Saïgon*, Year II, No. 5, pp. 79-80. Saïgon, March, 1920.

The cultivation of the coca plant was already widely spread in the Dutch East Indies, before the war ; very diverse opinions had been expressed as to its future as a crop, as it was threatened by the preparation of synthetic cocaine. All the same, several planters have extended the area under the crop, and factories, established in the Dutch East Indies, have done good business, possibly owing to the circumstances at that time.

The future of coca cannot be foreseen, and it will be useful to survey the progress of the production of the coca leaf, its trade and its consumption. Practically all the pre-war production went to Europe and, in

1916, Amsterdam was still one of the great centres for the product. In the appended table, the author indicates the reserves of coca leaves, in packages at Amsterdam ; the gradual depletion of the stocks is marked.

	1916	1917	1918
End of January	10 296	5 540	403
February	10 164	4 867	237
March	10 149	3 792	143
April	9 745	3 715	87
May	9 797	5 225	30
June	9 235	3 989	30
July	9 011	2 507	30
August	8 777	1 287	30
September	8 237	448	30
October	7 932	448	54
November	6 336	403	0
December	5 877	403	0

As the stocks diminished, the average unit price naturally increased ; in 1916 it was 14.45 cents and in 1917 it was 20.09 cents. In hand to hand buying, the differences in price varied from to 30 to 70 cents. In 1917, the export of coca leaves to Holland and the United Kingdom began to diminish, largely owing to the lack of tonnage, and, in 1918 export to Europe ceased completely, but as the appended figures show, the total export from Java increased not diminished.

Export of coca leaves from Java.

	1917 kg.	1918 kg.
Holland	17 043	—
United Kingdom	4 105	—
United States	151 601	282 555
Japan	6 423	211 629
	179 172	494 182

It will be seen that the consumption of the United States increased considerably from 1917 to 1918, but not to such an extent as that of Japan. The consumption of leaves by cocaine factories was thus very large.

It will be of interest to see if these proportions will be maintained or if, now the seas are free, the large export to Holland and the United Kingdom will be re-established. It is to be feared that, as the war has displaced so many markets, Europe will find it difficult to recapture them.

The factory established at Soekaldemi, Java, has regularly worked coca leaves, obtaining an extract with over 50 % of alkaloid.

The treatment of the raw material in the producing country should undoubtedly be encouraged, as it would procure a great benefit for the colony and its native inhabitans.

651 – **Mulberry Plantations** (1). — Bucci P., in the *Rivista di Ampelografia*, Year 1, No. 4, pp. 51-58. Alba-Leghorn, Feb. 15, 1920. VARIOUS CROPS

In 1914, the author established at the Torretta farm of the "R. Scuola Enologica," at Avellino, a mulberry plantation of an area of 240 sq. m., with 14 lines, of young mulberry trees at distances of 70 cm. between the lines and 40 cm. in the lines which works out at 35 700 trees per hectare. In spite of the close planting, the trees grew vigorously. The author has obtained the following data:

The cost of establishing and cultivating 1 *hectare of mulberry trees at Avellino.*

Interest on estate capital, considering the land as bare, but of first class type	200
Expense of hoeing 35 cm. deep; 60 days to 3 fr.	180
Tracing lines for the trees; 10 days at 3 fr.	30
Planting the young trees; 20 days at 3 fr.	60
Value of 35 700 young trees at 0.03 fr. each.	1 071
Weeding twice; 24 days at 3 fr.	72
Estate tax	60
General expenses at the rate of 5% of the preceding expenses, less interest on the estate capital	73.65
Interest at 3 % on the capital represented by the preceding expenses, less interest on the estate capital	46.40
Total	1 793.05 fr.

Interest on estate capital as in 1914	200 fr.
Weeding twice; 24 days at 3 fr.	72
Replacing young or dying plants at the rate of 5 % of the number of trees; value of the young trees 53.55 fr.; 5 days at 3 fr.	68.55
Gathering leaves as branches; 10 days (women) at 2 fr.	20
Estate tax	60
General expenses calculated as in 1914	11.05
Interest at 3 % on the capital represented by the preceding expenses, less interest on the estate capital	6.95
Total	438.55 fr.

Interest on estate capital as in 1914 and 1915	200 fr.
Weeding twice; 24 days at 3 fr.	72
Gathering leaves as branches, 12 days (women) at 2 fr.	24
Estate tax	60

(1) See *R.*, Jan., 1916, No. 57. (*Ed.*)

General expenses calculated as above.	7.80
Interest at 3 % on the capital represented by the preceding expenses, less interest on the estate capital	4.90
Total . . .	368.70 fr.

Interest on estate capital as above.	200 fr.
Weeding twice; 24 days at 5 fr..	120
Gathering leaves as branches; 12 days (women) at 3 fr.	36
Estate tax	60
General expenses calculated as above.	20.80
Interest at 3 % on the capital represented by the preceding expenses, less interest on the estate capital	16.10
Total . . .	452.90 fr.

Interest on estate capital as above.	200 fr.
Weeding twice; 24 days at 7 fr..	168
Gathering leaves as branches; 12 days (women) at 3 fr.	36
Estate tax	60
General expenses calculated as above.	23.20
Interest at 3 % on the capital represented by the preceding expenses, less interest on the estate capital	14.60
Total	501.80 fr.

(Unless otherwise stated the working days mentioned above are those of a man).

If the expenses of the fifth year are assumed to be the same for the following five years, the total expenses for the ten-year period would be 7968.02 fr., which gives a constant annual expense of 625.40 fr.

In the branches (gathered in this way for rearing silkworms in the Friulan way), the pure leaf represented: — 44.39 % in weight in 1916; 46.71 % in 1917; and 41.58 % in 1918. If these coefficients are applied to the weight of leaf as branches actually gathered, the yields in pure leaves per hectare are: — 4499.209 kg. in 1916; 8819.876 kg. in 1917; 11 212.312 kg. in 1918; total, 24 531.397 kg.; annual average 8177.132 kg. It can be assumed that this average holds good for the other 5 years, because, though the production increased during the first 2 years, it decreased in the following years. From these figures, and valuing the leaf as branches at 15 fr. a quintal, the total value of leaf produced during the 10-year period would be 23 241.82 fr., which gives an annual constant value of the leaf of 1824.25 fr. The annual net return from the plantation is, therefore, 1824.25 fr. — 625.40 fr. = 1198.85 fr.

The leaf produced by one hectare of mulberry plantation will serve to rear at least 15 ounces (of 30 gm.) of silkworm eggs.

The author compares these data with others furnished by Prof. J. DI GADDO, director of the travelling chair of agriculture of the districts of Oderzo and Motta di Livenza (province of Treviso.) The latter considers

hat a mulberry plantation lasts 13 years and that, at the end of the 13th ear, the expenditure per hectare is 180 fr., to clear out the roots; he esti- nates the production of leaves in the different years of the duration of the plantation starting from the 2nd. year, at 70, 150, 300, 400, 450, 400, 400, 350, 300, 200, 150 quintals per hectare for each year, respectively; he constant annual value of the products (valuing the leaves at 6 fr. a quintal) at 1602.24 fr., and the constant annual expenditure at 825.30 fr- In respect of this estimate, the author observes that the mulberry planta. ion may last longer than M. DI GADDO admits, *i. e.*, 17 to 20 years instead of 13, and that the cost of removing the roots in the last year could be placed at a much more modest figure because it can, at any rate to a large extent, be debited to the grass crop that follows the mulberry plantation and for which it constitutes an excellent precursor in the rotation.

Prof. BUCCI gives detailed information on planting and on the care of the plantation, and he remarks that his experiments on the action of nitrogenous fertilisers, on the digestibility of the mulberry leaf, and on the influence of leaves from manured trees on the quantity and quality of the cocoons lead him to fear the use of quick-acting nitrogenous manures at the moment of planting if the leaves of the mulberries (as happens in the case of plantations) have to be removed after the second year. It is thus preferable to give a thorough application of farmyard manure at the rate of 200 quintals per hectare, together with at least 2 quintals of super- phosphate per hectare, or a good green manuring with some leguminous crop manured with superphosphate.

In years when the spring defoliation is carried out normally, the plant- ation can be treated with quick-acting fertilisers, preferably, ammonium sulphate or sodiun nitrate because, as the authors' experiments have shown, leaves from mulberries manured at the rate of 1 quintal of ammonium sulphate per hectare are more digestible than those from plantations that have received the same amount of nitrogen but in the form of nitrate of soda (*i. e.*, 130 kg., per hectare.)

The author also found that it was best to prune the young mulberries in the autumn, the same year as planting (carried out in spring), but care must be taken, both in the first and subsequent prunings, to leave a stump above ground and not cut the plants down to the ground, because, with a small trunk emerging, tillering is favoured, thus leading to the produc- tion of a greater number of branches and considerably increasing the quantity of leaves produced.

652 - ***Saccharum aegyptiacum* in the Dunes on the Algerian Littoral.** — LA- MOTTE DUCAMPS, in the *Bulletin agricole de l'Algérie-Tunisie-Maroc, Annales de l'Expé- rimentation agricole et de la Colonisation de l'Afrique du Nord*, Series 2, Years XXVI, Nos. 1-2, pp. 23-25. Algiers, Jan.-Feb., 1020.

Saccharum aegyptiacum, a common plant in Egypt, has long been used on the east coast of Sicily as a windbreak and grows wild near Bône. Following on the suggestion of the Botanical Service, the Algerian Forest Service has used it successfully for some years for binding dunes.

The author describes the results obtained from his plantations of *Saccharum* at Achachas, near Lapasset, in the department of Oran. Since it was imported in 1915, the plant has been used in three ways by the author as the estate was gradually formed. At first, cuttings were placed in the sand dunes which they were to fix and, in case of success, they constituted a kind of reserve nursery for subsequent use. This first plantation extended so considerably that it is now quite a *Saccharum* forest, certainly small but sufficiently high to hide a man on horseback and bushy enough to cover a herd of cattle.

The first paths on the estate were afterwards bordered with 2 rows of cuttings placed at a distance of 40 cm. in and between the rows ; the borders are now from 1.5 to 2 m. thick and have a very pleasant appearance They are easily kept in order and to prevent them extending too much it is sufficient to run the plough along close to them.

The third use is the chief and most satisfactory aim, *i. e.*, as a windbreak.

Thanks to *Saccharum*, the vineyard can easily be divided into long, parallel rectangles with a witch of 25 m. in the case of soils that are sandiest or most exposed to the wind, and of 50 m. in more compact and better-sheltered soils. These hedges grow very rapidly and form a very efficient windbreak. The vines are planted 1. m. apart in the rows and 2.5 m apart between the rows ; as soon as the vines are strong enough the windbreaks will be left only at regular intervals 50 m. apart. The sand, enriched by cultivation, will be less blown about and there will be less fear of scorching from it. For this reason, starting from the initial hedge, all the hedges placed 50 m. apart are permanent and replace a row of vines. The cuttings are planted at distances of 40 cm. apart. The hedges placed 25 m. apart are temporary and grow in the space between two rows ; as they have to exert their maximum effect as quickly as possible, they are planted more closely, *i, e.*, at distances of 30 cm. in every direction. Plantation took place in October in ground that still retained some moisture and in January and February after abundant rain in ordinary soil. Almost everywhere cuttings 80 cm. long were used and buried 40 cm. in the soil so that the wind, which is constantly shifting the level of the soil, always leaves the plant buried sufficiently ; 95 % of the plants struck roots. The young plant always develops at the eye placed at the level of the soil or slightly below it. When there are two shoots, the upper one is always weaker and, as a rule, all the upper part of the cutting, some 30 cm., dies.

The last plantations made in soils where the sand is fixed are cut level with the ground. A greater number of cuttings can be obtained with the same quantity of material and the young plants grow more quickly and better.

As the cuttings are planted in January, the young shoot grows in the spring and is 1.2 to 1.5 m. high at the end of the year. In the following spring, each plant forms a small tuft and the windbreak plays its part as soon as the vines begin to grow, for by then, the hedges are already close, and are 2. to 2.5 m. high at the end of the year.

The hedge increases in density and height during subsequent years. As there was no straw left in 1919, the leafy tips of the *Saccharum* were fed to horses, which ate them eagerly. The plant has given astounding results at Oued Kramis and should be propagated for estates exposed to the wind ; it ought to be better known.

653 – **Market-gardening in Italy.** — Séano. G., in *Il Coltivatore*, Year 66, No. 3, p. 66. Casale Monferrato, Jan. 30, 1920 ; No. 5, pp. 125-130, Feb. 20, 1920 ; No. 7, pp. 171-181, March, 10, 1920 ; No. 9, pp. 240-243, March 30, 1920. HORTICULTURE

Market-gardening in Italy occupies 111 000 hectares, of which 51 000 hectares are occupied by vegetables grown on a large scale and 60 000 by permanent market-gardens ; there are also 48 000 hectares of market-gardens in which fruit-growing is carried on. The 111 000 hectares mentioned represent barely 0.39 % of the whole area of the country, 42 % of the agricultural and forestal area, and 0.84 % of the arable land. Industrial horticulture, therefore, might play a much more important part in Italy than it does at present. The appended table shews the vegetables grown on a large scale and the area they occupied in Italy, in 1916-17, when the total area covered was 83 987 hectares.

Tomatoes	28 225 hectares	Onions and garlic	6 005 hectares
Fresh vegetables	23 565 »	Artichokes	5 775 »
Cabbages and cauliflowers.	9 090 »	Celery, cardoons, fennels .	2 025 »
Melons and water-melons.	8 510 »	Asparagus	792 »

The tomato, then, occupied 33 % of the total area employed for large-scale vegetable crops, and it is of most importance in the regions where tinned tomatoes are prepared, such as the province of Parma and parts of Sicily and Sardinia. The 83 987 hectares planted with large-scale vegetable crops were distributed as follows (in hectares) : — Northern Italy, 20 2670 ; central Italy, 9747 ; southern Italy, 42 610 (Campania 22 665, Apulia 18 470) ; islands 10 960. Market-gardening is, therefore, practised most in southern and insular Italy.

The author rapidly considers the extension of the different crops in each region during the period 1916-17, and gives the absolute and unit production. He desires to attract the farmers' attention to the question and to give him information that will lead him to start market-gardening in places where it is absent, or if present, to develop and improve it.

The different vegetable crops in the various regions of Italy and the area they occupied (in hectares) are given below : —

Piedmont : — Fresh vegetables 1100, cabbages and cauliflowers 1025 onions and garlic 255, asparagus 200, celery, cardoons, fennel 120, tomatoes 50.

Liguria : — Fresh vegetables 3700, tomatoes 1425, cabbages and

cauliflowers 1200, artichokes 475, celery, cardoons, fennel 250, asparagus 220.

Lombardy : — Melons and water-melons 510.

Venetia : — Onions and garlic 1950, fresh vegetables 410, cabbages and cauliflowers 590, artichokes 340, asparagus 300, tomatoes 190.

Emilia : — Tomatoes 5885, melons and water-melons 375, onions and garlic 170, celery, cardoons, fennel 130.

Tuscany : — Artichokes 1270, cabbages and cauliflowers, 555, tomatoes 510, onions and garlic 320, melons and water-melons 70.

Latium : — Artichokes 800, tomatoes 730, cabbages and cauliflowers 550, fresh vegetables 500, onions and garlic 450, celery, cardoons, fennel, 275, melons and water-melons 250, asparagus 75.

Abruzzi and Molise : — Fresh vegetables 2250, tomatoes 685, melons and water-melons 330, celery, cardoons, fennel 140.

Campania : — Tomatoes 8580, fresh vegetables 5250, cabbages and cauliflowers 3165, melons and water-melons 2635, onions and garlic 1720, artichokes 705, celery, cardoons, fennel 610.

Apulia : — Dry vegetables 7650, tomatoes 3935, melons and water-melons 3480, cabbages and cauliflowers 2205, onions and garlic 560, celery, cardoons, fennel 240.

Calabria : — Tomatoes 1200, fresh vegetables 275.

Sicily : — Tomatoes 3400, fresh vegetables 2430, artichokes 1145, melons and water-melons 515, onions and garlic 280, celery, cardoons fennel 100.

Sardinia : — Tomatoes 1645, artichokes, 800, melons and water melons 345, onions and garlic 300.

The percentage of market-garden crops compared with the area cultivated are, for each region : Cämpania 26.99, Apulia 21.99, Sicily, 9.37, Liguria 8.00, Emilia 7.81, Latium 4.23, Venetia 4.26, Abruzzi and Molise 4.05, Sardinia 3.68, Piedmont 3.27, Tuscany 3.23, Calabria 1.67, Lombardy 0.61. In the Marches, Umbria, and Basilicata large-scale vegetable crops are not grown.

The Italian production of vegetable during the agricultural year 1916-1917 amounted to 9771.9 metric tons, distributed in the following manner : —

	Metric tons		Metric tons
Tomatoes	4 316 50	Onions and garlic	657 50
Cabbages and cauliflowers	1 776 50	Artichokes	511 00
Melons and water-melons	1 286 50	Celery, cardoons, fennel	335 50
Fresh vegetables	862 50	Asparagus	25 90

In *Piedmont,* over a half of the total production (40 580 tons) consisted of cabbages and cauliflowers (23 500 t.) ; the remainder was : Fresh vegetables 8350 t., onions and garlic 4200 t., celery, cardoons, fennel 2350 t., tomatoes 1550 t., asparagus 630 t.

In *Liguria*, nearly half the total production (121 385 t.) consisted of tomatoes (56 800 t.); the remainder was: — Cabbages and cauliflowers 35 500 t., fresh vegetables 17 750 t., celery, cardoons, fennel 7750 t., artichokes 2700 t., asparagus 885 t.

Lombardy only produces melons and water-melons (6450 t.) as industrial garden crops.

In *Venetia*, the total production is 32 600 t; the first place is occupied by onions and garlic with 15 000 t., followed by cabbages and cauliflowers 3200 t., tomatoes 3800 t., fresh vegetables 2500 t., artichokes 2200 t., and asparagus 900 t. This region produces 34.75 % of the total production of asparagus in Italy.

In *Emilia*, the total production of 137 600 t. is distributed as follows: Tomatoes 125 800 t. (or 29.14 of the total Italian production), melons and water-melons 4900 t., onions and garlic 4550 t., celery, fennel, cardoons 2350 t.

In *Tuscany*, the total production is 41 500 t., the chief crops are artichokes (17 000 t., or 33.27 % of the Italian production) and cabbages and cauliflowers (12 750 t.); other crops include: —8100 t. of tomatoes, 2850 t. of onions and garlic, and 800 t. of melons and water-melons.

Latium, the total production is 36 225 t., including: — Tomatoes 11 810 t., cabbages and cauliflowers 7500 t., artichokes 5600 t., onions and garlic 4850 t., celery, cardoons and fennel 3000 t., melons and water-melons 2500 t., fresh vegetables 1000 t., asparagus 175 t.

In the *Abruzzi* and *Molise*, 16 550 t. of garden crops is produced including: — Tomatoes 8250 t., fresh vegetables 3850 t., melons and watermelons 2900 t., celery, cardoons and fennel 1550 t.

Campania has the highest production with 280 400 t., and in proportion to the whole Italian production, produces 44 % of the melons, 25.84 % of the cabbages and cauliflowers, 31.56 % of the onions and garlic, 28.17 % of the celery, cardoons and fennel. The figures are: — Tomatoes 121 650 t., melons 56 600 t., cabbages and cauliflowers 46 t., onions and garlic 20 750 t., fresh vegetables 19 150 t., celery, cardoons and fennel 9450 t., and artichokes 6900 t.

In *Apulia*, the total production (151 000 t.) comprises: Cabbages and cauliflowers 44 500 t., melons 43 250 t., tomatoes 28 200 t. fresh vegetables 10 900 t., onions and garlic 6 200 t., celery, cardoons, fennel 5100 t., and artichokes 3050 t.

In *Calabria*, the industrial production of garden crops is represented by 16 900 t. of tomatoes and 2550 t. of fresh vegetables.

In *Sicily*, with a total production of 64 950 t., there are: — Tomatoes 33 050 t., fresh vegetables 10 200 t. melons 7600 t., artichokes 7450 t., onion and garlic 4650 t., celery, cardoons and fennel 2000 t.

In conclusion, the total production of garden crops in *Sardinia* is 28 501 t., including: — Tomatoes 15 750 t., artichokes 6200, t., melons 350 t., and onions and garlic 2900 t.

The author deals with the various species of vegetables grown industrially in Italy.

Tomato. — This is the most important garden crop, and is grown over the largest area in southern Italy and the island, the first places being taken by Salerno, Parma, Naples, and Lecce. The chief absolute productions are, in descending order, in the provinces of Salerno, Parma, Naples, and Genoa. The average unit yield in Italy is 153 quintals per hectare varying from a maximum of 399 quintals in Liguria and 310 quintals in Piedmont to a minimum of 72 quintals in Apulia.

Cabbage and cauliflower. — These cover 9090 hectares the total yield being 177 650 tons. The largest areas under these crops are in the provinces of Lecce Naples, and Salerno, and the highest yields are obtained in the provinces of Lecce, Naples, Turin and Bari. The average unit yield in Italy is 195 quintals per hectare with a maximum of 296 quintals in Liguria and a minimum of 145 in Campania and 135 in Latium.

Melons and water-melons. — These occupy 8510 hectares, which produce 12 8650 t. The provinces where these crops are most important are Lecce and Naples. The average unit yield in Italy is 151 quintals per hectare, varying from a maximum of 250 in Latium and a minimum of 88 in the Abruzzi and Molise.

Fresh vegetables. — These cover 83 565 hectares and yield 86 260 t., the largest areas of production being in the province of Naples, Lecce, and Bari ; those where the absolute production is highest are Naples, Bari, and Lecce. The average unit yield for the whole kingdom is 37 quintals per hectare, with a maximum of 93 quintals in Calabria and a minimum of 17 in the Abruzzi and Molise.

654 – **Grafting the Aubergine (*Solanum Melongena*) on *S. Schoenbrunnense*.** — De Gregorio, A., in the *Nuovi Annali di Agricoltura siciliana*, Series VI, Year VIII, Pt. 1, p. 27. Palermo, 1919.

Solanum Schoenbrunnense (syn. *sodomaeum*) is a Sicilian weed that grows vigorously, attaining almost double the height of the cultivated aubergine (*S. Melogena*). As it is perennial and not so exacting as the cultivated species, the author has used it as a grafting stock for the latter, with satisfactory results, even as regards the quality of the fruit produced.

FRUIT GROWING

655 – **Banana Cultivation and Trade in the Canary Islands.** — Padavera, in *L'Agronomie Coloniale, Bulletin mensuel du Jardin Colonial*, New Series, Year IV, 1919-1920, No. 28, pp. 110-113. Paris, Jan.-Feb., 1920.

Banana cultivation is progressing in the Canary Island, especially at Teneriffe and in the Grand Canary, the total area under the crop being from 2500 to 3000 hectares. The tendency of the plantations to expand is limited by the lack of water. The value of a hectare planted and in full bearing is about 80 000 fr., and the price of a banana stock is now 5 fr. In a banana plantation in full bearing, there are 1300 to 1500 plants per hectare yielding from 1600 to 2000 bunches a year.

The price per hectare of land suitable for banana growing varies between 30 000 and 50 000 fr., whilst 25 000 to 30 000 fr. are required to plant it, etc. The time required for a plantation to attain a good

oduction is from 2 to 3 years. To obtain an average production, two ars must elapse and it must be remembered that the first crop usually nsists of small or medium fruit. The production is normal at years.

The ordinary working expenses are from 5000 to 7000 fr. per hectare r annum, including the cost of manuring, watering, gathering, etc. he average quantity of irrigation water required is 12 000 cu. metres r hectare per annum; for the months from November to July 7000 u. metres is required and 5000 cu. m. for the months from July to Octo- r. The water comes from springs or from tunnels driven into the ountain to tap impermeable strata, or from large reservoirs formed by ams built between two mountains to retain the rain water. On an estate 1 to 2 hectares, 2 men suffice to ensure irrigation throughout the year; ie day wage is 4 to 5 fr. The water is distributed by concrete channels, tilising the natural slope of the land; water is rarely raised. The ater required to irrigate 1 hectare costs from 1000 to 1600 fr. a year, ut this varies as most plantations own their water-rights. Owners who ave no water, or have not enough buy it by the day or the year at the price f 0.14 fr. per cu. metre, which gives annual cost of 1600 to 2100 fr. for rigation water.

Farmyard manure and fertilisers are used for improving the soil. he average composition of the fertiliser used in the island is as follows: ulphate of ammonia 35 %, superphosphate of lime or bones 35 %, sul- hate of potatsh (containing 48-50 % of soluble K_2O) 20 %, sulphate f iron 2 %, and gypsum 8-10 %.

The life of a banana plantation when well cared for and manured ppears to be almost without limits. The soil of the Canaries is of poor uality and as it is of volcanic origin, it requires to be supplemented vith fertilisers, particularly nitrogen, phosphoric acid, and lime; the oil containg, naturally, a certain amount of potash.

The banana is considered to be the best crop in the island, especially s the sale of the fruit increases every year. Only fresh bananas are xported, but, during the war-time lack of shipping, large quantities of anana flour had to be made. Since a normal tonnage has become avail- ble, there has been no necessity to make the flour.

The full, green bananas are exported just when they require 20 days r so to ripen. Their chance of keeping and the methods to keep them s sound as possible depend on the cutting, the packing and the storage n board ship. The bunches of Canary bananas are of two classes, market- ble and suitable for export, and waste or unsuitable for export. The unches for export comprise at least 8 volutes or "hands" (8, 9, 10, 11, 11, 12, 13) and bunches with 7 hands or less are considered as waste. The aleable bunches are to day classified in the following way: —

1. — On the plantation, the price of the bare bunches is: — Giant 21 fr., extra 18 fr., firsts 12 fr., seconds 8 fr., and discarded bunches sell at 2 to 4 fr.

2. — On the quay, the prices are 28, 24, 18 and 15 fr., respectively.

Name of the bunches	Weight
Giant, with 250 fruits and over.	28 kg. and over
Extra, with 200 fruits and over	about 25 kg.
Firsts with 160 fruits and over.	20-22 kg.
Seconds, with 125 fruits and over.	12-20 kg.

3). — On the boat. — The above prices have to be increased by 0.50 fr. for loading on board ship.

On a good plantation, the discarded bunches are in the proportion of 6 to 10 %.

The bunches are packed in crates, at the rate of two bunches a crate, The crate costs 2.20 to 2.50 fr., labour 0.50 to 2.50 fr., wadding 0.60 fr. paper 0.25 fr., nails 0.25 fr., straw 0.60 to 1 fr., handcart for transport 0.20 to 0.50 fr. The total cost of the crate, packing, and transport to the quay is from 5 to 7 fr.

In the Canaries, the average cost of investing money, guaranteed by mortage, is usually 6 %.

The total export from the Canaries is probably over 4 million bunches a year, of which France takes just over a million and England about 3 million.

656 – **Researches on the Harvesting and Storage of Pears, carried out in the Rogue River Valley, Oregon, U. S. A.** — I. Lewis, C. J., Magness, J. R., and Cate, C. C., in the *Oregon Agricultural College Experimental Station, Bulletin* 154, pp. 24. Corvallis, Oregon, 1918. — II. Lewis, C. J., Murneck, A. E., and Cate C. C., *Ibid., Bulletin* 162, pp. 39. Figs. 12. July, 1919.

I. — Researches carried out on 8 orchards in soils of various types and cultivated in different ways. In each orchard, the fruits of 6 varieties were gathered at intervals of 4 to 5 days during the whole harvest season, beginning slightly before the period of commercial maturation for all the varieties. The fruits were stored under the following conditions :— Ordinary fruit-loft, dry or ventilated; ordinary damp fruit-loft; storage at the temperature usual in railway waggons : cold dry storage ; retarded storage, i. e., the fruit placed in store some time after the harvest; damp, cold fruit-loft. Samples were taken from each group and determinations made of the specific gravity of the juice and the content in starch, sugar, acids and moisture. The results, relating to the year 1917, are summarised in tables and discussed at length.

The experiments show that, when the fruit can be left on the tree for a longer time than usual, the harvest is greater both in volume and weight. Thinning out the fruit by successive harvests has no influence on the fruit remaining on the tree, but fruit treated in this way and those not treated, increase in size if left on the tree till the end of the period of harvest. This increase in size is less marked in orchards whose soil is lacking in coolness.

A great part of the Rogue Valley fruit is gathered too quickly to allow them to attain their best flavour, although fruit gathered before ripe keep better under ordinary conditions of storage. When Bartlett pears are gathered too early their flavour is harmed less than when varieties kept a long time on the tree, such as Clairgeau, Anjou and Bosc, are gathered early.

With all types of storage, except the ordinary loft, i. e., with storage at the usual temperature of railway waggons, in a cold room, or in a cold, damp room, fruit gathered early does not keep as well as that gathered later.

There is apparently no relation between the size of the fruit and keeping properties as regards pears gathered at the same time from the same tree. Both small and big fruit ripen and decay together.

The authors attempted to ascertain the right moment for harvesting by estimating the starch content but with negative results, the same effect was obtained as regards the specific gravity. It was not possible to establish any direct correlation between the period of gathering, the property of keeping, and the flavour of the fruit on the one hand, and the content in sugar, water, and acids on the other. Small fruit contains a little more sugar and, in the case of the Bartlett, much more acids than large fruit from the same tree.

II. — Report of the chief results obtained during the 1918 season.

The authors examined the increase in volume of Bartlett pears from a statistical point of view. The results, given in tables and diagrams; show that these pears gradually increase in size and volume with a rapidity that increases up to complete ripeness, independently of climate or cultural conditions. The increase in transverse diameter is proportionately more rapid than that in longitudinal diameter. The number of grains that develop (i. e., do not abort) probably has an influence on the shape of the pears. No important change was observed in the average length and diameter of the petiole of the fruit.

Seeing that a storage experiment is of little value as an index of the best time for harvesting, a new " pressure test " was employed to measure the degree of ripeness of the pears at harvest time. The test consists in pressing a steel ball half sunk in a block of hard wood against the central part of the side of the fruit until the wood touches the pear ; the pressure required is recorded. There is apparently a definite relationship between the degree of ripeness of the pears and the resistance to pressure of the tissues of the cortex and epidermal regions. This resistance and, consequently, the degree of ripeness, was measured at intervals of 3 or 4 days. With Bartlett pears, there was a gradual average decrease of resistance amounting to half a pound every 24 hours, using equal surface of pressure during all the ripening period. Experiments carried out 6 hours after gathering are safer than those made about 24 hours after, owing to a change in the degree of ripeness in the fruit after it is gathered. There was no correlation between the transverse diameter of the fruit and its resistance to pressure on the same date. Pressure tests applied to Bosc pears gave similar, if

less obvious, results, for Bosc is a variety that ripens much more slowly and has a thicker epidermis.

Storage investigations with Bartlett pears showed that the size of the fruit is related neither to the degree of ripeness nor to the rapidity of decay. Pears gathered half-way through or at the end of the season kept in a cold store a little longer than those gathered early.

Fruit gathered early is distinctly inferior in quality to that gathered later. A relatively high temperature, combined with a high degree of humidity, prevented Bartlett pears gathered early from ripening to best advantage. Within the limits of a temperature conducive to ripening, no difference was observed in the speed with which stored Bartlett pears ripened when a change of temperature of 10° to 15° F. was registered, provided that the degree of humidity remains approximately constant. Pears gathered very late showed exceptional flavour and keeping qualities, and the authors suggest that this may be due to the late ripening of fruit left on the tree a long time owing to the high temperatures that prevailed during the mid-season.

As regards the storage of Bosc pears in a fruit-loft, it appears that, when they are kept beyond the normal limits of the life of that variety, the humidity should be increased to correspond to the decrease in temperature.

Out of 12 methods of storage tested, the best were :— The ordinary fruit-loft ; storage at the temperature of railway waggons ; storage, 14 days after harvest, at the usual temperature of railway waggons for 12 to 15 days, followed by cold storage. It seems especially important that Bosc pears, if they are to be cold-stored, must be put in at least two weeks after the harvest. The higher the humidity, the shorter can be the interval between gathering and cold storage. A relatively high temperature with low humidity was as harmful to the proper ripening of Bosc pears as was a low temperature with high humidity.

VINE GROWING

657 – **Productivity of Italian Vines.** — *Giornale vinicolo italiano*, Year XLVI, No. 13 pp. 117-127 ; No. 15, pp. 137-138. Casale Monferrato, March 28, April 11, 1920.

The following averages, extracted from the *Bulletin of Agricultura Statistics*, of the Italian Ministry of Agriculture, are for the 9 years, 1907 1917, and relate only to specialised vineyards, as the density of plantatio of vineyards is extremely variable. The numbers express the quantity of grapes in quintals.

Piedmont. — Alessandria 47, Cuneo 42, Novara 33, Turin 26 ; regiona average 40.

Liguria. — Genoa 46, Porto Maurizio 43 ; regional average 44.

Lombardy, — Bergamo 36, Brescia 17, Como 37, Cremona 48, Mantua 3 Milan 88, Pavia 42, Sondrio, 33 ; regional average 33.

Venetia. — Belluno 19, Padua 35, Rovigo 64, Treviso 42, Udine 3 Venice 54, Verona 13, Vicenza 39 ; regional average 27.

Emilia. — Bologna 28, Ferrara 30, Forlì 42, Modena 15, Parma 4 Piacenza 69, Ravenna 23, Reggio Emilia 39 ; regional average 34.

Tuscany. — Arezzo 42, Florence 48, Grosseto 43, Leghorn 37, Lucca 4, Massa and Carrara 38, Pisa 45, Siena 47; regional average 42.

Marches. — Ancona 63, Ascoli Piceno 38, Macerata 51, Pesaro and Urbino 50; regional average 50.

Umbria. — Perugia 34.

Latium. — Rome 42.

Abruzzi and Molise. — Aquila 22, Campobasso 26, Chieti 28, Teramo 37; regional average 28.

Campania. — Avellino 45, Benevento 46, Caserta 47, Naples 61, Salerno 27; regional average 43.

Apulia. — Bari 19, Foggia 25, Lecce 25; regional average 23.

Basilicata. — Potenza 21.

Calabria. — Catanzaro 22, Cosenza 20, Reggio Calabria 44; regional average 28.

Sicily. — Caltanisetta 34, Catania 53, Girgenti 35, Messina 40, Palermo 44, Syracuse 31, Trapani 27; regional average 39.

Sardinia. — Cagliari 18, Sassari 28; regional average 19.

General average for the kingdom: — 32.

Of the 16 Italian regions the productivity of 10 is above the average; these include all those of central Italy most of those of northern Italy, and southern regions such as Campania and Sicily. Amongst the regions whose productivity is below the average for the Kingdom are all the remaining southern regions in Sardinia and Venetia.

There are also considerable differences in the productivity of the vineyards in the different provinces even if in the same region. The productivity varies:—

from	26	to	27	quintals	per	hectare	in	the	provinces	of	Piedmont.
»	43	»	46	»	»	»	»	»	»	»	Liguria.
»	17	»	88	»	»	»	»	»	»	»	Lombardy.
»	13	»	64	»	»	»	»	»	»	»	Venetia.
»	15	»	69	»	»	»	»	»	»	»	Emilia.
»	37	»	48	»	»	»	»	»	»	»	Tuscany.
»	38	»	63	»	»	»	»	»	»	»	the Marches.
»	22	»	37	»	»	»	»	»	»	»	Abruzzi and Molise.
»	27	»	61	»	»	»	»	»	»	»	Campania
»	19	»	26	»	»	»	»	»	»	»	Apulia.
»	20	»	44	»	»	»	»	»	»	»	Calabria.
»	27	»	44	»	»	»	»	»	»	»	Sicily.
»	18	»	28	»	»	»	»	»	»	»	Sardinia.

By classing productions not above 20 quintals of grapes per hectare as poor, those from 21 to 30 quintals as medium, those from 31 to 50 quintals as good, and those above 50 as abundant, the 69 provinces of Italy can be arranged in increasing order of productivity in the following way:—

Provinces with a poor production. — Verona, Modena, Brescia, Cagliari, Belluno, Bari, Cosenza.

Provinces with a medium production. — Potenza, Aquila, Catanzaro,

Ravenna, Foggia, Turin, Campobasso, Lecce, Salerno, Trapani, Bologna, Sassari, Chieti, Ferrara, Udine.

Provinces with a good production. — Syracuse, Sondrio, Novara, Caltanisetta, Perugia, Girgenti, Padua, Bergamo, Como, Leghorn, Teramo, Massa and Carrara, Mantua, Ascoli Piceno, Vicenza, Reggio Emilia, Messina, Lucca, Arezzo, Forlì, Treviso, Cuneo, Grosseto, Parma, Porto Maurizio, Rome, Reggio Calabria, Palermo, Avellino, Pisa, Genoa, Benevento, Siena, Caserta, Alessandria, Cremona, Florence, Pesaro, and Urbino.

Provinces with an abundant production. — Macerata, Catania, Venice, Naples, Ancona, Rovigo, Piacenza, Milan.

The major part of the provinces of Italy, consequently, produces from 31 to 50 quintals of grapes per hectare in specialised vineyards. One third of the provinces, however, has either poor or medium productivity and, in a few others (8), the production is abundant.

Amongst the first ones are those belonging to 13 different regions in which, however, only Tuscany and Liguria, as well as Latium and Umbria, figure with all their provinces. In 3 regions, i. e., in Basilicata, Apulia, and Sardinia, the vines in all the provinces produce less than 20 quintals of grapes per hectare. Some of the provinces of 6 regions are abundant producers, with over 50 quintals of grapes per hectare.

The average productivity of the specialised vineyards, therefore, varies, in the different provinces, between very wide limits and very large differences exist between provinces in the same or adjacent regions.

The author believes that some of these figures are below the actual amount. Thus, the Apulian vineyards produce an average of 35 to 45 quintals of grapes per hectare and, in Sardinia, the vineyards at Campidano easily produce 50 to 60 quintals per hectare, whilst the production in the northern part of the island is at least 30 quintals per hectare.

658 – **Vines with Small and Large Grapes.** — Sannino, E., A., in the *Rivista di Ampelografia* (1), Year 1, No. 1, pp. 7-8. Alba-Livorno, January, 1920.

Varieties of vines such as Barbera, Freisa, and Sirah have two forms equal as regards the external characters of the leaves and bunches, but different in so much as one has small grapes and the other large ones. The composition of the must is a further difference that also corresponds, as that of the sub-variety with small grapes is sweeter. The Barbera with large grapes is mainly grown at Montefalco, in Umbria, and at Casale, whilst that with small grapes is cultivated in the Tanaro valley. The Tanaro wines are much more alcoholic than those of Casale. There is also another variety whose forms differ solely in the size of the grapes ; this is the Ver-

(1) The object of this new Review, edited by Prof. T. A. Sannino, Director of the "Regia Scuola di Viticoltura ed Enologia" of Alba, is to make ampelography the basis of viticulture, in other words, the study of each variety of vine, so as to make it possible to choose the most productive types for each locality and to make better wines. In addition, the Review will deal with specialised or associated viticulture, œnology, the production of wine, trade, etc. (*Ed.*)

diso of the province of Treviso which has 2 sub-varieties, the " Verdiso gentile " and the " Verdiso grosso " or " Verdisone ". These are grown together and to obtain an abundant production of wine, the Verdisone is given prominence, though it is well known that a better wine is obtained when " Verdiso gentile " predominates. The grapes of " Verdiso gentile " usually contain but one pip, few containing two ; with Verdisone, however, grapes with 2 and 3 pips predominate. The well-known influence of the number of pips has the result that must from " Verdiso gentile " grapes is richer in sugar than must from Verdisone grapes. The origin sub-varieties of this kind must be attributed to a bud mutation. The vines known as Aglianico, Aglianicone, and Aglianichiello, of the province of Avellino, constitute 3 different varieties.

The case of the Sangiovese of Tuscany (that with an oval, fairly large grape) is different ; in certain years, it bears bunches with numerous small grapes, pipless though ripe, and a small number of large grapes that are not so sweet. The formation of very small grapes in the Sangiovese vine depends on the year, and it seems that, if it rains at flowering time, bunches are formed that have pipless grapes.

659 - **Yellow and Green Grapes.** — SANNINO, F. A., in the *Rivista di Ampelografia*, Year 1, No. 5, p. 74. Alba-Livorno, March 1, 1920.

Some white vines produce fine golden-yellow grapes, while others produce a grape that is more or less greenish even when completely ripe. The general opinion is that the greenish colour indicates a small sugar content, whilst the yellow colour indicates the reserve. But this is not always so and the author mentions several exceptions. Amongst grapes of an intense yellow colour, even with orange tones, are those of the following vines: — Erbaluce from Caluso (Ivree, province of Turin), Garganeza from the hillsides of Verona and Vicenza, Ribolla from Friuli, Lussuriet from Piedmont, and Malvoisy from Lipari. Ribolla and Lussuriet, however, are poor in sugar and Ribolla even lacks acidity. The Lussuriet vine grown by the author yielded grapes with but 14 % of glucose and wine of excessive acidity that could still be detected even after blending with other wines. Amongst vines with grapes that are more or less green, even when completely ripe, are Verduzzo, Verdiso, Verdea, Verdicchio, Verdone (all different vines), almost all of which have grapes rich in sugar, especially the Verduzzo from Friuli, which has small grapes and yields must rich in sugar, 20 % and more. Another peculiarity of the Verduzzo grape is its very tannic pulp, a condition which does not occur in the other grapes, even if their skin is very rich in tannin.

660 - **The Catarratto Moscato Cerletti Vine.** — SANNINO, F. A., in the *Rivista di Ampelografia*, Year 1, No. 3, pp. 33-36. Alba-Livorno, February 1, 1920.

The author describes the cross obtained by Baron A. MENDOLA in 1869 by fertilising white " Catarratto " with pollen from " Moscatellone " (also called " Zibibbo " or " Salamanna "), and observes that this vine deserves to be better known and more largely grown, especially in Apulia, where the reconstitution of the vineyards is being undertaken so enthusiast-

ically. The vine is of value for the abundance and good quality of its grapes, which combine the qualities of the parents and can thus be used either for the table or for the manufacture of liqueur wines. Almost all the modern muscatels have bare leaves, but Catarratto " has cottony leaves, such as PLINY describes for the " apiane " grapes, which, according to M. MENDOLA, correspond to the modern muscats.

661 – **The " Dolcetto " Vine and its Variety with Red Leaves.** — SANNINO, F. A., in the *Rivista di Ampelografia*, Year I, No. 6, pp. 81-82. Alba-Livorno, March, 15, 1920.

The author states that the " Dolcetto " vine, grown on the hillsides of the Alba district (province of Cuneo) has a form whose leaves turn red in autumn much earlier than the leaves of the ordinary form. This is correlated with the reddish coloration of the peduncles of the grapes, with a lower content of glucose in the grape, and with a shorter period of ripening.

662 – **Phylloxera in Italy and the Best Grafting Stock.** — SIGNORINI, M., in the *Giornale vinicolo italiano*, Year XLVI, No. 5, pp. 37-39. Casale Monferrato, February 1, 1920.

A good grafting stock should satisfy the following conditions: — It must be sufficiently resistant to the phylloxera, it must be adapted to the climate and soil of the region where it is planted, particularly to the lime content of the soil, and it must have a good affinity with the scion. Starting from these considerations, the author advises the use in Italy of the following grafting stock as worthy of being widely grown and of full consideration by the vine-grower, particularly as regards their general affinity for all the Italian vines:—

FOR NORTHERN ITALY: — *Riparia Rupestris* 3306, in fresh compact soils or in rather dry, but well-manured soils with not more than 25 % of lime, and for all Italian vines.

Riparia Rupestris 101-14, in good, deep, fresh, somewhat light soils, with not more than 25 % of lime, and for all Italian wines.

Aramon Rupestris Ganzin 1, in all save very arid soils, even if very compact, clay or calcareous, but with not more than 50 % Ca CO_3, provided that the sub-soil is sufficiently cool, for all Italian vines, especially if whip grafted.

Mourvède Rupestris 1202, as the preceding one, but with greater tolerance for lime (60 %) and a greater facility for taking grafts.

FOR SOUTHERN ITALY:— *Rupestris metallica*, in arid, compact soils, in gravelly soils, in tuffs with not more than 15 % of lime, for all the Italian vines, especially those with white grapes.

Rupestris du Lot, even in arid, compact soils, and in stony, poor soils, with not more than 35 % of lime, for all the Italian vines.

Berlandieri Riparia 420 A, even in arid, gravelly, and calcareous (50 %) soils, for all the Italian vines.

Berlandieri Riparia 751-11, like the preceding one, but with less resistance to drought.

FOR CENTRAL ITALY:— All the above mentioned vines can be successfully grown there. Other good vines are worth special attention for vine-growers (e. g., *Riparia gloire de Montpellier*), and others have not a

good affinity for all the Italian vines (*Riparia gloire de Montpellier*, Riparia × Rupestris 3309, etc.) ; others are particularly suited for special soil conditions, such as *Chasselas Berlandieri* 41 B for very calcareous soils (70 %), very arid, poor soils, for all the Italian vines ; *Solonis Riparia* 1616 for all very damp soils, and saline soils, with more than 30 % of lime.

The distinction made between vines suited to northern Italy and those suited to southern Italy is not absolute, because there are vines such as *Berlandieri Riparia* 420 A which, although more adapted to southern Italy, are successfully grown in northern Italy and *vice versa*.

63 – **Two Good Grafting Stocks from the Trentino.** — Zanotti, L., in the *Rivista di Ampelografia*, Year 1, No. 3, p. 38. Alba-Livorno, Feb. 1, 1920.

The Agricultural Institute of St. Michele and the Provincial Agricultural Council of Trentino, have imported into the Trentino Americo-American hybrids, selected in Hungary and Germany, and which were known as good grafting stock. They also distinguish themselves in the Trentino for their robust growth, their adaptability to most of the soils of the region, and by their efficacious resistance to phylloxera. On account of their value from these points of view, the author advises that they should be tested in other regions of Italy, especially where other grafting stocks have not given very satisfactory results. Amongst these vines, mention should first of all be made of two hybrids selected by Teleky in Hungary, starting from grapes of French origin, i. e., Riparia × Berlandieri Teleky No. 5 and No. 8, and Rupestris × Berlandieri Teleky 10A.

Riparia × Berlandieri Teleky Nos. 5 *and* 8. — Very vigorous vine, with large, trilobate leaves of a dark brilliant green that makes it resemble a Riparia rather than a Berlandieri. The buds are light, bronzed, whilst the shoots are greyish long, and uniform in colour. The root system is well developed and tends to penetrate deeply in the soil. It has a good resistance to phylloxera, it adapts itself to soils rich in lime, even stony soils ; it specially suits cold regions and does not suffer much from drought. It stands grafting well and gives vigour to the scion, whose production seems improved. The wood matures well, but the cuttings do not root very strongly.

Rupestris × Berlandieri Teleky 10A. — Vine of robust growth, with much ramified roots that tend to go deeply in the soil. The large, rounded leaves are like those of Rupestris. The shoots are vigorous and ripen their wood well, much being produced, provided that the vines are far enough apart to permit of lateral growth. The resistance to phylloxera is excellent, as is that to lime, whilst drought is resisted well ; the vine is thus suitable for stony, dry and calcareous hill soils. It supports grafting well, and gives off roots more easily than the preceding stock. The grapes produced by the scions ripen normally and are of good quality.

To sum up, both stocks show the good characters of their parents, whilst being free from their defects. The Riparia × Berlandieri Teleky, however, has the disadvantage of taking rarely from cuttings, a disadvantage generally found in all the descendants of Berlandieri.

664 – **The Behaviour of Frozen Vines in North Italy.** — GABOTTO, L., in *Il Coltivatore*, Year 56, No. 5, pp. 20-120, fig. 1. Casale Monferrato, Feb. 20, 1920.

The frosts that were rife in upper Italy at the end of April, 1919, enabled the author to make observations on frosted vines, and on the effects of the pruning usually recommended for such vines. He concluded from his observations that, when frost has destroyed most of the opened buds, it is radically necessary to prune the vine, especially if it is full grown; in fact, it is impossible, even under the most favourable conditions, for the vine to repare the harm by producing supplementary shoots on that years' branch. Even if such shoots appear, they can not develop to any useful extent. Radical pruning, however, concentrates all the vitality of the plant on a few latent buds which, once the inevitable arrest of growth due to pruning has passed, are abundantly nourished and can produce shoots which, if they bear no fruit, will reconstitute the branch for the next year.

Topping the frozen buds was found to be useless as it did not vivify the under buds to any noticeable degree, i e., in such a way as to develop normally and produce fruit.

But a doubt remains regarding the productivity of the shoots developed after pruning the branch radically for, as they are not borne by second season wood they ought, so it is generally thought, to be sterile.

665 – **Mechanical Cultivation of Vineyards: Ploughing with Two Motor Windlasses of the "Établissements Albert Douilhet" and a Chapron Tractor.** — See No. 686 of this *Review*.

FORESTRY

666 – **The Forest Resources and Woods of the French Colonies of the Ivory Coast and Gabon.** — DABAT, L., Director General of the Woods and Forests Service. Report presented in the name of the Agricultural Committee on the Colonial Forestry Mission of Commander BERTIN, in the *Bulletin de la Société d'Encouragement pour l'Industrie Nationale*, Year CXIX, Vol. 132, No. 1, pp. 17-21. Paris, Jan.-Feb., 1920.

The pre-war production of timber in France was well below the needs of the country and the annual excess of the imports over exports averaged 880 000 metric tons, corresponding to 2 000 000 cu. metres of standing timber. This deficit will have been greatly increased by the war and the French requirements will have been considerably augmented because, in addition to the normal consumption, provision has to be made for replenishing exhausted stocks, for reconstituting the liberated regions, for remaking the railroads and because, to satisfy the needs increased in this way, there will only be a production that has been reduced by the extensive exploitation and the destruction of forests due to the war. Considerable quantities of timber will, therefore, have to be imported. Instead of buying the timber in foreign countries that will require payment in gold, France has every interest to obtain supplies from her colonies, as these possess immense forests. Besides, the exploitation of the colonial forests would be equally advantageous both to the home country and the colonies. The difficulty is that colonial timber, except for valuable woods for cabinetwork, is hardly, if at all, known and is neglected by the trade.

During the war, the French Government dealt with the utilisation of colonial timber, and a mission headed by Commander BERTIN, Inspector

of Woods and Forests, was sent by the Ministries of War, Armaments, and the Colonies to study on the spot the forest resources of the French colonies. The first work of the mission, carried out in 1916 and 1917, bore on the timbers of the colonies of the Ivory Coast and Gabon, and M. BERTIN published the results in a work entitled *Mission forestière coloniale* (1). This work is in 3 volumes, the first two of which were published in 1918, while the third has just appeared.

The third volume, "La Question Forestière Coloniale", should, as the author himself remarks, logically have preceded the other but, during the war, it was much more important to prepare for the future by publishing the results obtained than to go back to the past and show the reasons which led to the organisation of the mission. The third volume, therefore, will be considered first: it is divided into 6 books.

In *Book* I, written at the beginning of 1918, there is a copious documentation, extracted from the best sources, on the pre-war production and consumption of timber in France, on the estimated requirements and resources at the end of hostilities — such as could be foreseen at the time of writing — on the value of colonial timber compared with that of other common timber, on its cost and pre-war trade.

M. BERTIN comes to the conclusion that the exploitation of her colonial forests is the only way in which France can meet her increasing needs without diminishing her financial reserves and that, consequently, the State must place these timbers on the French market, ensure immediate exploitation, and build up stocks in the colonies to be made use of as circumstances permit.

Book II consists of a study on the tropical forests in the Ivory Coast, Gabon, Cameroons, and in general of equatorial Africa, where the varied flora comprises from 1000 to 1200 species, amongst which 200 or 300 are very common. Valuable information is also given regarding the prospecting carried out by the mission.

Book III is a summary of the technology of colonial forestry and deals with exploitation, cutting up, conservation, transport and loading of the timber; appendices contain interesting notes on saw-mills in Canada, the United States, Sweden, etc.

Book IV deals with the beneficial influence of forests on the climatic conditions and fertility of tropical regions, with sylviculture and the management of colonial forests, and with forest regulations in the colonies. M. BERTIN concludes that the organisation of a colonial forestry service is necessary.

In *Book V* the technical properties and industrial classification of colonial timbers are discussed, and the tests carried out on the timbers bronght back by the mission are described. The physical and mechanical tests were carried out in the testing laboratory of the "Conservatoire des Arts et Métiers" the industrial tests at Aubervilliers, Charenton and Vil-

(1) This report was dealt with in the first part of a general article on the same subject which appeared in *R.*, June, 1919, No. 742. (*Ed.*)

lers-Cotterets, and the tests for conservation and life, still in progress, at the Jardin Colonial at Nogent.

Book VI reproduces the report by M. BERTIN on the colonial forest question and on the steps required for the immediate intensification of the production of colonial timber.

Of the first two volumes, one deals with the Ivory Coast and the other with the Gabon, and both are so presented as to facilitate comparison.

The mission attempted to ascertain which were the commonest trees in tropical forests and which of these could substitute European timber for ordinary uses ; 300 species were studied out of some 800 and submitted to practical tests for resistance to bending, resistance to elongation and splitting, and the resistance of assembled pieces. Only some 40 trees were retained in each of the two colonies, and it apparently was not possible to reduce this number. A profitable industrial enterprise requiring the installation of costly means of transport, is obliged to exploit numerous trees contained in a restricted area, a condition that cannot be realised in tropical stands, mixtures of varied trees, unless a fairly large number of different species utilised. The species in question constitute about two thirds of the population.

M. BERTIN's report has the aim of making known these trees and the technical properties as much to traders and to industrialists that utilise timber as to foresters and those who exploit tropical forests. A vocabulary of the usual woods of the colony is given for the timbers retained after examination ; the names have been borrowed from the native languages, the most common and easily pronounceable having been chosen from the various names, whilst attempting to retain the names already given by exploiters or known in the European trade. The vocabulary gives for each tree its scientific name, the vulgar name suggested, and the name in the various dialects. The terminology thus proposed has been submitted to the Governors of the interested colonies and approved by the Ministry for the Colonies.

In the second chapter lists are given of the timbers that could replace the common European woods for most ordinary uses and of the timbers suitable for special purposes. The first list comprises 27 trees from Gabon and 17 from the Ivory Coast, and the second 22 from Gabon, and 17 from the Ivory Coast. The lists give the ordinary, scientific and local names, possible uses, similarities with the fine timbers used in Europe, and the minimum girth at which the tree can be exploited. The last mentioned detail is to ensure the conservation of the forests and to prevent the felling of trees that are too young.

The timbers are grouped according to quality in 3 classes :—

(1) Inferior whitewoods, that can replace inferior poplar, chestnut, etc.

(2) Superior whitewoods, than can replace choice poplar, pine, etc.

(3) Hardwoods that can replace oak.

When there is occasion to do so, the accessory products such as fruits, seeds, latex, bark, etc., that each tree may produce are indicated.

The physical properties of the timbers are described in a third chapter,

which gives general information as to appearance, grain, density, hardness, working qualities, and the behaviour of cut timber.

Each volume concludes with a list of local names to enable the trees to be identified and with an alphabetic list of the scientific names with references to the usual names.

The work is illustrated with photographs of various aspects of the tropical forest, of exploitation, and of transportation.

The practical results of the mission will doubtless considerably influence the question of colonial timber, on the solution of which the economic future of France depends to a large extent. In the book in question, besides the results of examining the colonial timbers, which are thus placed before the public, there is a mass of statistical, economic and commercial information on the production of timber in France and the colonies, and information on the technical properties of woods, the collection of which in a single volume will be of value to all those interested in the exploitation of forests and the utilisation of timber and in trade.

LIVE STOCK AND BREEDING

667 – **Identification of the Trypanosomes of the Italian Colony of Eritrea.** — PRICOLO, A and FERRARO G., in *La Clinica veterinaria, Rassegna di Polizia veterinaria ed Igiene*, Year. XLIII, No. 4, pp. 111-123. Milan, Feb. 29, 1920. HYGIENE

A critical summary of previous investigations on the trypanosomes of African animals and a description of researches carried out by the authors in Erythrea. The following conclusions were arrived at:—

The presence of two trypanosomes in the Italian colony of Eritrea is demonstrated; these are *T. Evansi* of the camel and horse and *T. vivax uniforme* of cattle.

It has not been demonstrated that *T. Evansi* is found in cattle in a natural state, nor that *T. vivax uniforme* occurs in camels and horses. The camel was refractary to *T. vivax-uniforme* under experimental conditions.

668 – **The Fowl Tick and its Riddance from Hen-Houses** (1). — BISHOPP, F. C., in the *U. S. Department of Agriculture, Bureau of Entomology, Circular No.* 170, pp. 14, figs. 9. Washington, December, 1919.

The fowl tick (*Argas miniatus*, syn. *A. persicus*) is extremely widely distributed; it is an important pest of poultry in Rumania, Southern Russia, Persia, India, North Africa, South Africa, Australia, Brazil, British Guiana, Panama, West Indies, Mexico and the United States (2). It is a serious pest in the last-named country and causes losses estimated at millions of dollars annually. It is specially abundant in the warm areas

(1) For further information on the fowl tick and the diseases it may propagate, see *R.* 1913, Nos. 42 and 823; *R.*, 1916, No. 318; regarding ecto-parasites of poultry in genera see *R.*, 1915, No. 1313; *R.*, 1917, No. 830; *R.*, 1918, No. 779; *R.*, 1919, No. 496; *R.*, 1920 Nos. 338 and 339.

(2) In Europe, the most important tick of poultry is *Argas reflexus*, but it appears to be rare in England and Germany, whilst it is common in France and Italy. — PESCE, A., Diseases of Fowls, p. 248, Milan, Hoepli, 1912. (*Ed.*)

of the arid and semi-arid region, *viz.*, Western Texas, the south of New Mexico and Arizona, and Western California. It has also been reported in Florida and Iowa, but it will probably never become of continuous importance as a parasite in the states to the east of Texas, owing to the damp climate.

Although fowls are the host most frequently attacked. *A. miniatus* also attacks ducks, geese, turkeys, ostriches, pigeons canaries, and wild birds. It has been recorded as an occasional parasite of cattle and horses, and, in experimental cages, it has attacked rabbits and other small rodents, though it does not appear to attack rats and mice under natural conditions. It is said that, in certain countries, especially Persia, the tick attacks man, causing serious disturbances, but there is no authentic record of such a case in the United States. It may cause the death of fowls directly through exhaustion and by continual irritation or indirectly by transmitting spirochetosis. It may cause other losses by decreasing the vitality of the fowls, by rendering them more liable to contract disease, by seriously diminishing the capacity for laying eggs, by disturbing sitting hens and by causing pullets to grow more slowly.

The eggs of *Argas miniatus* hatch in from 10 to 100 days. The larvae, furnished with 3 paired appendages, attach themselves to a chicken and feed on its blood for from 3 ½ to 10 days, then they fall to the ground, particularly at night time and hide in some crevice. In 4 to 7 days, the larva becomes a nymph, with 4 pairs of appendages and again attaches itself to a host, gorges itself with blood in a few hours, drops off and hides. The nymph moults after each of the 3 meals of blood, and the sexual organs appear after the last moult. After a fresh meal of blood, the female is ready to lay, and can lay 8 separate times, each laying being followed by a fresh meal of blood. Each female lays from 500 to 900 eggs. The tick can complete its life cycle in about 40 days, but the number of generations in a year has not been determined ; there are, however, probably six in the southern part of its zone of distribution.

The tick has remarkably few enemies ; the small black ant (*Monomorium minutum*) and certain spiders that live in houses destroy its eggs and larvae, whilst rats and mice also destroy them. Fowls eat ticks greedily, but the ticks are largely protected by their habit of hiding during the day and coming out for food at night.

Regarding preventive measures, any fowls from another hen-house must be rigorously quarantined before allowing them to mix with poultry free from the parasite. If the hen-house is not of much value, it should be burnt ; in other cases, any unnecessary boxes, planks, etc., that might shelter ticks should be removed and the hen-house sprinkled with pure kerosene, crude petroleum, carbolineum, milk of lime containing carbolic acid, a strong kerosene emulsion, boiling water, or with a fluid used to destroy ticks on cattle (1).

(1) See *R.*, 1911, Nos. 2198, 2425, 1753 ; *R.*, 1912, Nos. 146, 359, 810, 934 ; *R.*, 1913, Nos. 42, 43, 691, 815, 1264 ; *R.*, 1914, No. 1019 ; *R.* 1915, No. 1170 ; *R.*, 1918, Nos. 541 and 1376. (*Ed.*)

Boiling tar should be used to fill up the cracks and kill any ticks hidden them. The fowl tick, however, is a parasite which is most difficult o destroy, insecticidal powders and fumigations with hydrocyanic acid eing quite useless.

The fowls can be cleared of the ticks on their bodies by dipping them gasoline, but this treatment is too hard on the fowls to be recommended. simple and cheap method of prevention consists in hanging the roosts om the roof with wires, in such a way that the fowls do not come in con- act with the sides of the hen-house ; the roosts should be quite smooth nd free from bark and cracks.

Applications of insecticides also destroy chicken mites (*Dermanyssus allinae*) and chicken fleas (*Echidnophaga gallinacea*). The fowl tick can e kept away from the hen-house by means of scrupulous cleanliness and onstant attention. In Texas, the pest has been avoided by using all- netal hen-houses, made of corrugated iron. Such hen-houses, however, annot be used in hot climates as they are not cool enough. Nesting- oxes that are easily cleaned are very useful ; those consisting of wire auze on which the straw is placed can easily be freed of parasites by assing the wire basket through a flame. Metal boxes, through which cks cannot pass, placed on legs standing in saucers filled with kerosene ould also be used.

69 – **The Tropical Fowl Mite (*Liponyssus bursa*) in the U. S. A.; Biology and Control.** Wood, H. P., in the *United States Department of Agriculture, Department Circular* 79, pp. 8, figs. 2. Washington, Jan., 1920.

Up to the present, two cases of infection by the tropical fowl mite *Liponyssus bursa*) have been recorded, one from Madison, one from Illi- ois (at Raymond). The risks that this fowl ectoparasite may become stablished in the United States has made it necessary to study its biology nd means of control, the work being carried out by the author at Raymond ll. Mr. H. Hirst, of the British Museum (Natural History), has recorded *L. bursa* for Africa, China, India, Mauritius, the Comoros Islands, the Bahama Islands, South America, countries where the ordinary fowl mite *Dermanyssus gallinae*)) does not occur. Apparently, *L. bursa* transmits pirochetosis and, besides fowls, it attacks wild birds (particularly spar- ows) and, so it is said, man. On the contrary to *Dermanyssus gallinae*, t attacks its host both day and night.

The author found, in the course of his work, that *L. bursa* lays its ggs either on its host or in the nest. Many of the eggs are stuck to the asal, softer portion of the feather by a sticky material. The eggs, ob- served away from the host, hatch in 3 days. The tiny larva does not feed t first, but it moults in about 17 hours, after which it is ready to suck lood. The nymph resulting from the first moult again moults in 102 hours, fter which its history is uncertain.

The most effective remedies are :— (1) A bath containing sulphur 150 gm., soap 75 gm., and water 10 litres ; (2) dusting sulphur and pyre- thrum under the feathers ; (3) bath composed of a teaspoonful of 40 %

nicotine sulphate in 4 litres of water containing about 10 gm: of soap. At Raymond, these treatments were followed by thorugh cleansing and disinfection of the hen-houses, etc., and finally the fowls were carefully dusted with sulphur and exposed to the rain. No ill effects were noticed after the treatment and the author considers that this curative method, combined with a continual war against sparrows, which harbour the same parasite, would completely suppress the present infestation.

ANATOMY AND PHYSIOLOGY

670 – **Variations and Mode of Secretion of Milk Solids.** — GOWEN, J. W., in the *Journal of Agricultural Research*, Vol. XVI, No. 3, pp. 79-102, bibliography of 40 works. Washington. D. C. Jan. 20, 1919.

Work carried out in the Biological Laboratory of the Maine Agricultural Experiment Station, utilising data from the registers of the Holstein-Friesian Association and relating to pure-bred Holstein-Friesian cows.

The author gives the means deviations and the variation coefficients of the annual registrations. The mean annual production of cows at a mean age of 4 years was 15417 lb., of milk, 528 lb. of butter fat and 1303 lb. of solids not fat. The standard deviations were 3742 lb. of milk, 134 lb. of butter fat and 260 lb. of solids not fat (at 2 years) and the coefficients of variation were, respectively, 24, 25, 20, and 50 %. In a table, reproduced herewith, Holstein-Friesian milk is compared with that of other breeds, and in another table comparison is made with that of other species. The author then considers the correlations that exist between the following variables :— Per cent. of butter fat and quantity of milk produced ; per cent. of butter fat and age ; per cent. of solids not fat and quantity of milk produced ; per cent. of solids not fat, and age. From these correlations the following conclusions were drawn :—

(1) With the increase of the quantity of milk produced, the percentage of fat in that milk decreases. The value of this decrease, measured statistically, is very significant, but, in practice, the decrease in fat content would be discerned with difficulty in small samples.

(2) The correlation between the age and the butter fat content is not significant.

(3) The correlation between the quantity of milk produced and the percentage of solids not fat is not significant ; in other words, the quantity of milk produced in one year is independant of the concentration of the solids not fat. From the genetic point of view, this fact signifies that the hereditary factors for high or low milk yield are separate and distinct from those which determine a high percentage of solids not fat.

(4) The correlation between the age and the solids not fat is -0.2191 ± 0.0351, that is, with increasing age of the cow, the percentage of solids not fat decreases.

(5) All the regressions are linear, i. e., they take place uniformly.

(6) There are thus two variables that have a divergent influence on the concentration of butter fat and solids not fat. This difference in action proves that the fat and solids not fat cannot be derived from a single chemical compound.

The author also gives the correlations that exist between the variables :— Weight of milk, butter fat, solids not fat

Average of the constituents of the milk of various breeds of cattle.

Breeds	Total solids. Per cent.	Fat. Per cent.	Solids not fat. Per cent.	Ratio of solids not fat to butter fat.

* This percentage is less than the real one as the average content of the milk of 4 900 Guernsey cows was 4.9 % of fat.

All the variables are in a close correlation, which ranges from $r = 0.8644 \pm 0.0093$ to $r = 0.9497 \pm 0.0036$. The regressions are linear in every case. The partial correlation between the butter fat and the solids not fat for a constant value of the milk is 0.5635 ± 0.0252. This correlation, with those quoted above, provides the necessary data for establishing the conclusion that certain of the factors on which high fat content depends are also responsible for the high concentration for some of the solids not fat in cow's milk. From this correlation can be deduced the important practical conclusion that if, in a given herd, the concentration of fat or of solids not fat is improved, the increase of one of these constituents will also lead to a concomitant increase of the other.

In conclusion, the author gives a series of data showing the diurnal variation in the composition of cow's milk, from which it is seen that the morning milk contains an average of 0.678 to 0.723 % less butter fat than evening milk, there being no appreciable difference between the morning and evening milk as regards solids not fat. These data furnish criteria for choosing between the theories advanced to explain the secretion of the milk solids. According to the theories which postulate that the milk solids are derived from cellular disintegration, the cell must contain a fixed amount of solids not fat. The butter fat, however, varies in such a way that, in long intervals between milking, the cell accumulates less fat than in shorter intervals ; that is, the cell contains relatively more protein and sugar than fat if the interval between milking is prolonged. This does not agree with what is known as to the formation of the fat, because it is generally admitted that the cells, composed mainly of protoplasm, are formed first, and that, with time, the cell becomes more and more charged with fat at the expense of the protoplasm. Unless these mammary cells behave in an entirely different way from the other cells of the organism, the variation in the fat content with the variation of the interval between milking should suffice to discredit the hypothesis of cell disintegration and make it quite unacceptable. On the contrary, in as far as regards the variations of the secretory glands, the variations in the milk correspond quite well with the hypothesis that its solids are the products of secretion.

FEEDS AND FEEDING

671 – **Tea Leaves as a Feeding Stuff.** — ARUCH, E., in *L'Italia agricola*, Year 57, No. 1, pp. 17-19. Piacenza, January, 15, 1920.

The composition of tea varies according to its quality, origin, manner of drying and fermentation, etc., but it is always rich in nitrogenous matter, varying from 18 to 38 %, tannin (10 to 18 %), and water-soluble matter, which varies from 34 to 44 % for black teas and 39 to 43 % for green teas. The following percentages are given by KÖNIG (*Lehrbuch der Nahrungs: mittelchemie*, Leipzig, 1913), as an average of 70 analyses, and by VILLAVECCHIA (*Dizionario di Merceologia*) :—

KÖNIG	Per cent.	VILLAVECCHIA	Per cent.
Moisture	3.9 to 16.2	Moisture	9.50
Nitrogen	2.5 to 6.	Nitrogenous matter	24.50
Caffein	0.9 to 4.5	Caffein	3.58
Essential oil	0.5 to 1	Essential, oil, fats, resins, chlorophyll	6.30
Fat, chlorophyll, wax	0.5 to 10	Gum, dextrin	6.44
Crude fibre	9.9 to 15.7	Tannin	15.65
Ash	3.8 to 8.4	Peptic matter	16.02
Water-soluble matter	2.4 to 40	Ligneous matter	11.58
		Mineral matter	5.65

Tea leaves have lost practically all their tannin and caffein, but retain most of their protein.

Samples of black tea examined by the author and Dr. PULZONI were found to contain 2.10 % of caffein before infusion and 0.129 % after infusion. A sample of black tea, examined by Dr. L. BELLUCCI, contained, on a dry-matter basis, 37.95 % of nitrogenous matter before infusion, after which it had lost 12.95 %. In addition, tea leaves retain part of their fat and dextrin, and have thus a certain food value.

The author, using rabbits, found that dried and powdered tea leaves could replace quite well a third, or one half, or even the whole of the ration of meal and bran, and give satisfactory increases of weight. The rabbits liked the new food, which would probably be eaten by other domestic animals.

Tea leaves might constitute an important by-product for certain countries, as is indicated by the following figures from the *Atlas of the World's Commerce*, showing the annual consumption of tea, in metric tons, in various countries : — England, 115 600 ; United States, 36 900 ; Russia, 57 900 ; Holland, 3600 ; Germany, 3100. In Italy, however, the annual consumption only amounts to 200 metric tons.

672 - **Castor Cake as a Cattle Food.** — TRIVELLONI, in the *Rivista di Ampelografia*, Year 1, No. 4, p. 59. Alba-Livorno, Feb. 15, 1920.

Up to the present, castor cake has only been used as a fertiliser, as it is poisonous to stock. But Dr. TRIVELLONI has carried out a series of experiments (at the Agricultural Chemistry laboratory of the R. Scuola Superiore of Milan) which have shown that castor cake becomes harmless when heated to at least 115°C. for 90 minutes. In practice, stoving can be replaced by a slight roasting which is more certain to destroy the poisonous principle in the castor cake.

673 - **Fattening Steers on Summer Pasturage in Alabama and Mississippi, U. S. A.** — WARD, W. F., GRAY, D. T. and LLOYD, E. R., in the *U. S. Dept. of Agriculture, Bulletin* No. 777, pp. 24. Washington, July 10, 1919. CATTLE

The Bureau of Animal Industry of the United States Department of Agriculture has carried out experiments on fattening steers on pasture, collaborating with the Alabama Agricultural Station since 1908 and with the Mississippi Agricultural Station since 1915.

Results reported refer to 4 different experiments, 2 in Alabama (in 1912 and 1913, respectively), 2 in Mississippi (in 1915 and 1916, respectively), and concludes with a summary of the results obtained during the four years. The most important data are reproduced in the appended Table.

On comparing the averages of the 3 methods of fattening, it will be seen that there was but a small difference in the average length of the periods of feeding and pasturing.

The average increases in live weight per head per day, which are probably the best data to use in judging the efficiency of the rations, were :— 1.49 lb., for steers on pasture only; 1.83 lb., for steers which, besides pasture, were given cottonseed cake ; 1.53 lb., for steers which received supplementary pasture with a mixture of cottonseed cake and maize meal.

The initial cost of the steers per 100 lb., was the same for each of the 3 groups respectively, in each of the years of the experiment, but in every case the steers in Group I (pasture alone) were sold at the end of the trial at a lower unit price. The difference between the unit prices for the sale of the fattened steers and the purchase of steers for fattening was always in favour of those that received supplementary foods in addition to pasture. This difference was, on an average, 24 1/2 cents per cwt. for Group I, 90 cents per cwt. for Group II, and 81 1/2 cent. for Group III.

The data on the yield on slaughtering are incomplete, but they suffice to show that steers receiving, in addition to pasturage, cottonseed cake or a mixture of this and maize meal gave higher percentage yields on slaughtering than those which had pasturage only.

The steers in Group I (pasture only) made an average profit of $5.78 per head, against $6.23 for those receiving pasture plus cake, and $6.48 for those that had pasture plus cotton cake plus maize. The average profit made by the group that received cotton cake as a supplement would have been much higher had not the average been reduced by the loss that occurred in 1916; the poor result in that year was due to various circumstances and to the use of steers of low value.

Valuable information can be extracted from the appended Table, which shows that the steers in Group I gave a very cheap gain in live weight, the total gains, however, being low, whilst the steers were not highly finished. This lack of finish resulted in a lower unit sale price and a lower percentage yield on slaughtering, so that the gain made by this group was less than that made by the other groups.

The steers in Group II gained weight more rapidly than those in Group I, but the gain cost more. They attained a better finish, however, gave a greater percentage yield on slaughtering, and were sold at a higher unit price, thus compensating for the rather high cost of producing a unit of gain in live weight and leaving more profit per head than the steers in Group I.

Group III only contained two sub-groups of steers, one of which received besides pasture and cottonseed cake, maize meal, whereas the other was given cob meal; the results are not as conclusive as those given by the first two groups. However, they show that replacing half the ration of cottonseed cake by an equal weight of cob meal gave a smaller gain in live weight at a higher cost. But the steers in this group increased in weight more rapidly, attained a better finish and a higher price, as well as leaving a wider margin of profit per head than those of Group I. On an average, the gain per head was greater for Group III than for the other 2 groups, but, in 1912 and 1913, Group II surpassed Group III in this respect.

CONCLUSIONS. — The use of cottonseed cake as a supplement to summer pasture in the southern United States results in a quicker gain in live weight in steers, and these finish off better and more rapidly. On account of their higher finish, steers fed also on cottonseed cake sell at a higher price per unit than those fed on grass alone. The difference between the price

per unit of live weight of the fattened animal and the animal before fattening is nearly always increased when the pasture is supplemented with cottonseed cake or with cottonseed cake plus maize meal.

Steers that are not of selected quality may yield a higher profit when fed on pasture alone than when given supplementary foods as well as pasture, especially if kept on good pastures that are not expensive.

The cost of increasing the unit of live weight of steers on pasture becomes much higher when cottonseed cake is fed, but the higher price fetched by steers thus fattened compensates for the increase in cost due to the cake and leaves a higher average profit than that yielded by steers fed solely on pasture.

The substitution by maize meal of half the supplementary ration of cottonseed cake given to steers on pasture gave an increased live weight and a finish comparable to that given by cake alone ; but if maize meal does not cost less than cottonseed cake, it should not be used as a substitute. A mixture of equal parts of cake and cob meal, as a supplementary ration for steers on pasture, is less effective in producing the unit increase in live weight than cake alone or a mixture of maize meal and cake. When maize is cheap, it should preferably be given as grains or maize flour rather than as whole cobs.

When animals on pasture are given cake, the pasture utilises a large quantity of fertilising material that passes into the dung.

One of the distinct advantages of supplementing the pasture with concentrated foods is that the animals thus treated finish more rapidly and can be sold sooner than steers fed solely on pasture ; i. e., they can be sold before so many are placed on sale that the market price is affected. Moreover, when stock is sold quickly, the pastures have time to recover and will furnish good pasturage for other cattle in the autumn.

Steers of inferior quality do not respond quickly to the use of choice foods and, even if well fattened, do not fetch as high a price as well-bred animals of the same degree of fattening. Again well-bred or pure-bred cattle make better use of the food, fatten more quickly and always fetch better prices than inferior animals of the same weight. The better the quality of cattle, the more they should be given high-priced foods.

When bulky foods such as silage, hay, straw, cotton pods, etc., are available and when steers are to be fattened on summer pasture, it is advisable to buy the animals in autumn and winter them on roughage plus a little cotton cake rather than buy them in spring for fattening during the grazing season.

674 – **Winter Feeding of Cattle in Montana, U. S. A.** — ARNETT, C. N., in the *University of Montana Agricultural Experiment Station, Bozeman, Montana, Circular* 85, pp. 7. Bozeman, August, 1919.

In 1916-17, 1917-18, and 1918-19, the Montana Agricultural Experiment Station carried out experiments on the winter feeding of adult cattle ; the winter was very short and mild in the third period. The experimental animals were full-blooded descendants of Shorthorns and Herefords. They were kept on pasture during summer and on stubble during autumn. In the winter they were protected from the weather and thus required less food for maitenance. In addition a salt lick and relatively lukewarm drinking water were always available. The average results of the three winters are given, those of the first two being kept separate from those of the third.

CONCLUSIONS. — Cheap roughage such as straw can be used to advantage in wintering breeding beef stock. In mild winters and when the animals have a fair amount of flesh by autumn, straw may constitute the sole food during wintering. A ration of straw supplemented with 5 lb., of hay per head per day will enable good, strong animals that are not milk-

ing to pass the winter in good condition. The difference in condition at the end of winter between animals that were given a supplement of 5 lb., of hay and those that received double this amount was not sufficient to justify feeding the larger quantity of hay.

Results of hibernating cows on different rations.

Ration per head	Duration of experiment, (days)	No. of head	Average initial weight, in lb.	Average final weight, in lb.	Average loss per head in lb.
Averages of the winters 1916-1917 *and* 1917-1918.					
Straw alone	155	24	1229	1035	194
Straw + 5 lb. hay	155	24	1229	1134	95
Straw + 10 lb. hay	155	24	1229	1166	58
Winter 1918-1919.					
Straw alone	132	12	1132	1066	66
Straw + 5 lb. hay	132	12	1155	1143	12
Straw + lb. cottonseed cake	132	12	1146	1136	10

In the 1918-19 experiment, lb., of cottonseed cake was found to be roughly equivalent to 5 lb., of a good mixed alfalfa and timothy hay as a supplement to oat and barley straw in wintering breeding beef stock. The cattle that were given cottonseed cake as a supplement consumed relatively more straw than those that received hay as a supplement.

675 - **Experiments on the Feeding of Draught Oxen, in the Philippines.**—Lago, F. P., in *The Philippine Agriculturalist*, Vol. VIII, No. 3, pp. 79-91. Los Baños, Oct., 1919.

The experiments, carried out at the College of Agriculture, Los Baños, lasted two years and had the aim of ascertaining the foods best suited as supplements to the pastures in the Philippines for draught oxen. The oxen used in the experiment belonged to the Chinese, Indo-Chinese, and native breeds, their ages varied from 6 to 13 years, and they weighed about 375 kg. The native pastures contain the following species :— *Imperata cylindrica, Paspalum conjugatum, Saccharum spontaneum, Andropogon halepensis, Rottboellia exaltata, Mimosa pudica, Panicum* spp., *Cynodon dactylon, Leucaena glauca, Digitaria consanguinea,* and *Dromodium triflorum.*

Five experiments were carried out :— (1) Comparison between pasture alone and pasture supplemented with maize cobs ; (2) Comparison between pasture supplemented with sugar-cane tops and pasture supplemented with maize forage ; (3) omparison between native pasture supplemented with Guinea grass (*Panicum altissimum*) on the one hand, and pasture with maize forage on the other ; (4) Comparison between native pasture supplemented with Japanese cane and pasture with maize forage ; (5) Comparison between Japanese-cane and maize forage. The results of these experiments are summarised in the following table :—

Comparison between supplementary rations given to oxen on pasture.

* Grain.

The author has concluded from these results that feeding maize cobs in quantities corresponding to 0.2, 0.3 and up to 0.5 kg. of maize per day to draught oxen weighing about 375 kg., had no particular advantage as a supplement to natural pasturage (the supplement was only given when the oxen were working). It is possible that the small differences in favour of the group which was given maize might have been due to insufficiency of the pasture and that the animals given no supplementary ration might not have been given sufficient food.

Maize forage was a better supplement than sugar cane, the difference being mainly due to the relative tenderness of the maize, as this enables the animal to make a complete meal of it. The sugar-cane tops, although palatable, were so hard that the animals could not consume enough to make a complete meal.

Guinea grass was slightly better than maize forage as a supplement to pasture.

Maize forage was better than Japanese cane (entire plants were used which were, at the beginning of the experiment, 75 cm. high) as a supplementary food. One group of oxen was given Japanese cane exclusively for 26 days and another group was given maize forage exclusively ; both groups gained slightly in weight, the latter a little more than the former.

The author bases the following advice on these facts :— (1) When the grass of the natural pasture is abundant and succulent and when the animals have sufficient time for eating and resting, a supplement need not be given ; (2) animals doing hard work must be given supplementary foods if they are not left long at pasture ; these foods may be maize forage, Guinea grass, or sugar-cane tops ; maize forage being preferable because it supplies more assimilable food ; Japanese cane should be reserved for the dry season, during which it remains green and juicy ; (3) maize for use as forage should be sown somewhat thickly. This develops finèr and smaller stalked plants, softer in texture, with few or no cobs, whilst the food materials are more evenly distributed throughout the plant.

676 - **Pig Feeding Experiments with Various Fodder Plants, in Montana, U. S. A.** — ARNETT, C. N. and JOSEPH W. E., in : — I. *University of Montana, Agricultural Experiment Station, Bulletin* No. 128, pp. 61-106, figs. 7. Bozeman, Feb., 1919. — II. *Circular* 83, Jan., 1919. PIGS

The Bulletin 128, of which the circular is largely a summary, consists of two parts, the first of which deals with the economic utility of feeding different amounts of grain to weaned piglets put out to pasture. The following experiments are described :— (1) Comparisons of rations consisting respectively of 1,2 and 3 lb. of barley per 100 lb. of ground live weight given to piglets put out to pasture on alfalfa during 104 days of the year ; (2) a similar comparison with 29 piglets during 178 days in 1915, followed by a complementary period with barley, feed wheat, and tankage (75 : 25 : 8) until each one had attained an average weight of 200 lb. ; (3) comparison between a ration without grain, the barley being given in a pig feeder, and rations of 1, 2, and 3 lb. of barley per 100 lb. of live weight given to 42 piglets pastured on red clover for 90 days in 1916, followed by a transition period of 30 days with pasture and a complete barley ration, and a complementary period without pasture and with barley and tankage in the ratio 25 : 2 ; (4) a similar comparison with 43 piglets in 1917, a year in which the pasture season lasted 110 days and the transitional period 20 days; (5) comparison between a ration of 1 lb. of barley per 100 lb. of live weight and a ration of lb. per cwt. of barley per head per day, made with 18 piglets at pasture on clover for 90 days in 1918, followed by a transition period of 20 days and a complementary period. In the second part of the Bulletin comparisons are made between various forage plants for weaned piglets which were also given barley at the rate of 2 lb. per 100 lb., of live weight ; the comparisons were :— (1) Between rape or barley, or rape with oats, or oats ; 28 pigs were used in the experiments in 1915 ; (2) between red clover or sweet clover pasture or rape ; these experiments were carried out in 1917 with 33 pigs.

In another experiment carried out in 1918, the pigs were kept in a meadow consisting of meadow-grass and white clover, and given 1lb., of barley per head per day. The results, given in Tables I and II permit of the appended conclusions.

Alfalfa pasture is better for young pigs than red clover pasture ; it was the only satisfactory annual fodder plant out of all those tested. When 1 lb. of barley is given with tankage as part of the supplementary ration, the best economic results are obtained.

TABLE I. — *Results of feeding different amounts of barley to weaned pigs at pasture on alfalfa* (137 *days*) *and clover* (100) *days.*

Clover pasture :							
Without grain	16	103	0.81	3.29	0.24	$11.45	$2.18
1 lb. per 100 lb. live weight . .	19	101	0.84	3.32	0.22	11.39	2.59
2 lb. per 100 lb. » » . .	21	95	0.88	3.48	0.20	11.67	2.01
3 lb. per 100 lb. » » . .	25	81	0.94	3.57	0.16	11.76	1.80
Self-fed	30	70	1.01	3.87	0.12	12.41	0.82

Favourable results were obtained by giving 1lb. of barley per head per day and, although the pig is small, this quantity is sufficient. The average of two experiments with alfalfa pasture (neglecting the complementary period) and the averages of two experiments with red clover pasture are given in table I.

In working out the costs, the following prices (taking the *dollar* at par) were used :— Barley, $3 per cwt. ; tankage, $2.75 per cwt. alfalfa pasture, $20 per cwt, initial cost; clover pasture, $25 per acre in 1916 and $20 per acre in 1917 ; initial cost of pigs, $20 per 100 lb. of live weight ; cost at end of pasture season $13 per 100 lb. cost at end of complementary period, $14 per 100 lb.

Table II gives the averages of the results of the two experiments with rape pasture and those of the experiments carried out in 1915 with pasturage on barley, oats, rape associated with oats. The receipts are

ıll calculated on the basis of the increase in live weight of the pigs, which was taken at 148.52 fr. per quintal.

TABLE II. — *Comparison between different pasturages for weaned piglets also receiving 2 lb. of ground barley per 100 lb. of live weight.*

Pasture	Pigs per acre	Duration of pasturage,	Average increase in weight per head per day	Barley consumed per lb. of increase in live weight,	Cost of forage and pasture required for 100 lb. gain	Cost of pasture	Returns per lot	Profit per head

677 – **Influence of Feeding Ducks with Rice and Maize on their Growth and Egg-Production.** — ALCASID, E. E., in *The Philippine Agriculturist*, Vol. VII, No. 8, pp. 255-266. Los Baños, March, 1919. POULTRY

All the domestic breeds of ducks are considered to be derived from the wild Mallard, *Anas boscas*. It is believed that the domestic duck of the Philippines is of Chinese origin and has been introduced comparatively recently by Chinese immigrants. Generally speaking, the Philippines offer favourable conditions for breeding ducks, and, at certain places, e. g. at Pateros (Luzón) and district, duck breeding is a well established industry.

The author has examined : — (1) The effect of various foods on the growth and egg-production of the duck ; (2) the effect of castrating the drake and the reaction of the castrated drake to various qualities of food ; (3) the possibility of rearing ducks in places where a pond to swim in and abundant animal food are not available.

In the Philippines, natural incubation, by means of hens, is used and it is believed that the ducklings hatched out in this way are stronger. Artificial incubation would give equally good results, but it would have to be in charge of competent persons.

Experiment I. — A group of 9 ducklings aged 67 days was fed on a mixture of 3 parts of rice meal + 2 parts of rice bran + 135 gm. of snails per day ; in a second group of 9 ducklings, of the same age, the rice meal was replaced by an equal weight of maize meal. Three meals a day were given during the first 41 days of the experiment and, during the remaining 83, two meals were given, the weight of snails being increased to 200 gm. per day. At the beginning of the experiment, the average weight per head of Group I was 392.44 gm. ; the weight at the end of the experiment, which lasted 32 weeks, was 1024.87 gm., the average gain per head per week being 23.84 gm. In the second group, these figures were, respectively, 426.55 gm., 1080,00 gm., and 23.91 gm. There was thus hardly

any difference between the two groups in respect of the quickness of growth.

The age at which the ducks in Group I laid the first egg was:— Maximum, 193 days; minimum, 189; average, 191; fur the second group the ages were, respectively, 207, 191, and 199. These ducks were hatched on February 2, i. e., in the rainy season, which is considered to be unfavourable for the growth of the duck. According to breeders in the Philippines, well-kept ducks lay their first egg, that is, attain sexual maturity, in the fourth month; if not treated properly; however, this may be delayed until the ninth or tenth month.

During the first laying period (August to February), three ducks in the first group laid in all 78 eggs of an average weight of 50.50 gm., and 3 ducks in the second group laid 39 eggs of an average weight of 52.34 gm. As regards the number of eggs laid, feeding with rice meal was clearly superior to feeding with maize meal.

Experiment II. — This was a repetition of Experiment I, with the difference that the ducklings were only 14 days old at the beginning of the experiment; the results, which confirm the first ones, are therefore more pronounced for the various groups. During their first 12 weeks of life, the ducklings in Group I (fed on rice meal and rice bran) made an average gain in weight of 17.72 gm. per week per head. From the 13th to 45th week, the average gains per week per head were, respectively, 26.33 gm. and 14.52 gm. For this second period, a third group was also formed, half of it being ducks from Group I, and half from Group II; besides rice bran, maize meal and rice in equal parts were fed. The third group made an average weekly gain in weight of 19.01 gm. per head. Sexual maturity was attained in 215, 298, and 287 days for each of the three groups, respectively.

The nature of the food had a marked effect on the colour and taste of the eggs. Ducks fed on rice meal and rice bran laid eggs, of a clear yellow colour, whilst those fed on maize meal and rice bran laid eggs with yolks that became of a dark orange colour when fried and a light orange when boiled. The eggs of ducks fed on rice meal and rice bran had a slightly greenish shell and had a somewhat putrid flavour when cooked; those of ducks fed on maize meal and rice bran mostly had a white shell and had a normal flavour when cooked.

The ducks which had a pond at their disposal laid eggs with a higher degree of fertility than those of ducks that had no pond; the first method is thus preferable for eggs that are to be incubated.

678 – **Ostrich Rearing in Sardinia.** — Ottolini, R., in *Bassa Corte* (1), Year 1, Part. 3 pp. 109-112, figs. 4. Piacenza, Feb. 5, 1920.

An ostrich farm has been established at Baccarasa (in the Tortoli district, province of Cagliari), a locality situated to east of the Tortoli

(1) According to the first number published (Jan. 5, 1920) of the periodical, *Bassa Corte*, the object of this publication is to further the rearing of farm animals such as pigs, sheep, etc., as well as the smaller agricultural industries, so as to help to increase the production of

Arbatase railway, in a wide plain bounded on one side by the sea and on the other by the Ogliastra mountains. The site, covering some 50 hectares, consists mainly of a deep, very permeable, sandy soil, covered with bushes of rock-roses and cork oaks. The birds are kept in enclosures in pairs or in groups, according to their age and the temperature. The enclosures are made by stretching iron wires 30 cm. apart on reeds planted vertically every 25 cm., and on juniper stakes spaces 3 cm. apart. The height of the fence is about 2.5 metres and the enclosure has an area of 30 × 80 m. for pairs and more for groups. The enclosures are separated by paths planted with trees and oach enclosure is provided with a house where the birds can shelter during bad weather and lay their eggs.

The houses are divided into two parts by a temporary partition; one part has a concrete floor, and the other is covered with a thick layer of sand in which the birds can dig a hole 50 or 60 cm. deep. The hen lays its eggs and hatches them, helped by the cock, in this second part. The cribs and watering places are placed around and inside the houses. A separate building contains the incubator room and that for rearing the chicks, both rooms being provided with means of heating and outside runs where the chicks can go during the warm hours of the day. The staff includes 3 agricultural labourers and 2 men who prepare and distribute the food. The incubator room and the chicks are looked after by the director's family.

A pair aged at least 2 years is chosen and isolated in an enclosure; the hen begins to lay at about the end of February and continues to lay until the end of June, one hen laying from 12 to 20 eggs in a season. Artificial incubation begins as soon as the first eggs are laid, as the season is still cold and renders natural incubation difficult. Towards the end of May or beginning of June, the eggs are left entirely to the care of the parents, who hatch out the eggs themselves.

About 60 % of the eggs hatch, whether the incubation is natural or artificial, the former having no advantage over the latter, even as regards the strength of the chicks. Incubation lasts between 40 and 45 days. The most difficult period is that following on hatching, after which the ostriches are not subject to any disease, even of an infectious nature. They are affected by sudden changes in temperature, however, and they are consequently kept in their houses on rainy days or nights. They rarely suffer from indigestion, except when the temperature drops suddenly; the remedy consists in administering purgatives, particularly sulphate of magnesia dissolved in water.

The food varies according to the age, season, breeding and brooding time. The first meal is given 5 days after hatching, and consists of a mash of chopped raw meat, bone powder, and lucerne. The meat is gradually

meat in Italy. The following subjects will be dealt with in the periodical :— Economic problems of rearing; pig breeding; sheep breeding; rabbit breeding; poultry keeping; bee keeping; sericulture; hunting dogs; fish breeding; snail breeding; mushroom growing; smaller agricultural industries; review of the chief Italian and foreign periodicals; market reports. (*Ed.*)

replaced by grains (wheat, barley, oats, maize), acorns, beans, chopped ha (especially lucerne), all kinds of grass, fruits of cactus (*Opuntia*), gourd turnips, tubers, mulberry leaves, elm leaves, etc. During brooding an ovulation, a richer and more concentrated ration of forage is given. Dr or green forage must always be chopped up before being fed to the birds The weight on hatching is about 1.5 kg., whilst the adult ostrich weigh about 100 kg., and stands 2.8 to 3 metres high.

At hatching, the plumage on the body is grey and striped in the di rection of the length, with alternate light and dark bands, on the hea and neck. The feathers at first aculeate, have longer vanes at 3 months At one year, the male colours can be distinguished from those of the fe male :— the upper half of the neck and legs loses all the plumage or onl retains a slight down ; the black feathers grow on the body and the whit feathers on the wings and tail. The females retain their grey colou Gathering the feathers can be begun at an age of one year and a few month and is repeated each year in September and October. The method is a follows :— The ostrich is taken by the neck by means of a special iron hook and 2 men hold it taking care to avoid kicks (the only dangerous defenc possessed by the ostrich), whilst another man cuts off the feathers 3-5 cm above the skin ; 3 months after, the stumps are removed without pain b the ostrich itself and a month later, new plumes begin to appear.

The cock furnishes some 40 white and 40 black feathers, and the he an equal number of grey ones. The first feathers that cover the bod are not cut, but are collected when the bird moults. The largest whit feathers are 50-60 cm. long and 20-25 cm. wide, and the tail feathers a about half as long and wide as the wing feathers. The grey feathers c the female are the same length and breadth as the corresponding feathe of the male.

BEE-KEEPING

679 – **Aluminium Honeycombs.** — WESTBROOKE, G. V. (Apiary Instructor, Auckland in *The New Zealand Journal of Agriculture*, Vol. XX, No. 2, pp. 118-119, fig. 1. Wellington, Feb. 20, 1920.

The Horticultural Division of the New Zealand Department of Agri culture has made experimental use in its hives at Tauranga and Ruakura of the aluminium honeycombs now in use in the United States. In Eng gland, thin sheets of aluminium are on sale which can be given the honey comb shape by means of the roller used to stamp the sheets of wax.

The trial in New Zealand showed that the bees at once made use o the metal honeycomb which can serve both as brood chamber and hone store. As a larger proportion of nectar is converted into honey, the yie is greater. It remains to be seen whether the metal honeycomb woul have disadvantages for wintering under a severe climate.

SERICULTURE

680 – **The Improvement of Sericulture in Jugo-Slavia.** — *Bulletin des Soies et des So ries*, Year XLIV, No. 2236, p. 3. Lyons, April 3, 1920.

A conference has been held at the Jugo-Slav Ministry of Agricultu at Belgrade for the improvement of sericulture in Jugo-Slavia. In cons quence of the resolutions passed at the conference, the Commissariat f

olitical economy convened a meeting of the owners of sericultural establishments, i. e., the representatives of the Croat Agricultural Bank and f the Association of Syndicated Serbian Peasants, in order to outline a cheme for the improvement of sericulture in Croatia and Slavonia. After a long discussion, the following resolutions, *inter alia*, were passed:— 1) To make a census of all the mulberry trees in the country ; (2) to plant nulberry trees in meadows ; (3) to enforce the regulations concerning the protection of mulberry trees ; (4) to raise mulberry trees in the horticultural schools ; (5) to buy silkworm eggs ; (6) to establish local commissioners o inspect and direct sericulture, in the place of the present district inspectors ; (6) the organisation of a collaboration with the central administration, which should be established on behalf of whole State and be centred t Novisad ; (8) to ask the expert women workers at Cjevgjelija to instruct he peasant women in the rearing of silkworms ; (9) the foundation of as nany Sericultural Associations as possible ; (10) in the order to be issued egarding this subject by the Ministry of Agriculture, the interests of sericulture in Croatia and Slavonia must be safeguarded.

581 – **The Use of Fertilisers in Rice Fields and Fishing.** — BERNARDI, B., in *Il Giornale di Risicoltura*, Vol. X, No. 2, pp. 24-28. Vercelli, Feb. 29, 1920. FISH-BREEDING

As fishermen have stated more than once that the use of fertilisers on soil leads to a diminution of the fish population in watercourses and basins into which the irrigation waters from such soils (rice fields and "marcite") flow, the author has investigated the question.

Neglecting basic slag, which of late years has been almost entirely lacking on the Italian market, the fertilisers used in rice fields are :— Superphosphates, sulphate of ammonia, calcium cyanamide, sulphate of potash, sulphate of lime ; these are respectively applied at the rate of 3-4.5, 1-2, 1-2, 0.5-1 quintal per hectare.

The fertilisers are usually applied after the last ploughing and shortly before the first seeding, with the exception of sulphate of ammonia, half of which is applied at sowing time and half after the first weeding. Ridged rice fields may be given an average depth of water of some 15 cm., which corresponds to 1500 cu. m. of water per hectare. Consequently, even on admitting, which is absurd, that the fertilisers incorporated in the soil by hoeing undergo no changes, fertilisers applied in the proportions mentioned above would give, per litre of water:—

Superphosphate.	0.200 — 0.300 gm.
Sulphate of ammonia	6.066 — 0.130 gm.
Cyanamide	0.066 — 0.130 gm.
Sulphate of potash	6.033 — 0.066 gm.
Sulphate of lime	0.330 gm.

The question is, whether the fertilisers can harm fish in these concentrations. To ascertain this, the author kept trout and carp in water containing each of the fertilisers separately, beginning with the lowest concentration and ending with the highest.

The observations on superphosphate were made with the liquid obtained by lisciviating 50 gm. of the fertiliser (content 14-16 %) with half a litre of spring water; the liquid was afterwards diluted with various amounts of spring water. No signs of disturbance were shown by fish placed in water containing 2-4 % of the liquid, but in water containing at most 6 % of the wash water, the trout showed a certain agitation and finally died.

Sulphate of ammonia begins to be harmful at the strength of 0.26 gm. per litre, whilst cyanamide, harmless at strengths of 0.13 and 0.26 gm. per litre, is harmful at a concentration of 0.52 gm. per litre. Sulphate of potash does not harm fish, even at greater strengths than those mentioned above, i. e., even at strengths of 0.93 and 1.8 gm. per litre.

In another experiment, the cumulative effect of the various fertilisers was tested, using solutions with concentrations that corresponded to the maximum rates mentioned above. Fish and even shrimps lived in them in excellent health for long periods.

Sulphate of lime, even at a strength of 2 per 1000, is known to have no injurious action on fish.

It can therefore be concluded that the irrigation water from rice fields has no injurious action on fish and shrimps, and this is supported by the fact that, owing to its absorption power, the soil retains a large proportion of the fertilisers and that the water from the rice fields becomes diluted in the waters of streams, etc.

All that can be suggested is that the irrigation water from rice fields to which fertilisers have been applied may induce less favourable conditions of life for fish in the ponds into which they drain and that the fish may be forced to seek more favourable surroundings. Again the possibility that the fertilisers may act mechanically on the gills of the fish and prevent them from functioning normally can be excluded, because they are not carried away in the irrigation waters, which remain clear. Nor can it be thought that, owing to incorporation of the fertilisers in the soil, products more toxic than the fertilisers themselves are produced.

682 – **The Purification of Waste Waters.** — Carré, Prof., in the *Bulletin Suisse de Pêche et de Pisciculture*, Year XXI, No. 1, pp. 4-6. Neuchâtel, Jan., 1920.

The known methods of purification are either useless or not generally applicable in practice. As manufacturers cannot be forced to use a practical method for purifying waste waters, legislation is without effect and even irritating. The author believes that human methods for purifying waters should correspond with the mechanism by water spontaneously purified under natural conditions.

Colloidal clay is a natural purifier of water, the purification being due to the simultaneous precipitation of flocculated clay and the fermentable organic matter which is the essential cause of the contamination of water. The clay is flocculated only in water in which small quantities of salts of sodium, calcium, etc., are dissolved. If sufficient liquid manure is added to a test-tube containing water to colour it distinctly, and the tube is then

lled up with water containing a little suspended clay, the addition of a ew drops of a solution of common salt will, after shaking and allowing to tand for a few moments, precipitate the clay which will drag down with : all the suspended matter as well as the organic colouring matter. This rocess could be used practically in the following way :—

(1) The waste water is run into purifying tanks after been treated ith an amount of colloidal clay that is mechanically proportional to the olume of water requiring purification ; (2) it is next passed into settling anks where the water becomes clear on standing ; it is finally run off hrough sluices into adjacent watercourses ; (3) the fermentable deposits an be made into composts, nitrification being assisted by mixing with lenty of lime or marl.

583 – **Young Fresh-Water Stages and Biology of the Lamprey (*Pteromyzon marinus*).** — LÉGER, L., in *Comptes rendus de l'Académie des Sciences*, Vol. CLXX, No. 4 (Jan. 26, 1920), pp. 251-254. Paris, 1920.

Contribution to the study of the life cycle of the lamprey, which is as et almost entirely unknown. The author has been able to distinguish periods in the normal life of the lamprey which swim up the watercourses f central France, particularly in Vienne and the Indre ; these periods are s follows :—

(1) Larval period in fresh water lasting at least 4 or 5 years, with ixed food (vegetable and animal micro-organisms) and ending by metaorphosis, from which emerge young lampreys, 16-20 cm. long, already howing adult characters ; these go down to the sea at the end of autumn ith eels accompanying their descending migration.

(2) Period of growth in the sea, on an animal diet ; this period is pparently shorter, judging by the rapidity of growth of other potamotoctic ish such as salmon, and leading up to sexual maturity.

(3) Sexual period, with decreasing and finally no food, marked by he beginning of the return to the rivers, often with shoals of shad and almon ; this period is still shorter if it is admitted, with the author and nany other observers, that the nuptial journey in fresh water is the last tage of their existence.

584 – **The Minimum Quantity of Water required to a Few Salmon at a Constant Temperature of 12° C.**— HESSE, E., in the *Bulletin Suisse de Pêche et de Pisciculture*, Year XXI, No. 1, pp. 6-8. Neuchâtel, Jan., 1920,

From observations made in the Piscicultural Laboratory of the University of Grenoble, the author draws the following conclusions, which are of importance for rearing in a limited area :—

(1) Renewal of the water at the rate of 2 litres aminute is necessary and ample for succesfully rearing a hundred odd trout, of 1, 2 or more years, in an aquarium containing 400 litres of water kept at a constant temperature of 12° C., and with a free surface of about 1 sq. metre, but this is a *minimum* quantity, below which there is a chance of mishaps.

(2) In water kept at this temperature, fountain salmon resist asphyxiation better than rainbow trout.

(3) In these conditions of limited space and low renewal, *Salmo salvelinus* gives the best yields up to the beginning of the second year if it is not mixed with other species ; then come rainbow trout and fountain salmon. Apparently, the native trout does not grow nearly so well as the preceding species.

FARM ENGINEERING

AGRICULTURAL MACHINERY AND IMPLEMENTS

685 - **Colonial Power Farming** (1). — MAGEN (Head of the Agricultural Service of the Institut Scientifique of Indo-China), in the *Bulletin de l'Institut Scientifique de Saïgon*, Year II, No. 3, pp. 65-68, fig. 1. Saigon, March, 1920.

Power farming is perhaps more necessary in the colonies than in temperate countries, for if the latter possess powerful farm animals, this is not so in hot climates. Moreover, epizootic disease is infinitely more frequent and severe in tropical than in temperate regions, as hygienic conditions are not as good and inspection is not so efficacious.

Indo-China is favourably placed for power farming as the Annamites have a remarkable gift for mechanics. Thus, when the author gave a power-farming demonstration in Indo-China, on January 30 and 31, 1920, using a Caterpillar tractor, a Bajac plough, a Tracford, a Norwegian harrow and a scarifier, it was found that the Annamites, after only 5 or 6 days' training, managed the machines quite well.

Besides, without mechanical aid, it is impossible to work the ground properly in the colonies, as, the average type of oxen available cannot draw a plough cutting at a depth of 20 cm. This is so true that the administration of the Belgian Congo organised, in 1912, a power-farming competition for 1913 in Belgium that was extremely successful.

Cost is a secondary consideration and, in fact, the author calculated that ordinary ploughing under average conditions required some 36 litres of petrol, costing about 7 *piastres* per hectare, so that if an extra 100 kg. of paddy or 7 kg. of rubber per hectare are gathered, the fuel will be paid for.

The author has studied the existing types of tractor and has arrived at the following conclusions :—

In most cases, cultivation can be divided into 2 phases : ploughing and complementary work. Two types of tractor should correspond to these two phases, i. e., 30-40 H. P. tractors with great gripping powers for ploughing, and light 15-20 H.P. tractors for complementary work. With certain permanent crops, however, such as rubber, coffee, etc., which do not require deep ploughing, tractors of only 15-20 H.P. will be required for ploughing, the harrowing being done by oxen.

It has been claimed that a powerful tractor can simultaneously draw ploughs, harrows, etc., over a width of 8 or 10 metres ; this may be true in countries with immense stretches of very homogeneous soil, but it is im-

(1) See the trials on the mechanical cultivation of rice carried out in Cochin-China in 1919, and summarised in *R.*, 1919, No. 508. (*Ed.*)

practicable in rubber or coffee plantations or in rice fields split up into plots of 4, 5, or 10 hectares at the most.

A type of tractor should be chosen that is best suited to the conditions and the crop which is under consideration.

686 - **The Spring Power Farming Week** (1). — PASSELÉGUE, G., in the *Journal d'Agriculture pratique*, New Series, Vol. 33, 1920, Vol. I, Nos. 12-13, pp. 221-223. Paris, March 18-25 1920.

The "Chambre Syndicale de Motoculture" of France organised an international power-farming exhibition, which was held on March 4-14, 1920 on the Terrasse des Tuileries at Paris.

Only 39 machines were exhibited, including 19 French, 15 American, 1 English, 2 Italian, 1 Swiss and 1 Czecho-Slovak. A cursory account is given below.

CABLE SYSTEMS. — DE DION-BOUTON Co: two 50 H.P. motor-windlasses.

The A. DOUILHET Co. exhibited the ploughing set with two motor-windlasses, formerly shown by FILLET ET CIE. Each windlass, weighing 750 kg., is actuated by a 12 H.P. internal-combustion engine running on petrol. The drum has three different radii, so that the cable can be wound at 1, 1.5 and 1.8 metres per second, according to the part of the drum on which the cable is being wound. The machine can be used in a vineyard by fitting a crutch on the implement being drawn so that the cable is unrolled between the vines in the space that is to be worked next.

Société française des tracteurs-treuils DOIZY: a 25 H.P. windlass tractor.

Matériel de culture moderne: a 40 H.P. FILTZ-GRIVOLAS haulage tractor that is designed so as to diminish the couple resulting from attaching the implement laterally. The same company exhibited a 2-furrow double brabant, which they described as a plough with differential earthing and automatic lift; the stanchions of the axle are articulated with the beam and the drive acts through the axle, so that when the pull ceases at the end of the furrow as the tractor stops, the axle is pulled towards the mould-boards by two strong springs, thus automatically lifting the ploughs, so that the attendant has less to do. The company also exhibited a new 3-furrow balance plough which has automatic steering.

TRACTORS WITH ONE DRIVING WHEEL. — AGRICULTURAL Co.: 24 H.P. *Taureau* tractor.

AMERICAN TRACTOR Co.: 40 H.P. Gray tractor, which has been successfully used for cultivating rice-fields, the steering wheels being fitted with iron sheets to cover up the spokes.

TRACTORS WITH TWO DRIVING WHEELS. — AGRESTIC MACHINERY Co.: WHITNEY tractor with an 18 H.P., 2-cylinder horizontal engine running at 750 revs. per minute, and with 3 speeds: 2.8, 4 and 6.4 km. per hour

(1) See *R.*, March, 1920, No. 354. (*Ed.*)

and a reverse. It weighs 1300 kg. and the driving wheels have tyres 25 cm. wide. Angle-irons are fitted to give grip on the soil.

AGRICULTURAL CO. : 16 H.P. HAPPY FARMER tractor.

BEAUVAIS & ROBIN CO. : 30 H.P. AMANCO tractor, also known as the JOHN DEERE tractor.

BERNA CO. : 40 H.P. BERNA tractor.

CH. BLUM & CO. : 35 H.P. TOURAND-LATIL tractor. In previous models the plough was rigidly attached to the tractor, thus constituting a motor plough. As this practice had defects, a more supple attachment, consisting of a chain, has been provided. The manufacturers took some time before they devised this improvement on their first models, although the question had been settled long before by M. RINGELMANN in his studies on Mechanical Cultivation.

FRENCH CASE CO. : 18 H.P. CASE tractor.

M. CHAPRON has provides his vineyard tractor with a more powerful engine and higher wheels, whilst the gripping strakes are fixed on to an extra tyre which is in two pieces and attached to the wheel by wing-bolts. The grip of the steering wheel is obtained by weighting the end of the frame with cast iron.

Compagnie internationale des machines agricoles (C. I. M. A.) : 16 H.P. INTERNATIONAL tractor, 20 H.P. TITAN tractor, and 20 H.P. MOGUL tractor.

DENS & CO. : 25 H.P. SANDUSKY tractor.

M. R. DUBOIS, of Neuilly : 10 H.P. vineyard tractor. It is 95 cm. wide and can turn in a radius of 1.40 m. There is no differential, but a special device automatically brakes one of the wheels when turning. The engine runs on either petrol or paraffin and has two speeds, one at 500 revs. per minute, producing 6 H.P., is used to drive stationary farm machinery, whilst the other, at 800 revs. is used when running on the road or in the fields. The machine can be run as a locomotive on a track of 60 cm. gauge by fixing a flange on the tyres of the back wheels and placing the fore-carriage by a bogie.

Société FIAT : 25 H.P. FIAT tractor.

MALEVILLE & PIGEON : 22 H.P. FORDSON tractor.

TH. PILTER : 10 H.P. AVERY tractor, and 25 H.P. AUSTIN tractor.

Société RIP : 18 H.P. tractor.

Société de construction et d'entretien de matériel industriel et agricole (S.C.E.M.I.A.) : 14 H.P. E-10 tractor, and 25 H.P.U.-20 tractor.

WALLUT & CO. : MAC CORMICK tractors of 16 and 20 H.P., the same as the 20 H.P. TITAN tractor of the *Cie, internationale des machines agricoles.*

TRACTORS WITH 4 DRIVING WHEELS. — *Ateliers* ATLAS : 18 H.P. model *Picardie* tractor.

Société auxiliaire agricole : 25 H.P. *Agrophile-Pavesi* tractor.

CHAIN-TRACK TRACTOR : — PEUGEOT C. : model 3 tractor ; the shoes of the track are separated from each other by about 6 to 7 centimetres.

The RENAULT CO., exhibited an 18 H.P. tractor that is heavier than previous models and has a wider chain track. The suspension of the frame has been slightly modified, as has the transmission.

Motor Ploughs. — Amiot Co.: 30 H.P. motor plough known as *La Gerbe d'Or*.

Société des automobiles Delahaye: 30 H.P. *Tournesol* motor plough. The device for lifting the gang has been modified by the introduction of 2 windlasses fixed obliquely to the axis of the machine; the method of attaching the plough bodies to the frame has also been changed.

M. A. Ravaud: 40 H.P. *Excelsior* motor plough.

Fore-carriage tractors. — M. L. Dubois, of Asnières: 20 H.P. fore-carriage tractor.

Moline Plow & Co.: 18 H.P. fore-carriage tractor.

Motor Tillage Machines. — E. Bauché & Co.: 7 H.P. motor tillage machine.

Rotary Cultivators. — Pétard & Préjean: 8 H.P. rotafy cultivator, fitted with shafts for a horse to draw it.

S.O.M.U.A.: 5 H.P. model A Motoculteur and 35 H.P. model C. Motoculteur.

The general tendency is to simplify self-lift ploughs by placing the bearing of the cam on the hub of the lifting wheel.

Maleville & Pigeon showed an Oliver plough with lift mechanism consisting of a toothed, eccentric sector that meshes with a lantern pinion keyed on the hub of the wheel, thus lifting the frame.

Messrs Peugeot showed a French-made self-lift plough.

It is to be regretted that other French makers who have specialised in the construction of good ploughs do not make self-lift ploughs for tractors, as these have to be imported.

Most of the above tractors run on paraffin, which is cheaper than petrol. Considering the rise in the prices of petrol and paraffin, it is to be hoped the makers will study the use of "poor gas", as this has already been used in motor lorries.

Many of the exhibitors and other makers took part in public demonstrations of power-farming machinery, held from March 10 to 14, at Gally farm, in the Parc de Versailles.

687 - **Tillage with Rotary Machines.** — Pizzarelli, A., in *L'Industria*, Vol. XXXIII, No. 24, pp. 750-752. Milan, Dec. 31, 1919.

Rotary tillage machines can be made much lighter than ordinary motor ploughs and can thus be used in fields of small size and irregular shape. Consequently, during the last few years, tillage machines have been invented with all kinds of rotary apparatus. The "fraise" type, however, is the most popular and it has been used as a model for several machines known as motocultivators, which differ according to their engine.

The chief objections to this type of tillage are as follows:—

(1) The layer of soil that has furnished the crop is not replaced by that which has remained untouched, a change which takes place in ploughing.

(2) In most soils, a fine tilth should not be produced solely by

machinery, but also by the slow action of natural agencies such as heat, frost, air, etc.

(3) The rotary cultivator does not work the soil as deeply as the plough.

(4) When clay soils are worked with a rotary cultivator they easily crust over after rain, and this is harmful to land that has been seeded.

(5) In damp soil, rotary cultivation leads to the formation of small lumps which are penetrated with difficulty by plant roots.

(6) With rotary cultivation, excessive oxidation of the organic matter is to be feared and, consequently, hyper-nitrification and loss of nitrogen.

On the contrary, however, experience shows that :—

(1) The uniform mixing of the components of the whole arable layer of soil, obtained with the rotary cultivator, should yield better results than the simple substitution of layers brought about by the plough ; it should also distribute the fertilising principles more evenly.

(2) A fine tilth can be produced entirely by mechanical means, i. e., apart from the preponderating help of natural agencies, without harming crop production ; what is required is that the soil should be in the right physical condition: at the moment of sowing, etc. ; in addition, the rotary cultivator incorporates air in the soil in a proportion much greater than that produced by ploughing.

(3) Systematic rotary cultivation of the soil diminishes the need for deep cultivation with the object of conserving rain water, because it acts on the soil capillaries and thus limits the loss of water by evaporation from the deep layers.

(4) Deep cultivation can be carried out by attaching a plough to the tractor in place of the rotary organ.

(5) To avoid the formation of a crust on clay soils, the speed of the rotary organ or the number of hooks must be regulated so that too fine a tilth is not obtained.

(6) As with ploughing, the right time must be chosen for rotary cultivation.

(7) Many cultural practices have the object of favouring the nitrification of the organic matter of the soil ; nitrification could hardly become so active as to lead to the loss of nitrogen because, in most cases, the content of organic nitrogenous matter in the soil is very low ; moreover, if seeding is carried out immediately after rotary cultivation, the seedlings will at once benefit from the nitric nitrogen whose formation has been facilitated by rotary cultivation.

Tests of rotary cultivation, carried out recently in Italy under the most divergent agricultural conditions, have convinced Italian technicians and practical men that the method will rapidly spread. For example, it can replace the shallow cultivation given in summer with the object of destroying capillarity and thus avoiding the evaporation of water that has risen from the deeper layers of the soil.

688 – **French Types of Farm Buildings.** — DABAT, L. Report presented on behalf of the Agricultural Committee, on the collaboration of M.M. VIGNEROT and MAITROT in the publication of the "Modèles-types de Constructions Agricoles" of the Ministry of Agriculture, in the *Bulletin de la Société d'Encouragement pour l'Industrie Nationale*, Year CXIX, No. 1, pp. 21-24. Paris, Jan.-Feb. 1920.

FARM BUILDINGS

The French Ministry of Agriculture has published a work entitled "Modèles-types de Constructions Agricoles" with the object of assisting both farmer and builder in the improvement of rural buildings. The types dealt with result from work carried out in various parts of France by the engineers of the "Corps des Améliorations agricoles" (which has since become the "Corps du Génie rural") who, by their constant contact with the rural populations, have been able accurately to gauge local needs. The types also take into account the data furnished by projects that gained prizes in competitions opened by the "Service des Améliorations agricoles" for architects and builders who have specialised in rural buildings.

In deciding on these model types, recourse has been had continuously both to the most recent and practical information furnished by agricultural science and by hygiene, and to the results acquired by experience. The science and experience have been directed not towards the elaboration of entirely new models, but towards the improvement of regional types studied on the spot with their local characteristics derived from the soil, climate, customs, and economic life of each region.

The result is that these regional model types of agricultural buildings represent a combination of the precepts of treatises on agricultural buildings with a monographic documentation and model projects of a concrete character. They are applicable to the most varied kinds of buildings :— Farms, barns, stables, cattle-sheds, sheepfolds, houses for farmers and of labourers, co-operative works, etc. Each model type includes an introduction explaining and justifying any general or particular arrangements adopted, as well as the economics of the scheme, general and detailed plans, specifications for the work, a detailed estimate of the cost, a memorandum of such regional prices as could be ascertained easily, and a list of charges and conditions for the undertaking.

Farmers who wish to build or restore farm buildings will find in the work in question all information necessary for choosing the arrangements that are best and most suited to their particular region. Builders, architects, contractors, local workmen will be able to find the characteristics of all types of agricultural buildings as well as the basis for any special work they have to carry out.

The work is published in two forms : — (1) The work, text and plates, is bound in a royal-quarto album for each part ; (2) each project separately with large plates. The complete work comprises 4 parts including 80 model types from all the regions of France ; a fifth part will be published later dealing with co-operative factories for dairying, cheese and butter making, distilling, oil extraction and cider making, and with co-operative warehouses, etc. The work was ready for publication, but the advent of the war delayed it so that preparations for publication could only be begun in 1916.

The first two parts, corresponding with the North and East regions of France, have already appeared and will be of great assistance to those who have the heavy task of reconstructing the villages destroyed during the war. A considerable number of these model types of agricultural buildings has been distributed in the devastated agricultural regions by the Ministry for the Liberated Areas, and agricultural societies and other associations interested in the renaissance and development of agriculture in these regions have been supplied with the documents, which are kept by architects and contractors. In this way, the devastated regions in the North and East of France will be the first to benefit from this interesting and original work of the Ministry of Agriculture and, eventually, the other regions will be able to begin the work of improving rural buildings on sound and methodical lines, whilst avoiding the equally bad extremes of superfluous luxury and misguided economy.

The work of preparing and supervising the publication of the model types of farm buildings was confided in 1916 to M. VIGNEROT, a technical official of the Ministry of the Liberated Areas, who edited the whole work and gave homogenity ot the varied contributions from his colleagues. As M. VIGNEROT was sent abroad on a mission in 1918, the work was then placed under the direction of M. MAITROT, who succeeded to M. VIGNEROT'S position in the Ministry. M. MAITROT has mainly been occupied on the diffusion of the model types in the devastated regions, particularly amongst the 1534 co-operative building societies that have been established.

689 – **Royal Prize for a Competition for the Reconstruction of Farms in Belgium.** — Ministère de l'Agriculture. Concours de Reconstruction de fermes, 1920 : Prix du Roi, pp. 1-3. Imprimerie du Roi, Brussels.

By Royal Decree of April 8, 1920 a " Prix du Roi ", worth 25 000 fr., has been established in Belgiun for the best example of a group of farm buildings, including the provision of farm machinery and of furniture for the house, which shall be declared by a Royal Jury to satisfy most fully the requirements of hygiene, modern agricultural science and aesthetics, whilst respecting local peculiarities of style. All the farms situated within the area laid down by the Royal Decree of January 23, 1920, and which are completely built by December 31, 1920, can take part in the competition. In case that not more than 5 farms compete, the Ministry of Agriculture is authorised to extend the area to which the competition is limited to the full extent allowed by the Decree. Farms of over 10 hectares are excluded, as are those built by the State or for collective bodies.

The owner of the winning farm can place a tablet above his front door bearing the inscription " Concours de reconstructions de Fermes, 1920. Prix du Roi ". Entries can be sent, in to the secretariat of the jury (M. PAUWELS, Agronome de l'État, at Poperinghe) up to November 30, 1920. Each competitor will receive a copy of the Decree and the conditions of the competition as laid down by the jury and approved of by the Ministry of Agriculture.

AGRICULTURAL INDUSTRIES

690 - **The Chemistry of Concentrated Grape Juices and their Derivatives.** — GARINO CANINA, in the *Rivista di Ampeelografia*, Year I, No. 5, pp. 65-73. Alba-Livorno, March, 1, 1920.

Signor F. MARTINOTTI, director of the Royal Experimental Station for Oenology at Asti described the preparation of grape honey and the machinery for this purpose in Nos. 31 and 33 of the *Giornale vinicolo italiano* of 1917 (1). In Nos. 30 and 32 of the same periodical (1917), Signor E. OTTAVI described the refrigerating plant at the above-mentioned station, a plant which is also used for the manufacture of various grape products. The chief products obtained by concentrating grape juice are :—

Grape syrups. — Red or white, resembling liquid honey in appearance, with a density of about 1.3 at 15°C., and the aroma of the fruit itself. The first concentration is carried out in the cold and results in the separation of about 25 % of the water. The second concentration is carried out under reduced pressure, the water being evaporated at 35-40° C. until the density given above is reached. At this density the syrup keeps well without risk of fermentation. These syrups are used in the preparation of liqueur wines and as beverages.

Grape honey. — This is made by concentrating the juice to a density of 1.38 to 1.44, when first the dextrose and then the levulose crystallise in the form of micro-crystals, which give the product the appearance of solid honey. It can be eaten as a preserve. By adding yolk of egg, of milk, or blood to the syrup and concentrating to the right degree, products can be obtained that Signor MONTI calls ampeloplastine, ampelogalactine, and ampelohaematine, respectively.

Integral extract of marc. — This is prepared by systematically exhausting the residue left after pressing grapes with a slightly sulphurated water at 35-40° C. The liquid thus obtained, with a density about equal to that of the must, is concentrated to the density of the syrups. These extracts contain sugar, colouring matter, acids, and tannin and can be used in blending, to give body and colour to weak musts or wines, or in the preparation of preserves, jams, etc.

The author gives a table showing analyses of grape syrups, integral extracts, concentrated juice, ampeloplastine and ampelogalactine made by various authors, as well as the results of an analysis of honey made from the white grape " Favorita " by th author and which furnished the data reproduced in Table I.

TABLE I. — *Composition of honey from the " Favorita " grape.*

Density at 15° C.	gm. per cent.	1.4025
Extract	» » »	79.86
Reducing sugars	» » »	75.72

691 - **Disease Ferments in the Vinegar Industry.** — MEZZADROLI G. (Laboratorio tecnico fermentazioni industriali Mezzadroli, Rovigo), in *L'Italia vinicola ed agraria*, Year X, No. 10, pp. 102-104; No. 15, pp. 164-154. Casalmonferrato, March 7, April 11, 1920.

Cases of infection by eel-worms (*Rabditis aceti*) are common in the vinegar industry, but infection by bacteria is rare because there are few bacteria that can withstand even a moderate degree of alcoholisation of wines, which, in addition, are protected against bacterial action by their natural tartaric or tannic acidity. Usually it is not a case of bacterial action in the strict sense so much as of acetic bacteria that have become parasitic or too active. The author records a case like this which occurred in a vinegar works in the " Polesina "; 2 bacteria were isolated from the liquid in the acetifying vat, one of which was a slow acetifier, and the other acetophagous. The latter causes a considerable rise in temperature and, instead of stopping the action at the acetic acid stage, prolongs to the carbon dioxide and water stage. These two bacteria are quite distinct from true acetic ferments, not only on account of their chemical behaviour but also of the pigmentation produced in culture media. The cause o

these infections lies either in the bad quality of the wianes available for conversion into vinegar, or in the acetification of fruit wines that still contain considerable amounts of suspended organic matter and are liable to be invaded by disease-producing organisms.

The only remedy is to pasteurise wines that are to be acetified, whilst vats that are already infected by parasitic, inactive, or acetophagous organisms should be steamed or treated with sulphur dioxide followed by washing with pure water; after this the vat is charged with good vinegar and with cultures of acetic ferments that have been selected and tested.

592 – **The Enzymes in Germinated Barley.** — MAESTRINI, D., in the *Atti della Reale Accademia dei Lincei, Seris Quinta, Rendiconti, Classe di Scienze fisiche, matematiche e naturali*, Vol. XXVIII, Part 12, pp. 509-511. Rome, Dec., 1919.

The author has investigated the various enzymes present in germinated barley and has found amylase, protease, lipase, invertase, catalase, and oxydase to be present; he found no maltase, lactase or "labferment".

593 – **Milling and Baking Value of Sprouted Wheat.** — BIRCHARD, F. J. (Chemist, Federal Grain Research Laboratory), in *The Agricultural Gazette of Canada*, Vol. 6, No. 12, pp. 1026-1027. Ottawa, Dec. 1919.

The value of flour made from sprouted wheat is being studied at the Federal Grain Research Laboratory, Department of trade and Commerce Winnipeg. The samples examined had mostly been classed as No grade, No. 3, Northern, Rejected, tough or damp. The quantity and development of the germs in the different samples showed great variations, and as there were considerable differences in the characters of the original wheats before sprouting, it was necessary to be very cautions in drawing conclusions from the tests. The general conclusions given below, however, were deduced from the completed series of tests.

As far as regards the milling value of wheat, sprouting can be considered as a disadvantage as the scouring loss is increased and the yield of flour decreased, the loss generally increasing with the quantity and degree of sprouting.

As regards the baking value, the most striking character is the greatly increased volume of the bread obtained by using ordinary methods This was observed in every case when the original wheats were hard, even when sprouting was very advanced. The large increase in volume, however, was found to have a very bad effect on the texture of the loaves; when the baking methods were changed so as to obtain a smaller loaf, there was a corresponding improvement in texture. The colour of bread made from sprouted wheat that had simply been milled was more or less bad according as the proportion of sprouting was greater or less; however, when wheat flour classed Northern 1, 2 and 3 was mixed with different percentages (up to 25 %) of flour from sprouted wheat containing a large proportion of hard wheat, the colour and texture was always improved, but this improvement could not be obtained when the original wheat was of inferior quality. In each case, the absorption was slightly less. The general appearance and shape of

the loaves made from mixed flour were in every way excellent, and the improvement obtained by mixing flour from sprouted wheat with flour from normal wheat was very marked in respect of these characters.

The best method, then, of utilising flour from sprouted wheat is to mix it with hard wheat flour. The sole use of flour from sprouted wheat (No Grade, Rejected, No. 3) Northern, is not advisable, but it may be very beneficial to mix it with hard wheat flour, even in relatively large proportions. For example, it was found that 20 % or more of flour made from samples of germinated wheat can be mixed with flour of the Northern No. 1 wheat, and that the mixture produces a loaf equal in baking quality to that made from Northern No. 1 wheat alone. When the original sprouted wheat is of high quality, this percentage can be considerably increased.

The baking value of the Rejected (because of the sprouts) wheat No. 3 Northern, cannot be easily decided, because of the wide variations in the quality of the original wheat as well as in the degree and quantity of sprouting. However, when the original wheat was of poor quality and contained a large percentage of starchy kernels, the baking quality was bad ; but, on the other hand, hard wheat could carry a greater percentage of sprouted kernels without its baking value deteriorating to the same extent. In this case, only when the percentage was very large and sprouting far advanced did defects in texture and colour become evident.

694 – **The Extraction and Utilisation of the Textile Fibres of Mulberry Bark.** — Report by M. J. DANTZER, on behalf of the " Comité des arts méchaniques ", in the *Bulletin de la Société pour l'encouragement de l'Industrie nationale*, Year 119, Vol. 132, N. 1, Paris, Jan.-Feb., 1920.

The pre-war requirements of France in vegetable textile fibres were considerable, the chief being as follows :—

Carded, long-staple flax	about 51 000 000 kg.
Flax tow	» 50 000 000 »
Carded long-staple hemp	» 23 000 000 »
Hemp tow	» 14 000 000 »
Jute	» 110 000 000 »
Raw cotton	» 275 000 000 »

These materials, which played an important part in the economic activity of the country, were almost entirely of foreign origin and were never lacking. To day, the conditions have changed, the world's production becomes ever more scarce, and certain French industries that are now painfully reconstituting themselves are finding the greatest difficulty in obtaining even part of their requirements. The linen industry particularly, which depended on Russia for 90 % of its requirements, faces the future with the greatest anxiety and searches for some way out of the critical situation.

Starting from this standpoint, M. POL PAXION (8, Boulevard du 14 Juillet, Troyes), had the idea of reexamining the question of utilising the mulberry bark fibres known as " vegetable silk ". It has long been

known that mulberry bark, particularly that of young branches 1 or 2 years old, contains strong, supple, silky fibres of an average length of 25 to 35 mm. and even 40 mm. The extraction of these fibres had, however, not been put on such a practical and economic basis as would make it susceptible to industrial application (1).

Practically all the suggested methods, based on the use of caustic soda, soap, chloride of lime, etc., certainly bring about degumming, but, judging from the patents that have been filed, the greatest difficulty is to isolate the fibres after degumming so that they can be spun. This means that, as soon as the gum is removed, the chemical action must be stopped and prevented from going further. But if degumming is not carried far enough, the fibres stick together in straps when they are dried and yield a hard material that is refractory to spinning. If, however, the degumming is carried too far, the fibres are attacked, becoming too short and of no use for spinning.

M. Poi. Paxion who has had a long experience of spinning, took up the work where his predessors left off and, in collaboration with M. J. Dufour, discovered a process for extracting mulberry bark fibre after numerous experiments. In this process, after having freed the raw material by decortication and treatment to make it supple, the raw material is degummed in a warm bath of carbonate of soda, and then washed in a bath of cold water containing some neutral powder such as talc in suspension. M. Paxion found that the fibres then are easily separated and, after drying and beating, spin quite well, provided that they are garnetted before carding.

The inventor claims that the decorticating machine will deal with a branch 2 metres long in one second ; the machine is about 30 cm.wide, 60 cm. long, 50 cm. high, and has a capacity of about 2 metric tons of wood in 10 hours with a consumption of under 2 H.P. It is very simple and consists essentially in (1) a pair of feed cylinders, (2) a pair of dividing rolls, (3) a mobile double board bearing decorticating knives, and (4) a pair of extracting cylinders.

The small samples of the raw materials degummed and treated with talc, as well the strips and pieces of tape submitted to the author of the report by M. Paxion in illustration of his process represented laboratory tests rather than industrial results, but they sufficed to verify the claims made by the inventor, though they did not warrant the conclusions he would have wished. The author of the report will be glad to see whole bobbins, ribbons, etc., as a proof of the applicability of the invention, which is apparently quite sound and worthy of attracting attention in the industrial world, especially as it renders available a new raw material abundant supplies of which are available in silk-producing countries. In any case, the author believes that M. Paxion's process, though not yet capable of industrial application, can be recommended with confidence.

(1) See *R.*, Sept., 1918, No. 1040. (*Ed.*)

695 - **Tomato Silo and Moulds on Concentrated Tomato Juice.** — BERTARELLI, E. in *La Riforma agraria, Rivista mensile illustrata delle Organizzazioni agrarie parmesani* (1), Year 1, No. 1, pp. 18-19. Parma, Jan., 1920.

In considering the industrial preparation of preserved tomato juice, the author brings forward several points that require experimental investigation. The critical stage of the modern industry is the preservation of the whole fruit. The silos consist of refrigerated tanks with brick bottoms (which may be painted), usually rectangular in shape and sloping towards the median axis where is placed a small canal (with the endless screw that conveys the juice and tomatoes) with walls part brick part wood. The tomatoes are pushed towards the canal by their own weight and by pressure applied by sticks, boards, etc.

The author demonstrates that the silos should have a smaller surface, a greater height, a circular section, walls that are air-tight, and also shows that not whole tomatoes, but those that have been through the evaporator, should be put in, so as to avoid the enclosure of air in the mass, which should be fluid and even in texture. Data for the dimensions of cylindrical recipients, the limits of cooling (never below + 5° or + 4° C.), methods of refrigeration (systems of axial batteries such as are used for beer), are all points requiring discussion by competent persons and, in any case, they will have to be tested.

AGRICULTURAL PRODUCTS; PRESERVING, PACKING, TRANSPORT, TRADE

696 - **The Storage of Pears.** — See No. 656 of this *Review*.

697 - **Canadian Railways and Agricultural Development.** — MAC INTOSH, G. E., in *The Agricultural Gazette of Canada*, Vol. 6, No. 12, pp. 1032-1033. Ottawa, Dec.; 1919.

The chief problems now before Canadian producers of fruit and vegetables consist in, *firstly*, the improvement of the quality of their products, *secondly*, the creation of a greater demand for them and, *thirdly*, the perfection of an economically good system of distribution. The first two points can be realised by education work carried out on a wide basis, but the main point is that of distribution. A satisfactory system of distribution can only be obtained by the closest co-operation between the producers and the railway and express companies.

It is generally admitted that, in Canada, where perishable food products have to be transported under severe climatic conditions, the question of transport requires very special attention. Practically every branch of agriculture, especially fruit, vegetables, poultry, dairy and live stock interests are essentially dependent on transport facilities, and agriculture, including live stock, furnishes about 24 % of the total railway freight tonnage. In 1919, the Canadian railways carried over 15 000 car loads of apples alone.

Interesting statistics have been published in the United States showing

(1) This new periodical is published by the agricultural organizations in the region of Parma, organizations which are amongst the most advanced in Italy, with the object of dealing with all technical, economic and social questions affecting agriculture and thus helping towards improvement. (*Ed.*)

what the railways have done to help the agricultural districts that they have served. Before the war, one company had been organising agricultural societies for 8 years in the districts through which it ran, and to such effect that now there is hardly a village of 300 inhabitants in its area that has no active agricultural society dealing with the development of all kinds of crops. In 1915, that company carried 3500 cars of fruit and vegetables in 90 days, as compared with an insignificant number a few years previously, the progress being due to the work of organisation. Another company that had taken similar steps stated that the quantity of fruit and garden produce had increased by over 100 % in 5 years. Another company, thanks to this propaganda, now carries hundreds of cars of fruit and vegetables where it previously carried hardly any. One company publishes a monthly magazine and distributes it to its clients, whilst another has opened a locality especially suited to strawberry growing, and about 8 acres has been planted to strawberries in the first year ; this undertaking developed to such an extent that, in 1918, the railway company carried some 600 wagons in 1918. Eight companies have established experimental and demonstration farms.

The Canadian railways have the future of agriculture in Canada very much at heart. They have made experiments, organised large numbers of agricultural shows, and provided improved services when any reasonable requests have been made. But in spite of the progress made, much united effort is required to achieve still greater development.

The transport service of the Fruit Branch of the Canadian Ministry of Agriculture has the intention of establishing very intimate relations between all the interested parties (producers, carriers, consignees) and to receive complaints from the consignors, and do all that it can to improve the transport of fruit and vegetables as much as possible. It is obvious that a railway company wishing to be of as much service as possible to the producers of fruit and vegetables living near its line, must not limit itself to the construction of tracks, and the provision of trains and transport for goods, but it should take an effective interest, whether direct or indirect, in the work of the producers. The best way to do this is to deal with a central representative of the producers, and, in fact, at the producers' request a special study has been made of local questions of transport in all the provinces, in all the districts or at all the shipping points.

The question of safe, rapid and effective transport is to-day of more interest to the country than the question of the low cost of transport. This perhaps applies more to fruit and vegetables than to manufactured goods. The day is not remote when the railway time-table will be arranged for the transport of crops rather than of passengers. Even now, there is a low charge for collecting, the privileges of mixing have been extended, joint commodity rates have been established, good minimum rates are provided, preference is given to producers in allotting wagons, and, in many other matters, every help is given to the producer to enable him to dispose of his products.

The fact that, in Canada, the annual production of fruit and vegetables is valued at $50 000 000, and requires 500 000 cars or their equivalent for transport, and that the value of the fruit production will probably be doubled in 10 years, indicates that the transport and distribution of this immense crop of perishable goods constitute one of most serious problems that Canadian producers have to face. It is estimated that Canadian railway cars, at an average distance of carriage of 216 miles per car will be used 4 times in an ordinary season to transport the fruit crop. This illustrates the intimate relationship that exists between transport and agriculture, the fruit and vegetable industries particularly, and shows that the interests of all the branches of agriculture and of the railways are identical.

DISEASES OF PLANTS

DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN

698 – **The Mottling Disease of Sugar Cane at Porto Rico** (1). — STEVENSON, J. A., in the *Journal of the Department of Agriculture of Porto Rico*, Vol. III, No. 5, pp. 3-76, figs. 7, plates 3. San Juan, P. R., 1919.

A serious epidemic disease of sugar cane has for some years been, and is still, spreading in Porto Rico. Of the different names proposed for the disease, the author prefers that of " mottling disease '.

The disease appeared at first in the north-western area of the island (Arecibo-Aguadilla) and has since spread rapidly towards the east, so that only a part of the eastern and south-eastern coastal regions still remain free from attack; the spread of the disease still continues. Elevated ground, generally speaking, is usually affected most seriously.

In 1918, a loss of $2 500 000 was caused by the disease which has the main effect of lowering the crop or the quantity of sugar in the cane juice There are often difficulties in extracting the juice from infected canes.

Mottling disease has been observed on several varieties at San Domingo, where, however, the infection was not epidemic in character. An infected region at St. Croix (Lesser Antilles) has been reported. The white variety (" Blanca ", or " Otaheite ") was the first to be seriously. attacked at Porto Rico, but, later, the striped (" Rayada ") and other native varieties were attacked. The numerous foreign varieties that have been introduced into the island vary very greatly in their resistance to the disease, as some are very subject to it, whilst others are apparently resistant.

The disease is characterised at first by the mottling of the leaves; in the advanced stages the whole tuft of canes wilts and grey depressed lesions appear on them. The appearance of the marbling varies greatly according to variety attacked. The disease approximately follows a course of 3 years, becoming more serious at each successive production of shoots, and finally causing the death of the clumps of cane. So far, the disease has not been observed on other plants.

Observations made in the plantations confirm the opinion that the

(1) Cf. *R.*, May, 1919, No. 655 and *R.*, June, 1919, No. 785. (*Ed.*)

nature of the soil, the number of years for which the soil has been cultivated, the method of preparing the soil, the drainage and other cultural factors have no direct connection with the appearance of the disease. Observations carried out in the field and in the greenhouse as well as experimental work show that fertilisers, liming, the treatment of the cuttings, the burning of the cane residues, the dampness of the soil, etc., have no direct influence.

The disease has not yet been transmitted artificially. Chemical examination of the juice has not revealed the presence of an abnormal proportion of glucose or of any constant difference between the juice from normal or diseased canes. The bacteria and fungi found on the leaves and stems cannot be considered as causal agents of the disease. The cankers observed on the cane are due to the general weakening of the plant and are not produced *ab origine* by fungi, though these may attack the plant when weakened by the disease.

The experimental planting of stems with partially mottled leaves has only shown that the infection is present throughout the diseased plant. The disease is transmitted by diseased cuttings used in new plantations, and probably also by other means that are not yet ascertained It does not persist in the soil and, consequently, infection does not take place through the root system ; this suggests that insects may be concerned in the propagation of the disease.

The disease is considered to be an infectious chlorosis due to a virus or an ultra-microscopic organism. The theory of the degeneration of the cane has now been completely abandoned.

LYON considers that the yellow stripe disease of sugar cane in Java and Hawai is the same as this one. In fact, there are many points of similarity, but the author thinks that LYON'S opinion is not acceptable, at any rate for the present. Sereh is a disease of sugar cane which has occasionally assumed an infectious character in Java and, though similar to mottling in certain respects, it is, however, quite distinct from it. It is considered that the causes of the two diseases are of the same nature.

There are certain diseases or anomalies of the sugar cane which have been or can be easily confused with mottling. Degeneration of the cane is due to the uninterrupted cultivation of the same variety over too long a period, to the lack or shortage of fertilisers, to unfavourable atmospheric conditions, or to other factors of a non-parasitic nature. It is distinct from the yellowing of the leaves and the withering of the clumps of cane.

There is also a disease of the roots caused by parasitic fungi which has not been definitely differentiated. Chlorosis is a yellowing or whitening of the leaves of whole tufts over limited areas due to the fact that the excess of lime in the soil prevents the plant from assimilating sufficient iron. Yellow spotting is characterised by the presence of spots on the leaves that resemble those of mottling, but are of a more intense yellow colour ; it is due to the lack of cultivation or to drought.

Long white stripes are liable to appear on the leaves of certain varieties of sugar cane and, in greenhouses, mites may cause the appearance

of stripes on the leaves that are almost indistinguishable from those of mottling. The grey pustules that appear on the stems are probably due to sunstroke or to the presence of fungi.

A very serious epidemic disease of sugar cane appeared in Porto Rico in 1872-80 and was studied by a Commission, without, however, its cause being ascertained. In certain respects it resembled mottling, but could not be said to be the same disease. It was controlled by natural agencies and by the use of resistant varieties. A late stage of the disease was found to be due to the attacks of insect larvae. Again, mottling has no connection with the rind disease (*Melanconium Sacchari*) or with the gumming disease (*Bacterium vascularum*).

The control of mottling is based on the use of healthy cuttings and the elimination of diseased canes either by ploughing in seriously diseased crops or by removing diseased tufts. In addition, active co-operation of all the cane growers is necessary. The most resistant varieties must be used and susceptible ones eliminated, whilst research should be continued with the object of finding varieties with greater resistance or, if possible, complete immunity.

DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS

DISEASES DUE TO FUNGI ETC., OF VARIOUS CROPS

700 – ***Bacillus Lathyri*** **(?) injurious to the Tomato in England.** — PAINE, S. G. and BOWLEY, W. F., in *The Journal of the Ministry of Agriculture*, Vol. XXVI, No. 10, pp. 998-1000. London, Jan., 1920;

The stripe disease of the tomato is common in English tomato beds and sometimes causes considerable loss. During the first half of 1919, about 25 % of the crop gathered in the greenhouses of the Experiment Station at Cheshunt (Herts) was so seriously affected that it could only be sold as refuse, and the whole crop was lost in greenhouses where the disease was very severe. In 1921, some plants affected, with stripe disease were sent to Kew from two localities where the disease was rife. Although the disease mainly appears in forcing houses, it has been observed in a garden where the plant were grown in a part with a southern exposure and protected by a high wall. A disease thought to be identical with stripe disease has been recorded from the United States and Canada and had once been observed near Toronto on tomatoes grown in the open field, 1 % of the plants being attacked.

The chief symptoms of the disease consist of brown stripes on the stem, brown sunken spots on the friut, and wrinkled brown areas on the leaves. The stripes on the stem may be scattered at intervals or may be so numerous as to cover the stem completely in severe cases. In some cases these are replaced by small brown spots and in others there are long furrows which sometimes extend from the base of a leaf to the nearest node below.

The disease frequently appears in seed beds, rapidly destroying the young plants and making a fresh sowing necessary.

The plants are usually attacked in their subterranean parts, the infecting micro-organism penetrating the bark of the roots and stem through wounds made by sucking insects. The aerial portions of the plants are also subject to infection through wounds produced by sucking insects, whilst an infected pruning knife may inoculate the plant with the parasite. The causal agent of the disease is an organism closely related to, if not identical with, the *Bacillus Lathyri* of Manns and Taubenhaus.

The Kondine Red and Comet varieties are much more susceptible to the disease than the Ailsa Craig variety when grown in the same ground and under the same conditions. Varieties which grow rapidly and have soft tissues in their early stages are usually more subject to infection.

Excess of nitrogen and lack of potash in the fertiliser employed, tend to reduce the resistance of the plant to the parasite, but the effect of excess of nitrogen can be largely compensated for by giving a larger quantity of potash.

Seeds from fruit gathered on infected areas should not be used for sowing. A variety resistant to the disease is required. Wherever the disease has appeared, the soil should be sterilised by means of heat. In applying fertilisers, an excess of nitrogen and a lack of potash should be avoided.

Special attention should be given to pruning wherever the disease has occurred. Once an infected plant has been pruned, the knife should be sterilised by rubbing it with rag soaked in 2 % lysol or any similar disinfectant, particularly when passing on to prune a healthy plant. The prunings from an infected plant should be carefully collected and burnt.

In cases where the infection has appeared on the upper part of a plant, the suppression of the infected stem and the development of a lateral shoot often suffice to re-establish completely the health of the plant, which then produces a healthy product.

When young plants are seriously affected, the further extension of the disease may be stopped by modifying the conditions of heating and humidity in such a way as to favour more vigorous growth.

701 – ***Phytophthora* sp., injurious to *Papaver nudicaule* in Victoria, Australia.** — BRITTLEBANK C. C., in *The Journal of the Department of Agriculture, Victoria, Australia*, Vol. XVII, Part. II, p. 700. Melbourne, 1919.

During recent years, *Papaver nudicaule* L. has been subject to a disease which, in certain cases, killed 80 or 90 % of the specimens of this plant in a garden. Usually, the period of attack or, rather, the moment when the disease first becomes perceptible, is just when or just before the buds form ; but the plants are subject to attack at all stages of growth.

Diseased specimens at first appear slightly wilted and then the basal portion of the leaves and the floral peduncles become brown and rot. When the attack is slight, only a few leaves are attacked, and as these die they give the plant an untidy appearance. Many of the plants that are slightly attacked bear leaves slightly smaller than normal ones, so

that the plant becomes close and bushy. Such plants rarely flower and the dense foliage retains the damp and this in turn favours the development of the disease.

The cause of the disease was unknown till, in the beginning of 1919, a species of *Phytophthora* was isolated from diseased plants.

The disease can be completely eliminated by spraying with copper-soda wash.

INJURIOUS INSECTS AND OTHER LOWER ANIMALS.

GENERAL

702 - **On the Presence in France of the Injurious Ant *Iridomyrmex humilis* (1).** — MARCHAL, P. and POUTIERS, N., VIDAL, HALLER, BOUVIERS, in *Comptes rendus des séances de l'Académie d'Agriculture de France*, Vol. VI, No. 12. (March 24, 1920), pp. 315-323, fig., Paris, 1920.

MM. P. MARCHAL and R. POUTIERS draw attention to the presence, in the south of France, of the ant *Iridomyrmex humilis* Mayr., known as the Argentine ant, which has become famous in various parts of the world for the damage it does to human habitations, rabbit-hutches, hen-houses, hives and, directly or indirectly, to crops as well.

The first record of the insect in France came from Tamaris, near Toulon, where it had probably been brought on plants from South America and its colonies now extend over an area of at least 10 hectares. In the Cannes district a still larger centre has been discovered, extending over some 150 hectares from Croix-des-Gardes to Bocca, and apparently introduced in a similar way to the preceding one. There is no doubt that these centres will extend from year to year through the transport of plants from an infected to a healthy region, and it is probable that, between Toulon and Cannes as well as other points on the coast, the Argentine ant has already established numerous colonies. Preparatory to a more complete study of the insect, the authors give a summary description of the insect, its habits, and the chief methods of control used in other countries, especially the United States, to prevent its spread.

MM. VIDAL, HALLER, and BOUVIER contribute the following supplementary observations :—

M. VIDAL states that a very simple method is used in the Hyères region for getting rid of ants, which consists in soaking a straw in water, than rubbing it in crystallised mercuric chloride and inserting into the ant heap. In a few moments, the ants come out and, under the influence of the poison, fight and eat each other. This remedy would be probably quite as effective against the Argentine ant.

M. MARCHAL says that in the United States, particularly in New Orleans, strips soaked in mercuric chloride are sold for use against the insect.

M. HALLER quotes BERTHELOT who states, in one of his works, that, wishing to prevent ants from entering into a laboratory, he surrounded it with a small trench filled wih tar and this the ants never crossed.

(1) See *R.*, June, 1911, No. 1968 and *R.*, Sept., 1913, No. 1114. (*Ed.*)

According to M. BOUVIER, the most important thing is to destroy the ant heap containing the queens, the best way to do this being the method cited by M. Marchal, which consists in making the workers carry into the ant heap some quick-acting, toxic substance.

703 – **The Influence of Rain on the Diffusion of *Tomaspis saccharina* a Weevil attacking Sugar Cane in Trinidad** (1). — WILLIAMS, C. B., in the *Bulletin of the Department of Agriculture, Trinidad and Tobago*, Vol. XVIII, Part. 3, pp. 153-167, figs. II. Port-of-Spain, 1919.

The author has shown that the alternation of wet and dry periods during the growth of the sugar cane constitutes an important factor in the determination of the preponderance of the disease known as froghopper blight and due to the cercopid *Tomaspis saccharina* Dist. A long dry period followed by abnormally abundant rain in June or July is often correlated with a wide diffusion of the blight.

However, the most important climatic condition appears to be the nature of the "Indian summer", or dry season of varying length which comes on almost every year in August, September, and October. An intense Indian summer constitutes a general condition either of the localities attacked by blight or of years of wide diffusion of the disease in any one locality.

The intensity of the blight can be attenuated, independently of its prime cause, by putting the field of sugar canes in such conditions that the effects of excessive damp or drought will be felt less. Much can be done towards this end by improving the drainage.

MEANS OF PREVENTION AND CONTROL

704 – **Observations on the Food of the Common Nightjar *(Caprimulgus europaeus)* in England.** — COLLINGE, W. E., in *The Journal of the Ministry of Agriculture*, Vol. XXVI, No. 10, pp. 992-995, fig. 1. London, 1920.

The nightjar (*Caprimulgus europeaus* L.) usually arrives in England from its African winter quarters about the first or second week in May and generally returns about the middle of September.

Like other nocturnal or twilight animals, this bird is feared and has given rise to many superstitions. During the last twenty years its numbers have decreased to such an extent that it no longer returns to localities where it was once common. Nevertheless, there are few birds so useful as this to agriculture and fruit growing for the control of injurious insects.

Although most ornithologists are agreed as to the nature of the food of the nightjar, no exact data on the subject are available. To fill the gap, the author has examined the stomach contents of nightjars from seven widely separated localities. On an average, he obtained for his investigations two nightjars each month from May to September. The whole food found in the stomachs of the 62 birds examined consisted of animal matter which was entirely composed of insects. The following species of insect were found :— *Hepialus humuli, H. lupulinus, Cheimatobia brumata, Mamestra brassicae, Agrotis segetum, A. exclamation*,

(1) See *R.*, April, 1917, No. 395 ; *R.*, Aug., 1918, No. 939 ; *R.*, May, 1919, No. 671. (*I.*)

Triphaena pronuba, Melolontha vulgaris, Phyllopertha horticola, Rhizotrogus solstitialis, Geotrupes sp., *Tipula oleracea,* and remains of other lepidoptera, coleoptera and diptera.

Of the total food consumed between May and September, 88 % was composed of insects injurious to agriculture and 12 % of insects of a neutral character. The injurious insects all belonged to widely distributed common species and included the greatest pests with which the farmer and fruit grower have to contend.

It is very difficult to calculate the actual number of insects destroyed by the nightjar when flying, chiefly between sunset and sunrise, but it will suffice to say that the stomach of a bird killed on an early morning in July contained the remains of 15 specimens of *Rhizotrogus solstitialis,* 57 specimens of *Hepialus lupulinus,* 40 specimens of *Agrotis segetum,* and 3 adults of *Tryphaena pronuba* ; another nightjar, killed in August at about 10 p. m., had the remains of 163 specimens and fragments of numerous lepidoptera and coleoptera in its stomach.

On account of its great utility, the nightjar and its eggs should be closely protected, by legislative measures if necessary, for the whole period during which it lives in England.

705 - **On the Action of Chloropicrin on the Parasites of Wheat and on Rats** (1). — PIUTTI, A., in the *Comptes rendus des Séances de l'Académie des Sciences,* First Half-year, 1920, Vol. CLXX, No. 14 (April 6, 1920), pp. 854-856. Paris, 1920.

The author states that recent experiments by M. G. BERTRAND and his collaborators (1919-20) on the toxic action of chloropicrin on various animals clearly confirm the experimental results obtained by himself and M. L. BERNARDINI and published in 1917 and 1918.

Regarding the action of chloropicrin on the parasites of wheat (*Calandra granaria, Tenebrioides mauritanicus, Laemophlaeus ferrugineus, Sitotroga cerealella, Tinea granella, Plodia americana*), it should be observed that the numerous experiments by MM. PIUTTI and BERNARDINI, which were always conducted with wheat that was very damaged, were carried out at first on a small scale under bell-jars, and then on a large scale on tons of wheat stored in a corn mill. All these experiments clearly showed that if chloropicrin acts on wheat for about a week at a strength of 20 cc. per cubic metre of space (whether occupied by wheat or not) at a temperature of about 15-20°C., excellent results are obtained as far as the death of the parasites is concerned. Under these conditions, the parasiticidal action of chloropicrin is greater than that of carbon bisulphide, which, if the same results are to be obtained, must be used in far greater quantities and has, moreover, well known disadvantages (inflammability). Other things being equal, it has been shown that a higher temperature greatly assists the parasiticidal action of chloropicrin, as this becomes more volatile.

(1) See *R.*, July-Sept., 1919, Nos. 1049-1050 ; *R.*, Jan., 1920, Nos. 6 and 148 ; *R.*, Feb., 1920, No. 274 ; *R.*, March, 1920, Nos. 374 and 378 ; *R.*, May , 1920, No. 595. (*Ed.*)

Flour and bread made from wheat treated with chloropicrin was quite harmless and had lost none of its food value. It is remarkable, however, that wheat treated with chloropicrin loses about 30 % of its germinating capacity. In M. BERTRAND'S experiments, the amount of liquid used per cubic metre was about 10 times that employed by M. PIUTTI and BERNARDINI; in this case, it can be foreseen (apart from the disadvantages of such high concentrations from the practical point of view) that the germinating capacity of the grain would undergo too violent a destructive action.

Experiments carried out by MM. PIUTTI and BERNARDINI in 1917, with the object of testing the use of chloropicrin for freeing ships from rats, were at first made in the laboratory in suitable chambers and afterwards in ships' holds of a capacity of 800 and 1075 cu. m., respectivelly. When the chloropicrin, placed in a tin on deck was allowed to fall drop by drop into canvas tube containing cotton-wool, all the rats that had been placed at varying heights in the hold were dead in two and a half hours. These results were obtained by using only 1.5 kg. of chloropicrin, i.e., 900 cc. of liquid. Experiments by M. BERTRAND, with much higher concentrations than those employed by MM. PIUTTI and BERNARDINI, confirm the results of these authors and also show that the rat fleas were killed as well as the rats, a result which is of vital importance as regards the transmission of disease.

INSECTS ETC. INJURIOUS TO VARIOUS CROPS

706 – ***Corcyra cephalonica*, a Microlepidopteron Injurious to Cacao Beans and other Stored Vegetable Products in the United States.** — CHITTENDEN, F. H., in the *U. S. Dept. of Agriculture, Bulletin* 783, pp. 1-15, figs. 2, plates 5. Washington, D. C., 1919.

Amongst the insects injurious to stored vegetable products that have been observed recently in the United States, the tiny larva of the microlepidopteron *Corcyra cephalonica* Saint. (fam. *Pyralidae*) has attracted attention on account of the damage it does. The insect has not previously been recorded as of any great importance and has not even a common or English name; but, as it has been recorded as particularly injurious to stored rice, it can be called the "rice moth".

The damage caused by the insect in a chocolate works in western Pennsylvania was only known in October, 1911 and, a year after, similar damage was caused in another works in the same State, but the species was not definitely established until 1916.

The first correspondent of the U. S. Bureau of Entomology to record the insect, wrote that imported beans of *Theobroma Cacao* were subject to attack by the larva of the insect. The moth apparently lays its eggs on the brans, which are often stored for several months in the country of origin. During this period of storage, several generations of larvae hatch out and destroy or render unsaleable large quantitie of cacao beans.

Before this, the Bureau of Entomology had received the adult, chrysalids and larvae of *C. cephalonica* from Porto Rico and California, where it was attacking stored rice.

The origin of the insect is unknown; it has been introduced into nu-

nerous places on other continents, but it cannot be said to be truly cosmopolitan. It is common in England, where it has been introduced on rice, mainly from India, and also on dried fruit.

The habit of feeding of cacao beans has been acquired and the insect obviously tends to be omnivorous, as it lives in rice, dried fruits, various cacao products (shells, cocoa powder, chocolate containing sugar or not), and sesame seeds and cake. However, it shows no preference for any one of these food substances.

The entire life cycle on the insect is not known, but apparently it breeds throughout the year. In the United States the attacks of the pest diminish from time to time, although they assume fresh vigour on the arrival of new cargos of cacao beans from Central or South America.

The insect covers the surface of the substances on which it feeds (rice, cacao, etc.), with silky threads and, in this respect, it resembles *Ephestia cautella* Walk, and related species as well as *Plodia interpunctella* Hbn.

Stores into which the insect has penetrated should be carefully and thoroughly cleaned. All the corners and nicks where the moth could hide should be vigourously swept and the dust, etc., should be burnt. The walls and floors should be washed with a solution of creosote or of kitchen salt. The same attention should be devoted to the machinery, etc. Sacks which contain or have contained food products infested by the insect as well as the machinery, etc., should be disinfected, either by heat or by fumigating with hydrocyanic acid or carbon bisulphide.

707 – ***Leptops hopei*, a Beetle injurious to the Apple Tree in New South Wales, Australia.** — FROGGATT, W. W., in *The Agricultural Gazette of New South Wales*, Vol. XXXI, Part. 1, pp. 56-60, fig. 1, plate 1. Sydney, 1920.

In an orchard in the Epping district of New South Wales, a large number of apple trees which had been uprooted on account of their unhealthy condition were found to be seriously damaged by the larvae of *Leptops hopei*. The larvae feed on the larger roots, gnawing the bark and the surface of the wood ; attacked roots die. The sole record of *L. hopei* as a root parasite in New South Wales dates back several years and relates to an orchard at Mount Pleasant, West Maitland, where, however, the insect has not been seen for several years since then.

The adult insect as well as other weevils have been found on several occasions causing considerable damage to the opening buds of the vine and other fruit trees. In 1918, the author recorded damage caused by adults of *L. hopei* to a vineyard near Glenfield, where thousands of the beetle could be taken by hand and destroyed when they were feeding at night on vine buds just about to open.

The eggs are laid on one part of the leaf blade and covered with the other part, which is fastened down with a sticky secretion. The larvae descend the trunk and enter the soil, where they begin to attack the roots. The adults emerge from the soil from the beginning of September to the end of November. If they can be prevented from reaching the leaves or

taken when they are ascending the trunk, the roots can be saved from the attack of further larvae. A simple method for doing this consists in fixing round the trunk, about 30 cm. above the soil, an inverted funnel made of metal or coarse oiled paper, and collecting and destroying each week, during the period when the perfect insects appear, all those hidden under the obstacle formed by the funnel. To catch the larvae that descend the tree, a band of paper covered with some sticky material should be fastened around the trunk.

Lead arsenate sprays applied to the topmost foliage will kill any adult beetles that have reached that part of the tree.

708 - **A Dipteron Injurious to the Almond Tree in Apulia, Italy.** — VIVARELLI, L., in *La Propaganda Agricola*, Series II, Year XII, No. 3, pp. 26-27. Bari, Feb. 13, 1920.

In February, 1920, a heavy fall of floral buds and flowers of the almond tree was observed, especially in the commune of Andria (province of Bari); there was no reason for attributing this fall to unfavourable weather.

The author examined numerous flowers that were opened or about to open, collected from various localities, and found that, in every case, tiny larvae of a dipteron belonging to the family *Cecidomyidae* were present round the base of the ovary.

As far as the author knows, a cecidomyid that is a specific parasite of the almond tree has not yet been studied or described, and even the oldest farmers in the district do not remember such an abundant fall of flowers caused by larvae similar to those recently observed. The author considers that it is a question of a chance parasite which has chosen the almond flowers as its host. As a rule, cecidomyid flies begin their cycle of active life in March, beginning it in southern Italy during the first few days of the month if the weather is favourable. In 1920, the season was in no way winterly up to the end of January and, according to the author, the warm days and a little occasional rain hastened the hatching out of one or more species of cecidomyid that are parasites of other plants which normally flower after the almond tree (pear, apple, cherry, plum, and apricot); as the fertilised females only found the almond in flower, they oviposited on it.

At the present stage all that can be recommended in the way of control is to gather the flowers as they fall and burn them, thus giving the larvae no time to enter the soil and pupate.

DÉVELOPMENT OF AGRICULTURE IN DIFFERENT COUNTRIES

09 – **Agriculture and the Measures Relating to it in the Report of the President of the Brazilian Republic.** — PESSÔA (President of the Republic), Mensagem apresentada ao Congresso Nacional ua Abertura da Terceira Sessão da Decima Legislatura. Agricultura. *Republica dos Estados Unidos do Brazil*, pp. 129-172. Rio de Janeiro, 1920.

In the Report which the President of the Brazilian Republic presents every year to the National Congress of Brazil, Dr. E. PESSÔA describes the condition of agriculture in Brazil and various measures for its development. In the first place the re-organisation of the agricultural services is urgently required, especially with regard to the protection of crops against disease, and the improvement of the cultivated species with a view to obtaining better varieties.

The centre of all measures of plant hygiene will be the Biological Institute for the protection of agriculture, established for the study of diseases and infection of the cultivated and forest plants of Brazil and the means for combating them. Its establishment is an indispensable preliminary to all precautionary measures against plant diseases, which assuming special characteristics due to the climate and soil, require measures which can be adapted to different local cases.

The study of plant biology, which is allocated to the Botanical gardens of Rio de Janeiro should act as a control and guide in the organisation of all matters dealing with the economic cultivation of plants. An early reform will enable the Botanical Gardens, without injury to their traditionally scientific character, to act more directly and effectively in favour of national economies. The results of the botanical research carried on

there will be utilised by the Agricultural Institutes, which in their turn will make experiments in order to obtain the best kinds of cultivated plants.

These Institutes will serve as experimental stations and their duty will be to deal with each of the more important crops grown in the districts where they are established. As soon as the type of plant to be adopted is decided, they will have to face the problem of reproducing on a large scale the seeds and plants necessary for distributing it over the country. With this object the trial plots already in existence will be converted into nurseries, but the Institutes will not abandon their original objective, i. e. the demonstration of the best methods of cultivation. In order to guarantee the superior quality of the seeds a technical seed testing station will be set up which will control the former trial plots or others which will be established at government Institutes.

With the assistance of subsequent reform the Department of Practical Agriculture (inspection and agricultural development) will institute in every state in Brazil, and in the Federal territory of Acre, 21 agricultural inspectorates entrusted with the application of prophylactic measures of plant hygiene for the control of plant diseases, as well as with the distribution of seeds and plants selected in consequence of the improvement of the local varieties.

The seed Department will also attend to the distribution of agricultural machinery and fertilisers as well as insecticides and fungicides recommended by the Biological Institute and dépôts will be established in land which will facilitate purchase by the farmers.

There will also be distributed during the present year 446.5 metric tons of various disinfected seeds whese germinating capacity has already been tested. This quantity is sufficient to sow 38 114.5 acres. There will also be distributed 33 288 fruit trees, grafted for the most part, for the planting of 131 acres. From 1910 to December 31, 1919, the Department distributed 2000 metric tons of seeds, or sufficient for seeding 131 739 acres and more than 200,000 fruit trees for 822 acres. Of the seeds distributed, 548 m. tons represented grain fodder crops, for the sowing of 102 359 27 acres. The distributing Department furnished moreover 7.5 m. tons of fertilisers and 16 m. tons of insecticides (for ants) as well as Paris green.

The great assistance which chemistry renders to agricultural operations has encouraged close co-operation between the different departments and the already existing Institute of Chemistry. The geological mineralogical departments, also will co-operate with the departments of inspection and agricultural development. Owing to the special needs of the present moment, measures will be taken to encourage the cultivation of cotton. The application of these measures will be entrusted to an autonomous Board of Superintendence (Cotton-Service). Similarly, as the need is felt and financial conditions permit, special Boards of Superintendence will be established for the protection and development of the selected crops. Autonomous experiment Stations for sugar-cane, cacao, tobacco flax, barley, and wheat, already in existence or under contemplation will form the nucleus of the future services. The encouragement of the

development and improvement of cotton growing is particularly important, specially in the North-Eastern States which are regarded as the chief producing centres in Brazil and which offer specially favourable conditions of soil and climate. The sugar industry also requires the introduction of modern methods, and should be re-organised as has been done in Cuba, Hawai, and the Philippines.

It is also necessary to develop the production of industrial alcohol and of tobacco for the growth of which, Brazil offers most favourable conditions.

The persistant decrease in the production of rubber shows the need of employing suitable methods of cultivation. The uninterrupted increase in the production of live stock necessitates the re-organisation of the Zootechnical Departments both as regards the supply of breeding stock and prophylactic measures. The importance of breeding in Brazil is revealed by the fact that whereas Brazilian exports increased by 40 % during the last 6 years the export of animal products shows an increase of 200 %.

But the breeders need to learn the importance of improving stock and in this they will be assisted by the Zootechnical Services of the Ministry of Agriculture.

Preventative measures against epizootic diseases will also be developed, but government action must be supported by sanitary regulations. Prizes and grants will be given by the Federal government for the production of thoroughbred horses. The Third National Cattle Show, which will be held from July 4 to 11, 1920, will help to stimulate the development of the animal wealth of Brazil. The Higher Agricultural and Veterinary School will be re-organised, and the courses will be improved as regards both the theoretical part and the practical and experimental side. Moreover, new chairs of agricultural zoology, applied biology, bee keeping and sericulture will be created. The teaching of agriculture will be subdivided into general agriculture, agrology, soil microbiology and specialised agriculture, forestry, the cultivation of fodder and food crops. In like manner, there will be subdivisions of general zootechnology, special zootechnology, feeding, inspection of foods, and cold storage industry; courses in industrial chemistry will be added and the practical side of the agricultural courses and related industries will be extended.

The sending abroard of students anxious to perfect their scientific knowledge has been attended with most satisfactory results. In the year 1919-1920, 19 students were sent to the United States, England, France and Switzerland.

One of the effects of the war has been to increase the export of cereals and pulse crops. The export of haricot beans and maize which has assumed special importance, has necessitated the study of measures for preserving these products. The Superintendence Board created for this purpose last year had to sterilise 13 858 bags of haricot beans and 6 361 bags of maize.

As it was advisable to amalgamate and simplify the services dealing with national production, comprised in two different departments, viz.,

the Department of Practical Agriculture and the Executive Delegation of National Production instituted in December 1917, the latter was abolished. It had distributed in the two preceding years 2 508 416 metric tons of seeds of wheat, barley, rye, oats, haricot beans, manioc, cotton, rice, various kinds of fodder, maize, flax, castor oil, ground nuts, peas, hemp, lentils, garden plants, tobacco, onions, and eucalyptus.

It also supplied 268 000 kg. of insecticides and fertilisers and circulated 270 467 pamphlets dealing with agricultural propaganda. The Board of Superintendence of cereals is authorised to sell agricultural machines at cost price, and the Department of Practical Agriculture will undertake the distribution of seeds, insecticides and fertilisers as well as agricultural propaganda.

The regulations dealing with the trade in fertilisers have also been elaborated and will shortly be ready, whilst measures for the control of insecticides and fungicides are in preparation. The chief difficulty lies in the lack of analytical laboratories, but this has in part been overcome. The precarious economic and financial condition in which the Brazilian Government has been for several years has led it to consider a system of agricultural credit and co-operation by means of local syndicates for the protection of agricultural interests, and co-operative societies dealing with credit, consumption, production, purchase and sale of crops, and agricultural implements and machinery. The Agricultural Schools for the education of foundlings have been re-organised ; 6 are self supporting, and 3 receive grants.

Forestry regulations (1) will be drawn up for the purpose of protecting the Brazilian forests. The Forecasting Service so important for Brazilian Agriculture, is at the Meteorological and Astronomical head office. The meteorological section has 235 stations at its disposal and requires at least 400, or one to every 20 000 km.

Finally, the National Museum has displayed the greatest activity through its various sections and laboratories.

710 – **Economic Wealth of Alsace-Lorraine.** — *Comptes rendus de l'Académie d'Agriculture de France*, vol. VI, N. 14, pp. 354-360. Paris, April 14, 1920.

M. MÉLINE presented to the academy M. EDMOND THÉRY'S book, *Richesses économiques de l'Alsace-Lorraine*, the chief object of which is to give a complete inventory of the resources of these departments. M. THÉRY lays special stress on the wealth of the soil and subsoil of Alsace-Lorraine and sets forth the immense progress attained in agricultural production by the use of highly perfected methods of cultivation. He shews how from 1903-1912, the average yield had risen, for wheat, from 14.75 cwt to 16.6 cwt. per acre, for barley from 18 to 26.6 cwt., for oats 14.75 to 17.7 cwt, potatoes 110.7 to 127.2 cwt, alfalfa 56.4 to 68.6 cwt.

To these general crops must be added special ones foremost among which comes that of the vine, which has placed Alsatian wines in the first rank ; they have a flavour and bouquet equal to that of the best Rhenish

(1) See No. 773 of this *Review*. (*Ed.*)

vines. The Alsatian vineyards, in spite of the ravages of phylloxera, cover an area of about 64 220 acres, and produce some 180 000 hectolitres of wine.

To the cultivation of the vine must be added that of the hop, which covers some 9 880 acres, representing nearly 8 % of the world's production. The Alsatian hops are of first class quality. The cultivation of tobacco occupies about 9 000 planters and produces 92 080 cwts.

Breeding has made considerable progress in Alsace Lorraine ; from 1883 to 1912 it has steadily increased. During this period the number of cattle rose from 429 000 to 523 000 head, the number of pigs from 322 000 to 431 000, but that of horses alone remained stationary and sheep had decreased. It is estimated that during this interval the value of the Alsatian herds had increased from 200 million to nearly 320 million marks, but this capital had been seriously encroached upon by the war.

The value of the forests had risen still higher. Inspector-General LAFOSSE estimates the value of the demesnial forests of Alsace-Lorraine at not less than 406 million marks, with an average value of 2 542 marks per hectare, but these are the prices of 1917 and the present value of the forests would be more than 800 million francs.

The subsoil of Alsace Lorraine is perhaps, considering its small area, the richest in the world for the importance and value of its deposits. The principal mineral is iron ore in the celebrated basin of Longwy-Briey, which enables France to add to the 18 million tons of iron ore from the basins of Briey and Longwy which she already possessed and 20 million metric tons from Lorraine and thus to become with the United States the richest country in the world as regards iron ore. The deposits of potash in Alsace are estimated to contain 250 million metric tons.

11 – **Agricultural Monograph of the Region of Urundi, a Former Province of German East Africa.** — DE GREEF, G. (Veterinary Surgeon in the Belgian Congo), in *Bulletin agricole du Congo Belge*, Vol. X, Nos. 1-4, pp. 3-69, 20 phot., 1 map. Brussels, March-Dec., 1919.

Urundi is a province of the former German East Africa, occupied by Belgium. It is bordered on the north by the Ruanda, on the east by the Ussuwi, on the South by the territory of Udjidji, and on the west by the district of the Kivu. At its greatest breadth it is bounded by natural frontiers formed by the rivers Rusizi, Akanyaru, Nyavarongo, Malagatasi, and Lake Tanganyika. It is a country which, although situated in the tropical zone, is temperate on account of its high altitude, which varies from 820 metres (altitude of Lake Taganiyka) to 2500 metres (Mount Musumbwa).

In Chapter I the author deals with general headings : — Agrology, hydrography, orography, vegetation, composition of the soil, and climate.

In Chapter II, he studies native agriculture : — *A*) cultivated food plants ; *B*) plants for various uses, European vegetables, fruits, bee keeping.

Chapter III deals with methods of cultivation: Chapter IV with the choice of ground, crops, etc. ; Chapter V with population, customs occupations ; Chapter VI with local breeding, and Chapter VII with the hygiene conditions of the live stock.

RURAL HYGIENE

712 – **The Nitrogen Balance and Lack of Vitamines.** — DESGREZ, A. and BIERRY, H., in *Comptes rendus de l'Académie des Sciences*, Vol. 170, No. 20, pp. 1209-1211. Paris, May 17, 1920.

In order to determine the balance ration in adults it is usual, at any rate as regards nitrogen, only to take as criterion the maintenance of weight and chemical composition. Although quite legitimate, this method is not of absolute value, for though the nitrogen equilibrium expresses a fundamental condition this is but one condition only of the total equilibrium.

From this point of view there is reason for investigating the question as to whether the nitrogen equilibrium is not liable to be influenced by the nature of the food, and also if, in a crude ration of sufficient calorific value containing the indispensable materials, it is not necessary for the constituent elements to be present in certain proportions varying according to their structure and chemical functions, in order that the animal may obtain an adequate supply of the required constituents. This implies the investigation of the extent to which isodynamic food principles may be isotrophic. This equilibrium can be obtained, for a time at least, in an animal living on food which is rich or deficient in vitamines, and the authors examine the latter case.

In their experiments, adult male rats were put on a diet composed of salts, water, egg albumen, pure sugars (saccharose, lactose, and fructose), and prepared fats free from nitrogen. Account was taken of the quantity of sugar supplied by the albumen itself.

The salts remaining fixed in amount, the proportion of the 3 elements albumens, sugars, and fats, was varied, in a ration of about the same energy value so as to maintain the weight at the same level, and to ensure the nitrogen equilibrium. Firstly, if the rat is suddenly changed from ordinary diet to a synthetic one containing a large proportion of albumen and fat as compared with sugar, the animal rapidly loses weight and nitrogen.

If the quantity of albumen and fat is then reduced and the proportion of sugar increased, the nitrogen equilibrium is soon recovered. The functional chemical action of sugar is rapidly manifested, especially in the case of levulose.

By allowing the rats to adapt themselves by degrees to the synthetic food containing the elements in suitable proportions, it is possible, avoiding constipation however, to keep the animals in nitrogen equilibrium for 25 or even 35 days before the results of lack of vitamine become marked.

CONCLUSION. — Rats can be maintained for a certain time in nitrogen equilibrium on a diet deficient in vitamines, with variable proportions of albumen, fat and sugar in a given ration of sufficient heat generating value.

The minimum of each of the 3 elements is dependent on the chemical nature and ratio of the other 2 elements.

The minimum of nitrogen is reached when a certain proportion of sugar is present in the ration.

AGRICULTURAL EDUCATION

13 – **Agricultural Education in Belgium.** — I. Ministère de l'Agriculture, *Situation de l'Enseignement agricole, Rapport triennal, avec annexes, présenté aux Chambres législatives, par M. le Ministre de l'Agriculture*, years 1912, 1913, 1914, 1915, 1916, 1917, xxvi pp. 412. Brussels, 1919. — II. Royaume de Belgique, Ministere de l'Agriculture, *Institut Normal Supérieur d'Economie ménagère agricole*. Brussels, 1920.

In Belgium the organisation of agricultural education is not solely in the hands of the Ministry of Agriculture. The Law of April 4, 1890, which supplemented that of July 18, 1860, permitted the promoters of this branch of education to spread over the country a wide network of classes and schools of all kinds, which are still working. This Law modified the functions of the Institut de Gembloux, amalgamated the agricultural sections with the Horticultural Schools of Vilvorde and Ghent, created a State School of Practical Agriculture (now established at Huy), and allotted grants to agricultural schools and courses attended by at least 15 pupils, taking the official syllabus and satisfying the State Inspectors. When the Bill was passed, the Directorate of Agricultural Education endeavoured, by its administrative regulations, by its permanent staff of inspectors, and by the allocation of grants, to organise various institutions on the right lines. The results were such that after 12 years' experience it was possible to draw up a general Code of official regulations dealing with agricultural education.

This code, which is contained in 22 pamphlets, each applying to a type of agricultural school or course, now serves as a valuable guide to those who are interested in the diffusion of agricultural knowledge. The regulations thus drawn up are observed by all the institutions which are under State Inspection, which are as follows :

A) SCHOOLS FOR BOYS.

(*a*) Higher Grade (Degré Superieur) : Institut agricole de l'Etat at Gembloux.

(*b*) Higher Intermediate Grade (Degré Moyen Supérieur) : Agricultural Sections.

(*c*) Higher Primary Grade (Degré Primaire Supérieur) : attached to these Grades are :

(1) *Primary professional sections.*

(2) *Travelling, professional agricultural sections,* organised and directed by the State agronomists.

(3) *Schools, sections and courses of agricultural mechanics,* whose number increases yearly, and which may be considered as professional sections with a specialised syllabus.

(4) *The Agricultural courses* organised in the State " athénées " and Intermediate Schools and in free " Collèges " and intermediate schools might, as regards their scientific standard, be considered as belonging to Lower Intermediate education. But the short amount of time allotted to this subject would rather class these courses, which do not aim directly at the professional training of farmers, with primary agricultural education.

(*d*) Lower Primary Grade or Instruction for adults: A large number of lectures on various subjects given to adult farmers and to soldiers during the winter.

B) SCHOOLS FOR GIRLS.

(*a*) Higher Grade: *Agricultural Training Colleges* at Héverlé and at Wavre Notre Dame; *Higher Training Institute* of Domestic and Agricultural Science at Laeken (Brussels).

(*b*) Intermediate Grade: Permanent Schools and Sections of Domestic and Agricultural Science.

(*c*) Lower Grade: (1) Travelling schools of Domestic and Agricultural Science.

(2) *Primary professional Sections for girls.*

(3) *Lectures for farmers' wives.*

The organisation of these different kinds of institutions is as follows:

***

A) AGRICULTURAL EDUCATION FOR BOYS.

(*a*) Higher agricultural education. — The *Institut agricole de l'Etat à Gembloux*, as well as the *Institut agronomique de l'Université de Louvain*, trains the heads of large agricultural enterprises, the directors of agricultural industries, landowners, professors of agriculture, State agronomists, the higher officials in the Department of Woods and Forests, etc. The regular students, Belgians or foreigners have to furnish a *certificat d'études moyennes complètes* (secondary school certificate) and pass an examination in mathematics. The only pupils exempted from these formalities are those who have entered the Military School, or a technical school of a university leading to an engineering degree.

The period of study last for 3 years, and the syllabus includes the following courses: — Cultivation, rural engineering, general chemistry, mineralogy, analytical chemistry, zootechnology, botany, zoology, book keeping, rural economy, social economy or legislation, technology, drawing and physics. The teaching comprises lessons, repetition, experiments an excursions. A model farm is attached to the Institute which serves both for practical teaching and as an experimental farm.

(*b*) Higher intermediate education. — This system of education is represented in Belgium by the free schools of Carlsbourg, La Louvrière, Leuze, and by the State School of Practical Agriculture at Huy. The last mentioned school is run on special lines, and it is supported by the State. The object of these schools is to train the heads of the smaller farms, directors of secondary agricultural industries, farm managers, etc. The period of study lasts for 3 years, except at Huy, where it only lasts two.

Pupils are admitted after finishing their higher primary or lower intermediate education. The number of hours allocated to agricultural studies (the minimum of which is fixed by ministerial decree) may not be less than 40 hours per week; 6 hours of theoretical and 6 hours of practical

work, in the third year. The syllabus includes the following compulsory essential courses and *optional courses:* — *Compulsory:* physics, chemistry, botany, zoology, agronomy, agricultural chemistry, zootechnology, special crops and book keeping; *Optional:* — Analytical chemistry, fruit growing, market gardening, forestry, poultry keeping, entomology, bee keeping, agricultural mechanics, rural buildings, and technology.

The 3 free schools mentioned above have added to their syllabus, in addition to the compulsory courses, the greater part of the optional courses, and the free time in the week (which comprises 28 to 30 hours of lessons each year) is devoted to the study of general knowledge.

(*c*) Lower intermediate agricultural education. — The "Lower intermediate" agricultural sections are established throughout the country. They are attached to free institutions, of general education (colleges, intermediate schools), and generally comprise a 3 years' course taken by pupils of from 14 to 17 years of age. The minimum syllabus required by the Ministry of Agriculture includes the following:— physics, chemistry, botany, zoology, agronomy, agricultural chemistry, zootechnology, and book keeping.

The greater part of the schools and intermediate agricultural sections therefore do not teach what is usually known as "practical agriculture," i. e., they do not teach the pupils to plough, harrow, sow, etc. But it must be observed that the pupils are mostly farmers' sons, living at home and thus in close contact with the work of the farm. It is there that they acquire the practical side of agriculture and professional ability much better than in the best of schools, as the naturally heavy scientific syllabus takes up all the time. The object of the Intermediate School of Agriculture is to teach the pupils the scientific basis of agriculture.

(*d*) Higher Primary Grade.

(1) *Primary sections of professional agriculture.* — These sections were started tentatively in 1901-1902. They may perhaps be compared to the winter schools of agriculture which exist in certain countries. They are, indeed, open during the winter season which is a slack time for the worker in the fields. At first all these sections were attached to the Primary Rural Schools; the teaching there was given by a master holding a Diploma for the teaching of agriculture. Afterwards their scope was enlarged and at the present moment there are in existence independant sections of the Primary Schools.

The Syllabus of the primary professional agricultural sections comprises general agriculture, agricultural chemistry special crops, some knowledge of animal anatomy and physiology, the feeding and management of animals (cattle, horses, pigs, poultry), agricultural societies, and book keeping.

This syllabus is not enforced *ne varietur.* It can be adapted to regional requirements, and in practice, the greater number of the sections have modified it according to the needs of their students.

These winter professional agricultural sections have met with great success as is proved by the figures of the attendance registers.

At first sight these winter sections may be confused with the agrono-

mic lectures given during the same season, in a large number of Belgian communes. However, these two systems of education are quite distinct as regards their duration, their syllabus, their methods and their examinations; the agronomic lectures comprise 10 or 15 lessons of about an hour's length, 6 to 10 of which are given to the study of fertilisers and of cattle-feeding: 1 or 2 lessons deal with hygiene, rural law, agricultural associations, etc. The development of these various points is naturally limited to facts capable of being applied practically, and the teaching is in the form of a lecture, the professor endeavouring to place himself in the level of his audience, but generally speaking he does not ask questions; those present reserve their difficulties and remarks for the discussion which usually terminates the lecture.

(2) *The travelling professional sections.* — These constitute a very interesting variety of the preceding sections. Whereas the latter are held every year in the same place, the travelling sections travel about from year to year, establishing themselves wherever they find a suitable locality and a sufficiently large audience (a minimum of 15 pupils). These travelling sections were started in 1904-1905 in the province of Namur.

Afterwards they increased, and at the present moment, the State Agronomists have organised them in the provinces of Namur (2 schools), Brabant, Limbourg (2 schools), Liège (2 schools), Hainaut (2 schools) and Antwerp.

Their system is based on that of the stationary sections, viz., the courses are given during the 3 winter months at the rate of 3 or 4 lectures of 3 to 4 hours per week.

The syllabus is fixed by the Minister in conjunction with the Direction of State Agronomy, who takes into account the requirements of local agriculture.

The greater number of the agronomists have added to the usual syllabus lessons of practical agricultural mechanics (the working, maintenance, etc., of agricultural machinery).

(3) *Schools, sections and courses of agricultural mechanics.* — By reason of the necessity which compels the farmers to have more and more recourse to agricultural machinery, or account of the lack of manual labour. Schools and courses of agricultural mechanics respond to a real need and their popularity is easily explained.

There are now 3 schools in existence at Mons, Leuze, and Namur, and 2 sections at Avelghem and Fleurus. Moreorer in the provinces of Brabant and Liège the State agronomists have established travelling sections which are open during the winter and move from one place to another every 2 or 3 months. Finally, courses of agricultural mechanics of 10 to 15 lessons are organised in the provinces of Namur, Limbourg and Luxembourg.

In the schools and sections the teaching is both theoretical and practical. Theory comprises elementary knowledge of agronomy, natural sciences, and legislation applied to agricultural mechanics; the description of agricultural machines steam, petrol, electric tractors, etc. Practica

work is chiefly confined to drawing, the fitting, taking down, and running of agricultural machinery, driving the tractors and working in wood and iron with a view to doing slight repairs.

To allow of this practical work being carried or under favourable conditions the schools in particular and the sections have put up large workshops which suffice for all needs.

Ambulatory sections of agricultural mechanics. — Established in 1912 by the State agronomists of the provinces of Brabant and Liège, these sections are financed entirely by the State with the exception of grants awarded by the provinces and certain agricultural societies.

With a syllabus and institutions similar to those of the permanent schools and sections, though on more modest lines because of their temporary character, these travelling schools, however, render great service.

Courses of agricultural mechanics of 10 to 15 lessons have been organised by the State on the initiative of its agronomists in the provinces of Lembourg, Namur, and Luxembourg, and by some professional sections of agriculture (Enghien, Thuin). They are given up entirely to the study of the working, assemblage, etc., of agricultural machinery employed or suitable for use in the district.

This strictly utilitarian syllabus has been greatly appreciated by the large numbers present at these lectures (an average of 20 to 50 per lesson).

(4) *Agronomic courses organised in official and free establishments.* — These courses were organised at the joint expense of the Departments of Science, Arts and Agriculture in 50 State "athénées" and Intermediate Schools, and at the sole expense of the Department of Agriculture in 50 free establishments; they comprise 1 or 2 hours of lessons weekly, given by an agricultural engineer or a professor of an Intermediate School. The syllabus includes the study of plants, animals, and agricultural associations. These courses do not afford training for the farming profession and that indeed is not their object. They are intended for young men some of whom, after their "études moyennes" will return to the paternal farm, with at least some notions of agricultural science, whilst others will proceed to universities to become notaries, lawyers, doctors, finally settling in the country where they will occupy important posts. It is thus very likely that they will have frequent opportunities for taking, to some extent expert, an interest in the affairs of the rural community in which they live.

(*e*) Lower Primary grade or Instruction for Adults.

(1) *Agricultural lectures for adults.* — These have been given for a great number of years in Belgian villages by the state agronomists, agricultural engineers, professors and masters holding teaching certificates for agriculture. They deal with various subjects of interest to farmers, such as fertilisers cattle feeding, hygiene, dairies, associations, rural law, means of combating the diseases and pests of plants and animals, apiculture, poultry farming, farriery, etc.

(2) *Courses in agriculture for soldiers* are regularly organised every winter from December to March in the barracks where at least 20 entries are received.

(3) Finally for some years past free agricultural associations and federations have instituted lectures with the financial aid of and inspection by the State.

(*B*) AGRICULTURAL EDUCATION FOR GIRLS.

(*a*) HIGHER GRADE. — The Higher Grade of education in Domestic Agricultural Science is represented in Belgium, since 1918, by the institution of a fifth year of specialised agriculture in the training Colleges for Certificated Mistresses (Ecoles Normales d'institutrices agréées) at Wavre Notre Dame and at Héverlé. In October, 1920, the courses of the Higher Grade Training Institute of Economic, Domestic and Agricultural Science will begin at Laeken (Brussels). These Agricultural Training Colleges are instituted for the training of future mistresses who teach domestic science in rural primary schools, but they also provide the necessary training for professors of professional schools of Agricultural Domestic Sciences.

Their syllabus comprises all the branches pertaining to woman's sphere of work in the country. The utility of these higher sections for the progress of agricultural domestic science teaching is incontestable.

(*b*) INTERMEDIATE GRADE. — In the Intermediate Grade, Belgium has permanent schools and sections of Agricultural Domestic Science.

(1) *Schools of Domestic Agricultural Science.* — They are scattered thoughout the various provinces of the country and form the Higher Intermediate Grade of this form of education. Generally the period of study usually lasts 2 years, and residence is the rule. Their syllabus comprises some instruction in natural science and agriculture, market gardening, flower growing, elements of zootechnology, dairy work, cheesemaking, domestic economy (cooking, sewing, etc.), infant welfare, hygiene, commerce, book keeping, and common law. The teaching staff is generally composed of mistresses of primary schools holding a diploma in Domestic Agricultural Science. The ministerial regulations prescribe a minimum of 10 hours of theoretical and 20 hours of practical work weekly in this course (dairy-work, cheese making, gardening, domestic economy, etc.).

(2) *Sections of Domestic Agricultural Science.* — These constitute the Lower Intermediate stage. The essential difference between their organisation and that of the schools is the shorter period of study. The syllabus extends over a year, and includes the study of the principles of agriculture applied to gardening, of dairy-work, cheese making, domestic economy and book keeping. Theoretical and practical work is to occupy at least 4 hours respectively per week.

(*c*) ELEMENTARY GRADE.

(1) *Travelling schools of domestic agricultural science.* — These schools constitute one of the most interesting features of agricultural education for girls in Belgium. For some years past their organisation has been adopted in different countries, particularly in France. where some of the mistresses of the Belgian travelling schools have been appointed temporarily to the management of the newly created departmental schools. These travelling schools correspond to the travelling agricultural schools

for boys with, however, the difference that the latter are only held during the winter whereas the former continue throughout the year.

At the request of the Communal authorities, official or independant agricultural societies and private individuals, the school is installed in succession in the Communes where there are suitable quarters and a sufficient number of pupils (15 to 20). It is intended for girls who have completed their primary education and are able to follow the work of the school. There are no school fees. The school syllabus comprises the study of dairying, cheese making, domestic economy (cooking, sewing, laundry, work, household management, care of utensils and furniture, etc.), hygiene infant welfare gardening (market gardening), aviculture, feeding human beings and farm stock (milch cows, pigs, poultry).

The teaching is both theoretical and practical. In the winter, the practical work is done in the morning (from 8 to 12 a. m.) and the theoretical lessons are given in the afternoon (from 1 to 3 p. m.). In the summer, the working hours are from 7 a. m. to 1 p. m. (practical from 7 to 8 a. m. and from 10 a. m. to 1 p. m., theory from 8 a. m. to 10 a. m.; or theory from 7 to 9 a. m. and practical from 9 a. m. to 1 p. m.). For the theoretical study of certain branches, such as domestic economy and dairying, the pupils generally use text-books. If these are not available, the professor supplies or dictates a summary of his lessons.

The practical work dealing with the different branches is carried on with the help of the apparatus which all the schools have. Apparatus for dairying and cheese-making (1 or 2 separators, a churn, a kneader, a refrigerator, utensils for making cheese, testing milk, etc.). For the practical work the pupils are divided into 4 groups of about 4 or 5 pupils to the group; the first group attends to the testing of the milk and the butter and cheese making. The second has charge of the kitchen (preparation of the mid-day meal, which the pupils of the group take at the school; bread-making, preservation of fruit and vegetables; waiting at tables, etc.). The third washes and irons, etc.; the fourth takes sewing (cutting-out, making and mending linen, simple garments and those most in use). Each group does the same work for 8 consecutive days, then they change round so that in 1 month the 4 groups have covered the whole ground. After 4 months, the pupils have therefore participated 4 times in each operation. The results attained by this itinerant system of domestic agricultural teaching are surprising.

(2) *Primary professional agricultural sections for girls.* — These sections correspond to the primary professional sections for young men. They are based on the same official regulations, which require 60 hours of theoretical lessons and 60 hours of practical work to obtain a grant varying from 350 to 750 fr.

The syllabus is a modified form of that of the permanent sections of domestic and agricultural science. The latter are intended for girls who can follow uninterruptedly a whole year's studies, whereas the primary sections are open to those who can only give a few hours a week and wish

to perfect themselves while at the same time they go on with their regular work at home.

(3) *Lectures for farmers' wives.* — In order to complete the system of education instituted for the benefit of country-women the Ministry of agriculture has organised during the last 10 years lectures on the different subjects of interest to the farmer's wife i. e., cattle-feeding, dairy-work, poultry keeping, growing vegetables, domestic economy (cooking, preserving of vegetables, etc.) infant welfare, hygiene, etc.

These lectures are instituted by the State at the recommendation of official agronomists or through the medium of circles or federations of circles of farmers' wives.

They have everywhere met with the greatest success.

*
* *

Agricultural instruction in Belgium is given, in its different grades and forms, by the following institutions :

HIGHER AGRICULTURAL EDUCACTION.

State Agricultural Institute at Gembloux.

INTERMEDIATE AGRICULTURAL EDUCACTION.

State Intermediate School of Practical Agriculture, at Huy.

Free grant-aided agricultural schools for boys at Carlsbourg, La Louvière, and Leuze.

Free grant-aided agricultural sections for boys at : Aerschot, Avelghem, Buggenhout, Capelle-au-Bois, Chimay, Court-St-Etienne, Dinant, Ellezelles, Enghien, Fleurus, Hal, Hasselt, Opwyck, Saint-Trond, Schadeck-Attert, Sottegem, Thielt, Thouin, Tirlemont (Collège Notre-Dame), Tirlemont (École provinciale), Virton, Visé, Warenme, Waterloo, Wawre.

Free grant-aided domestic and agricultural Science Schools for girls at Bastogne, Berlaerlez-Lierte, Bouchont, Brugelette, Celles (Hainaut), Ciney, Cortemarck, Cooreing-Wuestwezel, Gysegem, Herve, Héverlé (Higher School of Agriculture for girls), Maulde, Overyssche, s'Gravenwezel, Tessenderloo, Virton.

Grant-aided domestic agricultural science sections at Appelterre, Balegem, Champion, Jodoigne, Ressegem, Waremme, and Zeelhem.

Agronomical Courses attached to private institutions and *Agronomical Courses in the "Athénées royaux" and Intermediate State Schools* (About 100 lectures are organised every year in normal times).

ELEMENTARY AGRICULTURAL EDUCACTION.

Primary professional agricultural sections for boys at : Anseghem, Ath, Aywaille, Bassevelde, Beauvechain, Bergilers, Braine-le-Comte, Brugelette, Dilbeek, Frasnes-lez-Buissenal, Huldeuberg, Lichtaert, Londerzeel, Moll, Nodebais, Peruwelz, Proven, Saint-Gilles (Waes), Tirlemont, Thielen, Westerloo.

Grant-aided schools of agricultural mechanics at at Avelghem, Fleurus, and Leuze.

Professional agricultural schools and temporary schools of agricultural mechanics for young men.

Primary professional agricultural sections for girls at Borsbeke, Buret, Tavigny, Heverlé, Ter, Bank, Vezon (Hainaut), Vorst. (These usually each have about 20 pupils).

Travelling domestic agricultural science schools. During the 3 years 1912-1914, 55 courses very well-attended, were organised. The number of girls wishing to attend these schools is always much larger than space admits, which is a proof of the great utility of these courses.

POPULAR AGRICULTURAL EDUCATION.

Lectures given by State Agronomists. Generally given on the occasion of a meeting of agricultural or other Societies : these meetings afford opportunity for the agronomists to make themselves known to the farmers.

Agricultural lectures for adults (more than 2000 yearly).

Lectures for farmers.

Agricultural courses for soldiers (406 in 1914).

Lectures on poultry-keeping (428 in 1913-1914).

Lectures on bee-keeping (487 in 1913-1914).

Special lectures (organisation of agricultural loans at reduced interest, demonstration of rational feeding of cattle, experimental plots ; the latter have facilitated the comparison of the returns afforded by different kinds of cereals ; potatoes, beetroot ; they have also shown the advantage of using fertilisers.

STATE HORTICULTURAL SCHOOLS.

State Intermediate Schools of Practical Horticulture at Vilvorde (Ghent).

GRANT-AIDED SCHOOLS OF HORTICULTURE.

Horticultural Schools at Carlsbourg, Liège, Mons, Tournai.

Horticultural Sections for men at Affligem, Antwerp, Alost, Avelghem, Hoeylaert, Knesselaere, La Louvière, Lesdain, Lokeren, Mont-Saint-Amand, Namur, Overyssche, Roulers, Seraing, Tihange, Verviers, Weselmael, Wetteren, Zele. — For girls at Remagne (Rondu).

Lectures on Fruit growing at Antwerp, Bornhem, Malines, Lennicq-St-Quentin, Nivelles, Tirlemont, Vilvorde, Bruges, Roulers, Waereghem, Alost, Ghent, Grammont, Sottegem, Ath, Tournai, Huy (Statte), Liège, Hasselt, Tongres, Gembloux, Namur.

Lectures on Market Gardening at Antwerp, Tirlemont, Vilvorde, Ghent, Grammont, Tournai, Huy, Liège, Hasselt.

Temporary courses of Fruit growing (in 20 lessons on commercial methods of planting and exploiting Orchards ; the teaching, of the theory and practice of espalier fruit growing in the localites where this form of plantation is advisable, etc.).

Temporary courses of Market Gardening (in 20 lessons dealing with modern commercial methods).

Lectures on Fruit and Flower growing and Market Gardening whose main object is to introduce new methods into the professional centres.

STATE CENTRAL SCHOOLS OF PRACTICAL FARRIERY at Molenbeek St. Jean.

INSTITUTIONS ATTACHED TO THE TEACHING OF AGRICULTURE : *Station of agricultural chemistry and physics, State Station of Dairying, Station of phytopathology, Station of agricultural entomology, Station for the improvement of seeds,* attached to the Agricultural Institute of Gembloux. These stations also have an information department for the benefit of farmers.

State Botanical Gardens at Brussels.

Agricultural libraries (149 in 1914).

The estimates for agricultural education, the cost of which was defrayed by the State, allotted in 1914 489 310.75 francs for agricultural instruction, and 191 619.02 francs for horticultural instruction. In the same year the Institut de Gembloux disposed of a sum of 136 625 francs for the staff and 47 200 francs for apparatus : the state Intermediate School of Practical Agriculture at Huy had at its disposal 26 575 francs for the staff and 13 200 francs for apparatus, etc.

In 1914, the grants made to free agricultural schools and sections always varied from a minimum of 1275 fr. to a maximum of 5000 fr. ;

those apportioned to the grant-aided domestic and agricultural schools and sections varied from 245 to 6600 fr. The total grants amounted to 21 255 fr. for the primary professional agricultural sections ; 18 625 fr. for the courses in the private institutions of Intermediate education, 40 000 fr. for agricultural courses for adults ; 8 000 fr. for agricultural courses for soldiers, 6300 fr. for courses in bee-keeping ; 6 250 fr. for courses in poultry keeping, 15 750 fr. for lectures on agricultural subjects given under the patronage of independant agricultural associations, and 20 780,75 fr. for travelling agricultural schools.

The report reviews the conditions in each of these institutions during the scholastic years from 1912-13 to 1916-17 and their position at the end of hostilities. Many of the schools had lost, during the period of the war, their scientific collections and libraries, etc., this being particularly the case with the Institute of Gembloux. During the 6 scholastic years from 1912 to 1917 this Institute was attended respectively by 164, 179, 157, 75, 65, and 117 pupils.

CROPS AND CULTIVATION

AGRICULTURAL METEOROLOGY

714 – **Meteorological Stations in Ecuador.** — GODING, F. W., in the *Monthly Weather Review*, Vol. 48, No. 2, pp. 99-100. Washington, February, 1920.

Given the importance of forecasting weather conditions, a question already conceded in many countries, for the benefit of the agriculturist, the technical Office of the Association of Agriculturists of Ecuador has decided to inaugurate a network of stations throughout the coastal provinces, including the Galapagos Islands, particularly with relation to tropical crops.

With this object in view 50 farms have been selected at convenient distances, each being provided with maximum and minimum thermometers and rain ganges ; observations on the temperature and rainfall will be recorded daily, as well as the rate of plant growth. These observations will be published in a quarterly bulletin.

With data collected during several years it will be possible to forecast approximately what the weather will be for the month and season as well as the frequency of adverse conditions.

These determinations will enable the farmer to calculate in advance, as far as possible, the most favourable time to plant and harvest the various crops.

Stations have thus far been established at Baba, Barraganetal, Chobo Rocafuerte, and Tonguel.

715 – **The Climate of Cyrenaica with Special Reference to its Influence in the Cultivation of Cereals.** — MONTI, G., in *L'Italia agricola*, Year VI, No. 11, pp. 325-330, 5 plates. Piacenza, Nov., 1919.

There are 2 winds of special importance with regard to the cultivation of cereals : one beneficial the other injurious, namely, the north west wind fresh and wet, and the " ghibli " or desert wind which blows from the south. The strong winds of the south begin to blow in October and cease

in June, thus accompanying the entire vegetative growth of the cereals. They are most injurious during the months of April and May, especially in the latter half of May, because this period exactly corresponds with that of the formation of the grain, just when the plant requires a maximum of nourishment. The " ghibli " is a great obstacle to nutrition and, consequently, to the formation of the grain becauses it increases evaporation from the soil as well as transpiration, but it keeps the atmosphere dry and thus prevents the development of fungoid disease. Rust is almost unknown in Cyrenaica except at the bottom of some excessively damp valleys.

The north-west winds blow all the year round and their action is particularly favourable in the spring, when they prevail over the south wind and refresh the air, causing a fall in the temperature and increasing the moisture in the atmosphere, thereby avoiding the danger of scorching.

Temperature. — The average annual maximum temperature is 21.60° C and the average annual minimum temperature is 11.48° C, so that the average annual thermometrical variation is about 10° C. It can be affirmed that the difference between the day and night temperature is rarely more than 10° C ; the climate is then, strictly Mediterranean in type. The maximum temperatures occur in the months of June, July and August and it is exceptional for the thermometer to exceed 40° C. The minimum temperatures occur in February ; it is very unusual for the thermometer to fall to zero. During 4 years' observations the lowest temperature reached was + 1° C.

The following are the average temperatures, for each month in the year : — January, 8.71° ; February, 9.47° ; March, 12° ; April, 16° ; May, 18.12° ; June, 23.83° ; July, 24.60° ; August, 23° ; September, 17° ; October 14° ; and December, 11.23°. The important time for sowing is between the end of October and the end of December. Germination is rapid and during the succeeding months, vegetative development never stops. The month of January, with an average low temperature, greatly favours tillering ; March and April have temperatures which favour amazingly first the vegetative growth and then the inflorescence. May with its average of 18° C favours slow ripening in the hot weather of early June. It can therefore be concluded that the climate, as regards temperature, is very favourable to the development of all autumn and spring crops and, consequently, to production of cereals.

Light. — Generally speaking the sky is very brilliant and it is very rare to have the sky overcast for the whole day, whilst fogs are almost unknown. The months of December, January and February, have the greatest number of dull days ; the months with the largest number of fine days are May, June and July. Taking an average of 100 days, in one year there are : — 17 % dull days, 42.20 % cloudy days and 40.50 % fine days. From this point of view also, the conditions are excellent for the development of the chlorophyl tissue. The light is intense especially in the spring when the plants reach their highest point of development.

Atmospheric precipitations. — Snow and hail are unknown and sleet falls only on very exceptional days, melting as soon as it reaches the ground. Rains are usually frequent and, what is most important, well distributed. From observations taken during 3 years and reliable information it appears that rain falls from October to the beginning of May. In October and November the fall is slight but sufficient for the germination, of the seed. The rainfall for the whole of 1917 was 25.2 in. The rainfall during the period of growth of cereals from October, 1916, to May, 1917, was 14.3 in., and the rainfall during the growth period of cereals from October, 1917, to May, 1918, was 25.9 in. From observations extending over 3 years the following average data vere obtained for atmospheric precipitations during the growth period of cereals: —September *nil*; October 2.1 in.; November 1.2 in.; December 3.3 in.; January 3.3 in.; February 2.9 in.; March 2.7 in.; April 0.65 in.; May 1.2 in.; June, *nil*. Torrential rains seldom occur and the rain falls gently, often accompanied by wind. From certain information it can be concluded that, during a period of 10 years, it is possible to count on 4 wet years with more than 19.5 in., on 4 years with an average rainfall of 11.7 in. to 19.5 in., and on 2 dry years with less than 11.7 in.

Sowing time and meteorological conditions. — The following are the returns for barley.

Growth Period	Harvest time	Cwt. per acre	
		Grain	Straw
End of November	May 10	11.23	18.37
Mid December	May 20	9.08	13.27
December	June 10	4.1	7.9
January	June 10	2.65	2.65

These data show clearly (if the factors of labour, quantity of seeds method of sowing remain the same) that the crops obtained, both for whea and barley, are directly related to the period of sowing; if the seed is sow early, the harvest is earlier and the yield is considerably larger.

These data therefore indicate early sowing; indeed it is obvious tha it must be so, because in zones where there is not much rain, and where at the end of April it ceases entirely, every effort must be made for th cereals to ripen, soon after the first fortnight in June for wheat, and si milarly in May for barley. If the ripening process takes place withi these limits there will always be sufficient moisture in the soil to nouris the seeds. The best season for sowing is from October onwards, as soo as the ground is soft (rain penetrates to about 10 cm. in compact soils until the end of December.

716 - **The Climate of California and its Effect on the Growth of Fruit Trees and Vines.** — WICKSON, E. J., in *The California Fruits and How to Grow Them*, pp. 9-24, San Francisco, 1919.

The chief characteristics of the Californian climate are :— freedom from extremes of low temperature ; an abundance of sunshine ; an atmosphere with a low percentage of humidity.

THE FUNCTION OF HEAT IN FRUIT PRODUCTION. — The temperature conditions may preclude the success of a fruit tree either by destroying it outright, by dwarfing it, or by preventing it from setting or ripening its fruit. Extremes of temperatures may lead to the death of plants, whilst insufficient or excessive mean temperatures may prevent the formation of fruit without killing the plant.

The following figures indicate the lowest temperatures in several Californian localities (coast and coast valleys, interior valleys, and foothills) :

(1) *Coast and Coast Valleys :* — Eureka 11.1° C ; Ukiah 6.6° ; Cloverdale 9.4° ; Napa 10.0° ; San Francisco 6.1° ; San José 10° ; Gilroy 11.1° ; San Miguel 6.1° ; Los Angelos 15° ; San Diego 13.3°.

(2) *Interior Valleys :* — Redding 10° C ; Red Bluff 10° ; Oroville 8.3° ; Marysville 10.5° ; Sacramento 10.5° ; Merced 8.8° ; Fresno 9.4° ; Tulare City 10° ; Colton 10.5° ; Imperial 11.1°.

3) *Foothills :* Nevada City 2.2° ; Colfax 4.4° ; Auburn 6.6° ; Jackson 5.5° ; Porterville 10° ; Redlands 10°.

In cannot be said that in any region of California there is any reason therefore to fear winter killing of fruit trees. The absence of extremes of temperature, and the very long growing season combined with the summer heat are sufficent to ensure uniform ripening of the grape, a fruit very exacting in respect of temperature.

BOUSSINGAULT has shown that there should be a month at least, the mean temperature of which does not fall below 19° C, to ensure a thorough ripening of the grapes. In California, this temperature is maintained throughout the whole summer instead of lasting only 1 month.

TABLE I. — *Average Summer Temperature in California.*

Coast and Coast Valleys	Temperature °C.	Interior Valleys	Temperature °C.	Foothills	Temperature °C.
Upper Lake.	30°.0	Redding	26°.6	Auburn	23°.8
Napa.	18°.3	Oroville	26°,1	Colfax	23°.6
Livermore	20°.5	Marysville	25°.5	Georgetown.	29°.4
San José.	19°.4	Sacramento. . . .	22°.2	Caliente	27°.7
Hollister	18°.8	Merced.	26°.1	Fall Brook	20°,0
Santa Barbara . . .	18°.3	Fresno.	26°.1	Redlands.	25°.0
Los Angelos	21°.1	Tulare.	25°.5	San Bernardino. . .	23°.6
San Diego	20°.0	Riverside.	22°.7	San Jacinto	23°.6

High temperatures are accompanied by slight cloudiness, and, consequently, an abundance of sunshine, which is essential for the normal ripening of fruit. Table II gives the data for the normal cloudiness in California, rated from 0 to 10.

An interesting comparison may be made between these and the data referring to the eastern regions of the United States, where fruit growing is much less developed, and where vines are limited to small areas favourable to cultivation for topographical and hydrographical reasons (see. Table III).

TABLE II. — *Normal Cloudiness in California.*

	March	April	May	June	July	Aug.	Sept	Oct.	Nov.	Average for 9 months
Red Bluff.	4.4	4.2	3.6	1.9	1.0	0.7	1,3	2 4	3.4	2 5
Sacramento	3.9	3.5	2.7	1.5	0.5	0.4	1.1	2.0	2.8	2.0
San Francisco.	4.8	4.3	4.2	3.8	4,3	4.8	3.5	3.3	3.8	4.0
Fresno	4.3	2.9	2.7	1.5	0.7	0.9	1.4	2.2	2.8	2.2
San Diego	4,8	4.4	5.3	4,8	4.3	3.9	3.7	3.8	3,3	4.3

TABLE III. — *Normal Cloudiness in Eastern United States.*

Mese	March	April	May	June	July	Aug.	Sept.	Oct.	Nov.	Average for 9 months
Rochester, N. Y. . . .	6.6	5.4	5.2	4.9	4.6	4.6	4,9	6.0	7.6	5.5
New York, N. Y. . . .	5.5	5.3	5.2	4.9	5.0	4.9	4.7	4.9	5.2	5.1
Philadelphia, Pa. . . .	5.6	5,4	5.1	5.0	5.0	4.9	4,8	4.7	5.2	5.1
Baltimore, Md.	5.4	5.1	5.1	4.9	4.8	4.9	4.7	4.6	4.9	4.9
Cleveland, Ohio.. . . .	6.4	5.3	4,9	4.6	4.3	4.3	4.9	5.7	7.3	5.3
Grand Haven, Mich. . .	6,2	5.4	4.8	4.6	3.8	4.0	4.4	5.6	7.3	5.1
Jacksonville, Ha. . . .	4.2	4,1	4.1	5.1	4.8	4.9	5.0	4.2	4.5	4.5
New Orleans, La. . . .	4.8	4.8	4.3	4.7	4.9	4.7	4.3	3.5	4.5	4.5

It is noticeable that at the coastal points of California, the average cloudiness is almost twice that of the interior valleys, whilst in the east of the Rocky Mountains the opposite is evident, that is the interior regions of Western New York, Ohio, and Michigan have a greater cloudiness than the Hudson River, New Jersey and Delaware regions near the Atlantic sea board.

ATMOSPHERIC HUMIDITY. — Water vapour combined with high temperature favours the development of fungoid disease. But in California the percentage of humidity is high in the winter and low in the summer; on the east of the Rocky Mnts. conditions are reversed. It follows then that fungoid disease is rarer and less serious in California. The water vapour, however, absorbs a considerable amount of light and heat, both important in the ripening of fruit. Dry air is therefore more favourable to ripening.

TABLE IV. — *Normal relative humidity at certain Stations in California.*

	April	May	June	July	August	Sept.	October	Nov.	Average Apr.-Nov.
Los Angeles . . .	73.1	75.2	73.6	75.4	76.2	72.9	74.3	66.6	73.7
Fresno	59.3	52.7	42.4	34.7	34.7	43.6	55.1	64.1	48.3
Sacramento . . .	67.6	67.6	66.1	59.8	59.8	59.0	62.4	66.8	63.6
Red Bluff	61.9	56.8	43.7	35.6	35.3	43.6	51.6	60.7	48.6

An interesting comparison is made with the Eastern and Southern States where fruit cultivation in practised to the same extent.

TABLE V. — *Normal Relative Humidity in Eastern and Southern States.*

	April	May	June	July	August	Sept.	October	Nov.	Average April-Nov.
Jacksonville, Ha . .	72,3	73,0	77,6	78,6	80,9	82,9	79,8	82,2	78,4
Philadelphia, Pa . .	63,4	68,9	69,2	68,6	71,2	75,2	70,7	73,6	70,1
Rochester, N-Y . .	67,8	68,6	69,1	67,3	70,7	75,2	75,6	76,2	71,3
Grand Haven, Mich. .	70,9	71,4	73,7	69,0	73,1	75,0	75,7	79,1	73,5
St.-Louis, M.	63,7	67,8	68,8	66,3	67,3	70,2	65,9	71,1	67,6
New Orleans, La. . .	76,0	74,2	78,1	78,3	78,8	77,3	74,0	79,4	77,0
Galveston, Texas . .	84,6	78,0	79,0	77,4	78,1	77,2	75,6	80,4	78,8

In California, the constant high temperature, continuous sunshine and dry air, taken in connection with the soil fertility, and the length of season without frosts, ensures early and well formed fruits and abundant fruit crops from both trees and vines.

717 - **Effect of Temperature on the Geographical Distribution of Different Species of *Opuntia*.** — UPHOF, J. C. T., in *The Journal of Ecology*, Vol. VIII, No. 1, pp. 41-53 pl. 1, figs. 6. London, March, 1920.

The results of a study of the various degrees of resistance to cold of different species of cacti, growing in the desert of Arizona. The laboratory work was done in the Department of Botany of the University of Arizona, and the field observations were conducted in the deserts and mountain regions of Southern Arizona, especially in the vicinity of Tucson.

It appears evident that the geographical distribution and the height at which cacti being entirely adapted to a dry climate are found, is mainly dependent upon the resistance to cold of each particular species.

The vertical distribution of *Opuntia* spp. depends entirely upon the minimum temperature in winter. Some specimens taken from the desert and planted in the environs of Mount Lemmon (2790 m.), grew well in the summer, but succumbed in winter.

A comparison is made in the following table of the absolute minimum temperatures in and near this mountain group, 1913-14 :—

Elevation in metres	Absolute min. in winter o C.	Elevation in metres	Absolute min. in winter
—	—	—	—
723	— 2.2	2100	— 7.2
1200	— 3.8	2400	— 12.5
1500	— 5.0	2700	— 12.5
1800	— 5.6		

During the winter 1912-1913, the temperature at Tucson fell as low as — 14° C., and thousands of small plants of *Carnegia gigantea* were killed, whilst old plants with thick integuments (e. g. thick cuticle, crystal bearing layer and thick walled layer) were not damaged in the least.

The following experiment was performed : — Pieces of integument were dissected and wrapped carefully round the bulb of a thermometer, put into test tubes, the openings of which were closed with plugs of cotton. These were then placed in a glass cylinder filled with crushed ice, and in this way a temperature of 0° C. was easily reached. The rapidity of penetration of the cold is dependent upon the thickness of the integument, the specimens with the thicker cuticle obviously being more resistant to cold. The following table gives a summary of the experiments :

Name of plant	Thickness of cuticle μ	Thickness of crystal bearing layer μ	Thickness of thick-celled layer μ	Average time of penetration of 0° minutes
Opuntia fulgida	10–12	25–30	90–110	—
O. arizonica	12–18	20–25	95–120	—
O. Bigelowii	12–20	18–35	85–105	—
O. mamillata	15–20	15–25	90–115	—
O. castillae	15–20	30 42	100–120	63.3
O. sp. " Burbank special "	5–8	30–30	70–87	32.6
O. ficus indica (from Malta).	5–10	30–38	55–75	35.0
O. Ellisiana.	12–15	25–25	75–130	79.3
O. fusicaulis.	10–12	20–30	87–98	38.6
O. ficus indica (from Sicily)	12 15	30–40	62–74	40.6
Carnegiea gigantea	10–25	20–42	90–145	—
Echinocactus Wislizeni	10–20	25–35	90–120	—

Since the lowest winter temperatures in the desert are generally of short duration, a cactus plant having a thick integument may pass through such a period practically uninjured, even though the temperature may be low enough to be fatal to the protoplasm. A thick integument protects the plant against sudden and severe changes of temperature at any season.

At very high elevations, or in northern climates, where severe cold is of longer duration, the integuments even if thick are of no protection to sensitive plants, so that the geographical distribution of the species is in keeping with the capacity of the protoplasm to withstand certain low

temperatures. This quality, and also the fatal temperature, varies with particular species.

The following table shows the results obtained in the author's experiments :

	Temperatures		Difference in temperature	Temperature of Surrounding air
	Plant damaged	Plant skilled outright		
	°C	°C	°C	°C
Opuntia castillae	— 14°	— 17	3	— 20
O. sp. "Burbank special"	— 6	— 8	2	— 20
O. ficus indica, Malta	— 5	— 6	1	— 20
O. Ellisiana	— 16	— 18	2	— 20
O. fusicaulis	— 8	— 10	2	— 20
O. ficus indica, Siciliy	— 5	— 8	3	— 20

The cold resisting quality of protoplasm is an hereditary physiological characteristic.

718 - **The Factors of "Light" and "Temperature" in Relation to Crop Production in Southern Italy.** — See No. 724 of this *Review*.

719 - **A New Variety of Asphodel Produced by the Action of the Marine Climate at Côtes-du-Nord, France.** — DANIEL, L., in *Comptes rendus de l'Académie des Sciences*, Vol. 170, No. 22, pp. 1332-1333. Paris, May 31, 1920.

The author has obtained remarkable modifications in *Asphodelus luteus* by growing it for 20 years in his garden at Erguy (Côtes-du-Nord), which is laid out on sand dunes covered with 80 cc. of transported vegetable mould. The original plants came from the Rennes Botanical Gardens.

The new type differs from the old one in its greener hue ; its smaller, more numerous, and thicker set leaves with their very different structure ; its thinner stalks ; its branched, longer and looser inflorescences ; later flowering ; the shape and small size of its fruits and seeds ; etc.

The new form retains its acquired characters whether propagated by cuttings or seeds. *A. luteus* is a southern plant, which so far as the author knows, has hitherto produced no new varieties when cultivated in gardens.

720 - **The Colloidal Function in the Soil and the Characteristics Depending Upon it.** — PRATOLONGO, U. (Laboratorio di Chimica Agraria della R. Scuola Sup. di Agricoltura di Milano), in *Stazioni Sperimentali Agrarie Italiane*, vol. LIII, Parts 1, 2 and 3, pp. 5-2, 2 diagrams, bibliography. Modena, 1920.

SOIL PHYSICS, CHEMISTRY AND MICROBIOLOGY

The problem of the analytical determination of the sum of the colloidal constituents in the soil has arisen on account of the growing importance assigned to them. It will, however, remain entirely unsolved until the definition of the colloidal function upon which it necessarily depends is ascertained. Previous investigations by the author have shown that there is a simple proportion between the water content of the soil marked by VAN BEMMELEN's critical point (*écart critique*) in the vapour-tension curve, and the

amount of water present in the soil when the phenomena of wilting commence. Hence, it is of interest to determine the relations existing between this critical point and the data obtained by the physico-mechical analysis of the soil, using an easy and rapid method of determining the critical point. Having duly accomplished this, the author attempted to determine the effect produced upon the position of VAN BEMMELEN'S critical point of certain physical operations to which the soil is usually subjected. The experiments were made upon 12 soils, some coming from Argentina, and others from different parts of Italy.

The comparisons made between the data obtained by physico-mechanical soil analysis, whether carried out in the ordinary manner, or by the author's more accurate and complete densimetric method, and the results obtained by the above-mentioned method of investigation, revealed no relation of dependence upon the physico-mechanical constitution, as it is usually defined. On the other hand, the data furnished by this method, and taken as giving the colloidal content of the soil, clearly revealed a sensitivity to ordinary physical and chemical action (heating, freezing, etc.) which no other characteristic had hitherto attained ; these data thus represent, in an equally distinct manner, the variations, which from an agricultural point of view, are brought about on soils by this action.

The results obtained, and the deductions drawn from them, therefore, allow us to assign a scientific and practical value to VAN BEMMELEN'S critical point which has proved itself worth further study. The behaviour of the isotherm of vapour tension on the soil, which is a function of its colloidal content, is another soil characteristic that is important from the agricultural standpoint.

TILLAGE AND METHODS OF CULTIVATION

721 – **The Use of Explosives for Breaking Up the Land in the Province of Lecce, Italy** (1). — MANNARINI, A., in *I Campi*, Year III, No. 16, p. 2. Rome, April 18, 1920.

The results of some experiments on breaking up land by means of explosives in the Province of Lecce.

Mines with a charge of 300 gm. were drilled at a depth of 60 cm. in squares, 1.30 metres apart, in a heavy deep soil. The effect of the explosion of these mines was to break up the ground completely to the depth of from 80 to 90 cm. The radius affected, in the case of one isolated mine, was nearly 95 cm. In the central portion, the soil was reduced to small fragments ; towards the periphery, great clods were detached. At a distance exceeding 95 cm., there were many, deep, radial cracks in the ground with a maximum depth of 3 m.

In an experiment carried out at Ostuni, in compact calcareous soil, with a sub-soil of solid rock, a series of mines with a charge of 300 gm. was laid at a depth of 60 cm., the mines being 1.50 metres apart. The rock was entirely reduced to minute particles, and where the ground had offered greater resistance, there were deeper and more distinct radial cracks.

(1) See *R.*, 1911, Nos. 2259, 3135 ; 1912, Nos. 671, 777, 1398 ; 1913, No. 230 ; 1914, No. 1092 ;1917, Nos. 107, 1000 ; 1919, Nos. 19, 685, 821, 1091 ; 1920, No. 494. (*Ed.*)

The third experiment was made in shallow soil with a sub-soil of Lecce stone ; the holes were drilled 2 m. apart, and to a depth of 55 to 60 cm., the charges used being about 300 gm. The results of the explosion of an isolated mine were as follows : — For a radius of 40 cm. around the centre, the rock was blown to fragments ; between 40 and 90 cm. from the centre, there was a ring of shattered rock, great splinters and masses having been torn off ; beyond 90 cm., the rock was traversed in all directions by cracks splitting it up into polyhedric masses with sides from 15 to 20 cm. long. At a greater distance from the centre, large radial cracks appeared that were longer and wider than those produced in the other soils, perhaps because the rock was less hard. Where a series of mines had been exploded, although the interval between each was somewhat large, the rock was shattered, there being a quantity of minute fragments, few large blocks, and numerous cracks.

The fourth experiment was made on shallow soils with a tuff subsoil ; the results obtained were almost identical with those of the third experiment.

The cost of a charge of 300 gm. of explosive is in centimes, as follows : — Explosive 12 ; detonators 7 ; 1 m. fuse 7 ; priming 5 ; string and paper 5 ; total 36. This method would not be economical for hand-drilled mines. It would be necessary to use perforating machines, or mechanical drills capable of making 200 to 300 drills 70 cm. in depth daily. Landowners should form themselves into a *consortium* for the purchase and working of these machines.

722 – **Sulphuric Acid and Fertilisers.** — BAUMANN, in the *Chemiker Zeitung*, Year XLIV, No. 55, pp. 346-347. Köthen, May 6, 1920.

MANURES AND MANURING

The present scarcity of the raw materials required by the chemical industry naturally gives rise to restrictive measures, so that the riches of the soil have to be used with more foresight now, than before the war. A typical example of this is afforded by the sulphur and pyrites employed in the manufacture of sulphuric acid. The author has devoted his attention to the use of sulphuric acid in the production of the two main classes of chemical products, viz., phosphatic, and nitrigenous compounds. On the occasion of the celebration of the 25th. Anniversary of the Union of German Fertiliser Manufacturers, on Jan. 26, 1905, attention had already been called to the great problem, still unsolved, of the fertiliser industry and the dry treatment of phosphates without acids with a view to rendering them more available. Although the full economic importance of the question was not then realised, nevertheless experiments were undertaken for the purpose of partially, or wholly eliminating the use of sulphuric acid in the phosphatic fertiliser industry.

From the statistics on fertilisers published by the INTERNATIONAL INSTITUTE OF AGRICULTURE (1), it is possible to calculate the pre-war

(1) See : *World Production and Consumption of Chemical Fertilisers* : 2nd Edition 1914 — *International Trade* in Fertilisers and Other Chemical Products Used in Agriculture. Nos. 1 etc. Published by the International Institute of Agriculture. (*Ed.*)

consumption of sulphuric acid in the production of the above-mentioned class of fertilisers as follows:—

	Metric tons
World production of sulphuric acid	5 000 000
European » » »	3 700 000
World production of superphosphate	7 500 000
Corresponding world consumption of sulphuric acid	3 000 000
European production of superphosphate	5 600 000
Corresponding European consumption of sulphuric acid	2 240 000
World production of sulphate of ammonia	1 057 000
Corresponding world consumption of sulphuric acid	793 000
European production of sulphate of ammonia	941 000
Corresponding European consumption of sulphuric acid	710 000
Percentage of the world production of sulphuric acid used for superphosphate	60 %
Idem of the European consumption	65 %
Idem of the world production used for sulphate of ammonia	16 %
Idem of the European production	19 %

These figures show that $^3/_4$ of the world production of sulphuric acid is completely lost in the soil, when either superphospate or sulphate of ammonia are used, and at the present moment, we have no right to waste such an enormous quantity of sulphuric acid.

AGRICULTURAL BOTANY, CHEMISTRY AND PHYSIOLOGY OF PLANTS

723 – **The Composition of "Betratra" Cake Used as a Fertiliser.** — See No. 753 of this *Review*.

724 – **Biological Factors Affecting the Yield of Agricultural Crops in Southern Italy.** — RIVERA, V. (Memoria della R. Stazione di Patologia vegetale), in *Rivista di Biologia*, Vol. II, Part. II, pp. 22 Bibliography, 1 Plate, Rome, 1920.

In preceding articles, the author has briefly treated of the problem of the low yields produced by herbaceous crops in the southern regions of Italy (1). He now publishes the results of his recent investigations as to the influence of light and temperature in an environment like that prevailing in South Italy. As the data are based on laboratory experiments, they are not entirely applicable to ordinary field crops, but they prove that, while a high temperature produces an acceleration of growth, light has a very pronounced effect upon the accumulation of carbohydrates.

Of the two factors "intensity of light", and "duration of illumination," the second is the more important. It would even appear justifiable to state that, under natural conditions, excessive light does not promote the growth and activity of the green organs of many plants; on the contrary, the plant which grows both during the hours of sunlight and in darkness, regulates its development according to the number of hours of light it enjoys. The height, weight, and the amount of starch accumulated depend upon the number of hours of light, whereas the temperature influences the age of a plant. To be more definite the chief effect of a high temperature is to shorten the growth period, while longer illumination acts principally upon the formation of plant substance.

(1) See, *R.*, March, 1920, No. 304. (*Ed.*)

Productivity is thus closely connected with these two factors, the first (a very high temperature) shortening the period of photosynthetic activity, and the second (longer illumination) lengthening it. In a climate like that of southern Italy, both these factors concur in shortening the period during which photosynthesis can take place.

The problem of agricultural yield in southern Italy is principally a biological one, since the chief factors affecting the yield depend upon physical and meteorological causes, which if they produce a structure better suited to the environment, give rise to functional changes in the plant that are unfavourable to the production of heavy yields.

The cause of low yields must principally be sought for in the obstacles that the plant encounters during its life, and chiefly during the period that terminates its assimilating activity. The plant is a living laboratory, and the larger the total of work accomplished, the more it produces, accumulates, and increases in size. In the balancing of profit and loss that closes with the ripening the seed, the total results of the work which depend upon its intensity and duration are, when the accounts are made up, of the greatest importance. In the centre of southern Italy, intense work would, as a rule, be hindered by the brilliant light and high temperature, whilst the duration of the work is shorter owing to the longer nights. The working hours at the disposal of a plant growing in northern countries are usually much longer, although in these latitudes, the growth period tends to decrease. In the southern regions of Italy, the theoretical duration of the work, as far as it can be calculated from the hours of sunshine, is decreased by more frequent and longer periods of inactivity during the light. In regions of intense light and heat, the assimilation curve of wheat drops suddenly after midday. Whether this is directly due to too prolonged an exposure to intense light, or to an excessive acceleration of transpiration (though the plant protects itself against this by closing the ostioles of the stomata thus greatly reducing photosynthesis), or whether it is due to both these causes combined and also to the heat, it has the same effect, namely that for several hours of the day, in May and especially in June, no photosynthesis takes place. These hours must be regarded as representing the debit side of the plants budget, for what it loses by respiration is not balanced by a corresponding amount of assimilation, or by the absorption of sufficient food substances from the soil.

The injury caused by the dryness of the air or soil, when not such as to occasion the death of the tissues, is chiefly due to the same causes namely, the suppression of transpiration, and consequently the cessation of photosynthesis owing to the diminution, for a longer or shorter period, of the turgidity of the leaves. The fact that plants which have been liberally manured, especially with nitrogenous salts, or have been reared with copious supplies of water, wilt more easily, and thus produce lighter crops than unmanured plants in dry years, is also due the above-mentioned causes. This may be explained by the fact that the nutritive salts and the constant and abundant water supply produce tissues of less consistency and encourage a luxuriant development of leaf surface, thus increasing

transpiration and evaporation. The loss of water sustained in this way is not compensated for by a corresponding developement of the absorptive surfaces of the root.

While admitting a loss of profit due to this suspension of work, we do not in any way exclude the possibility that, owing to the suspension of the activity of the chlorophyll, it may produce indirect injury (scorching) to the general economy of the plant, especially at critical periods, such as flowering and setting. In this case, the suspension of assimilation becomes pathological, and the sign of a serious disorder affecting the most important functions of the plant's vegetative and reproductive life.

From what has already been said, it is clear that the problem of the low yield of wheat in southern Italy does not only depend on cultural, economic, and social factors, but also upon more or less serious functional disturbances of the photosynthetic activity of the plant ; therefore it ought first of all to be studied from the biological standpoint. The only means by which large yields can be obtained from these regions, even in the case of herbaceous crops, are the choice of the crops, combined with careful selection made with an eye to these difficulties, and the introduction of new species, or the creation of suitable varieties.

725 – **Observation on the Olive Flower in Italy.** — PIROTTA, R., in the *Atti della R. Accademia dei Lincei*, Fifth Series, Rendiconti, Classe di Scienze fisiche, matematiche e naturali, vol. XXVIII, 2nd. Series, Nos. 1-2, pp. 3-9. Rome, 1919.

As a result of repeated observation, the author is able to state, that the common olive tree (*Olea europaea*) bears 3 kinds of flowers : (1) Entirely monoclinal flowers with normal pistil and stamens producing fruit and seed ; (2) wholly polliniferous flowers ; (3) physiologically staminiferous flowers, that is, with normal pollen producing stamens, but with a pistil that has become abnormal by the greater or less reduction of the stigma and ovary. These three kinds of flower sometimes occur on different individuals, and there are olive-trees with monoclinal flowers (this is usually the case with cultivated trees, and those with staminiferous flowers (this type is the rarest among cultivated trees). Sometimes, on the same individual, two kinds of flowers are found, either monoclinal and physiologically staminiferous flowers, which often happens ; or monoclinal and staminiferous flowers, a much rarer occurrence.

The yield of the trees depends upon the character of its flowers ; those with monoclinal flowers are the most productive, whilst trees with monoclinal and physiologically staminiferous flowers are much less fruitful and their produce is often small, or of inferior quality, and those with little else but staminiferous flowers are almost sterile.

The staminiferous flowers of the olive, even when the pistil is much reduced, can easily be distinguished from the monoclinal kind, so that the tree bearing them, when it is in flower, differs in its whole general aspect. The inflorescences are longer, attaining ⅓ or ½, or even the total length, of the bract, whereas in the case of monoclinal flowers the inflorescences are short, and sometimes even so reduced as to be only ¼ of the

length of the bract. The inflorescences themselves are more ramified at the base, and therefore to some extent have the character of a cyme. The flowers are more numerous, the bud larger, whiter and spherical, and the fully opened flower is larger. The entire flower becomes detached and falls (whereas in monoclinal flowers, the corolla and stamens alone fall, the calyx and pistil remaining). The stamens are larger, and bear a greater quantity of yellow pollen; the pistil is either absent (the ovules also lacking) or is represented by a small central mucro.

726 – **On the Determination of the Poisonous Amanites by Means of Colour Reactions.** — BARLOT, J., in the *Comptes rendus de l'Académie des Sciences*, Vol. 170. No 11, pp. 679-851. Paris, March. 5, 1920.

I. — Amanites treated with 1 or 2 drops of aqueous solutions of bases or strong acids give a certain number of colour reactions which can be utilised in the determination of various species and, especially, to distinguish rapidly the most toxic species.

The 3 deadly poisonous Amanites react as follows :—

(1) *Amanita phalloides*, turns violet with ordinary sulphuric acid; the colour is particularly deep on the leaflets and under the epidermis. The author considers that the poison of the fungus takes part in this reaction. According to SELMI (*Sulle ptomaine od alcaloidi cadaverici*, Bologna, 1878), the ptomaines turn violet with sulphuric acid, if the acid is used carefully.

The other species studied gave the following shades with this reagent :.

Amanita pantherina : dark brown changing gradually to brownish-purple ;

Amanita citrina : greenish brown ;

Amanita muscaria : light brown at the edge of the lamellae ;

Amanita vaginata : pale brown ;

Amanita rubescens : loses its wine coloured appearance, and becomes discoloured or very pale brown.

(2) *Amanita pantherina*, with potash solution becomes vivid orange, especially at the base and edge of the lamellae. With this reagent, the other species give the following shades :

Amanita citrina : carmine brown no the edge of the hymenium ;

Amanita muscaria, *A. phalloides*, *A. rubescens*, *A. vaginata*. : nil.

(3) *Amanita citrina*, and its var. *mappa*, becomes at once intense deep greenish brown with nitric acid.

The other species give the following shades :

— *Amanita phalloides* : nothing at first, then a fairly deep yellow truit.

Amanita junquillea, *A. muscaria*, *A. spissa*, *A. rubescens*, *A. vaginata*, nil.

II. — In addition to these reactions, which enable each species to be distinguished, the 3 deadly poisonous Amanites may be distinguished by a commion haemoreaction.

A drop of fresh blood (the author used human blood and blood from sheep) is placed on the portions of periderm and stipe and potassium ferrocyanide is added. After a few minutes, *Amanita phalloides* and *Amanita pantherina* become black; this effect is also produced with *Amanita citrina*, but less intensely. Under similar conditions, the following species were not affected : — *Amanita caesarea*, *A. muscaria*, *A. vaginata*, *A. vaginata* var. *fulva*, and *A. strangulata*.

In the case of *Amanita rubescens*, the brown coloration due to the presence of an oxidase renders it very difficult to observe the shade.

III. — The author mentions the characteristic colour reaction of *Amanita junquillea*. This edible species is scarce, but easily confused with *Amanita citrina*. It turns instantly to yellowish brown, particularly just below the epidermis when a drop of ethyl chlorostannate dissolved in alcohol is applied.

None of the following species show this reaction : — *Amanita aspera*, *A. caesarea*, *A. citrina*, *A. muscaria*, *A. muscaria* var. *formosa*, *A. pantherina*, *A. phalloides*, *A. rubescens*, *A. solitaria*, *A. spissa*, *A. strangulata*, *A. vaginata*, and *A. vaginata* var. *fulva*.

727 – **Chemical Composition of the Australian Saltbush (*Atriplex semibaccata*,)** — See N. 749 of this *Review*.

728 — **The Effect of Drying on the Germination of Cereals.** — STAPLEDON, R. G. and ADAMS, M., in *The Journal of the Board of Agriculture*, Vol. XXVI, No. 4, pp. 364-381. London, July, 1919.

During experiments conducted at the Seed Testing Station the author obseved the effect on germination ot samples of wheat, barley, rye and oats : (1) Of drying the grain for 3 days at 40° C, and (2) keeping the grain without preliminary drying, for about 3 weeks compared with another part of the same sample whose germinating capacity had been determined when first received in the laboratory. The effect of drying was also observed on seeds that had already germinated or were germinating.

The results obtained are important both from the point of view of testing cereals und " conditioning " the grain (kiln-drying before storing the grain).

There is some risk in sowing the cereals early in the autumn immediately after thrashing. In such cases it is advisable with wheat, barley and rye to kiln or air-dry the grain ; black oats should be air-dried for 2 or 3 weeks.

The results of the germination test made before drying the sample under examination, or after keeping for some weeks, resembles much more the germinating capacity in the field than that resulting from the tests made after receiving the sample.

729 — **Formaldehyde Treatment of Maize Seed.** — RICHEY, F. D., in *The Journal of the American Society of Agronomy*, Vol. XII, No. 1, pp. 39-43. Washington, D. C., Jan., 1920.

The author observed the effect on the germination of maize seed, of treatment with formaldehyde solutions of different strengths and for different periods, with a view to preventing the growth of fungi on seedlings grown in water cultures. Samples were tested for germination both in water cultures and in sand. Treatment of maize with solutions of 5, 15 and 25 cc. of formaldehyde per litre materially reduced the development of the seedlings grown in water culture. The vitality of the seed, as evidenced by the development of the seedlings in either water culture or sand, was not affected by treatment with a solution of 5 cc. of formaldehyde per litre. Treatment with the solution of 15 cc. off ormaldehyde per litre did not

materially affect the seedlings grown in water culture, but nevertheless was injurious to germination and development in sand. Treatment with 25 cc. per litre was markedly injurious. Soaking maize for 2 hours in a solution of 5 cc. formaldehyde in 995 cc. of water, followed by a fumigation period from 2 to 24 hours in length, can therefore be recommended for checking the development of fungi, without interfering with the normal development of seedlings in water cultures.

730 – **Germination of Seed of *Tilia, Sambucus* and *Rubus*.** — Rose, R. C., in *The Botanical Gazette*, Vol. LXVII, No. 4, pp. 281-308, bibliogr. of 25 works. Chicago, Illinois, April, 1919.

The author attempted to determine the conditions favouring the afterripening and germination of the seeds of *Tilia americana*, *Sambucus canadensis*, and *Rubus Idaeus*, and some of the chemical processes involved therein. Air-dried seeds planted in the soil over winter give a low percentage of germination, and do not germinate if placed on a moist substratum at room temperature. Water absorption does not therefore seem to be the limiting factor for seed germination.

731 – **Response of Citrus Seedlings in Water Cultures to Salts and Organic Extracts.** — Breazeale, J. F., in the *Journal of Agricultural Research*, Vol. XVIII, No. 5, pp. 267-274, pl. 2. Washington, D. C., Dec. 1, 1919.

The experiments described were carried out mainly at Riverside, California, in connection with other investigations relating to the causes of the malnutrition of citrus plants. Lemon, grapefruit and several varieties of orange seedlings were grown in water cultures, to which was added solutions of various salts or organic matter.

Seedlings of various citrus stocks showed no characteristic differences in response to water cultures or in resistance to toxic solutions.

Very dilute extracts of organic matter from upland peat (10 parts per million or more) produced a marked stimulative effect on the root growth of citrus seedlings. Corresponding concentrations of sodium nitrate or potassium chloride did not stimulate the root development. Calcium carbonate stimulated the root growth and exerted a pronounced antagonistic action to toxic solutions of nitrates and ammonium sulphate. Peat extracts in very dilute concentration (20 parts per million), and calcium carbonate, both protected citrus seedlings to a marked degree against the toxins of distilled water.

The tolerance of citrus seedlings to alkaline salts is relatively high. The toxic limit for calcium hydrate was 100 to 120 parts per million, for sodium hydrate 250 to 300 parts per million, and for sodium carbonate 550 to 600 parts per million. When soluble organic matter (which is acid in reaction, and stimulating to citrus seedlings) in concentrations of 1000 parts per million or more, is added to a sodium carbonate solution of 400 parts per million, which in itself is toxic, a highly toxic solution is formed which kills the root tips of citrus seedlings. This reaction appears to be of practical importance in connection with the toxicity of soils containing small amounts of sodium carbonate.

PLANT BREEDING

732 - **The "Ardito" Wheat, Obtained by Hybridisation, in Italy.** — STRAMPELLI N., in *L'Italia agricola*, Year 57, No. 6, p. 177, 1 pl. Piacenza, June 15, 1920.

This new variety of wheat was obtained by the author at the Cereal Experiment Station at Rieti. It was derived from the cross Tarwe × Rieti which gives an excellent yield but ripens exceedingly late, after hybridisation with the a Japanese wheat « Akagomughi », of no cultural value, but very early. It has the following characters :

Ears red, with an average density of 26, and a number of fertile spikelets varying between a minimum of 18 and a maximum of 22 (average 20)

Spikelets bearing 4 to 5 fertile flowers ; the average number of caryopses per ear is 65 to 70, with a maximum of 75 and a minimum of 50.

Glumes oval, with pronounced keel with a red tip, principal vein and secondary veins, with reddish brown edges.

Palea, oval, lanceolate, edge reddish brown, beards of varying lengths increasing in size from the bottom of the ear (3, 5, 10, 15 mm.) to the tip, (45 or 50 mm).

Caryopses, fine reddish colour, varying in size and shape according to their position on the ear, but inclined to be oval and slightly inflated, lobes round in section, and concave ventrally. Average length 6.3 mm, average breadth to 3.3 mm, dorso-ventral diameter 2.8 to 3 mm.

Endosperm starchy. Weight of 1000 grains 35. 40 gm, weight per hectolitre 79 kg.

Stalks strong, barely 80 cm. in height.

Maturity very early ; in 1917, harvested on June 17 ; in 1918 (sown on the hillside, southern exposure, clay soil,, harvested on June 8 ; in 1919, cultivated on the cool plains, it was ripe on June 30, whilst Rieti, could not be harvested before July 15.

Yield. The last crop gave more than 24.49 cwt. per acre. This wheat must be sown somewhat thickly.

733 - **The Production of Wheat for the Highlands of British East Africa by Hybridisation and Selection.** — DOWSON, W. J., in *Bulletin No. 4, Department of Agriculture Nairobi, British East Africa*, pp. 1-16. Nairobi, 1919.

The principal object in selection consists in the production of a strain of wheat with a good yield and at the same time resistant to various rust fungi (black stem rust = *Puccinia Graminis*; yellow rust *P. glumarium* ; brown or leaf rust *P. triticina.*)

The most promising variety from the point of view of resistance to rust, found on Lord Delameres estate, was the Italian wheat Rieti, and this subsequently constituted one of the parents for hybridisation experiments later on.

In 1910-12, both at the Government Experimental Farm, Kabete, near Nairobi and also at Lord Delamere's estate, the following crosses were made :

No. 1, Rieti × Bobs (Australian).
No. 2, Rieti × Gluyas (»).
No. 3, Rieti × Australian

No. 4, Rieti × Thew (Australian).
No. 5, Egyptian No. 3 × Thew.
No. 6, » No. 1 × »
No. 7, » No. 4 × »
No. 8, » No. 2 × »
No. 9, Rieti × Federation.
No. 10, Early Rieti × Thew.

Rieti wheat was selected because of its resistance to all the forms of rust. It was also discovered that the Egyptian wheats exhibited a high resistance to *Puccinia Graminis* but were occasionally susceptible to *P. glumarum.*

The other parents, although not be relied upon to withstand rust, possessed on the other hand further outstanding qualities such as good quality grain, stiff straw, beardless ears, etc.

During the season January to February 1911, the following crosses were made at Kabete:

No. 11, Rieti × Red Fife:
No. 12, Egyptian No. 3 × Yellow Fife.
No. 13, » No. 3 × Nut Cut (Australian).
No. 14, » No. 3 × Moulds.
No. 15, » No. 3 × Thew.
No. 16, » No. 4 × Thew.
No. 17, Early Rieti × Moulds.
No. 18, Early Rieti × Chinese White.
No. 19, Red Fife × Golden Ball.
No. 20, Early Rieti × Bobs.

The results obtained were encouraging and justify better hope for the future. Even now this work demands a special officer, who shall devote his whole time to the problem of plant breeding in general, in addition to experimental work with wheat.

A recent cross between the Canadian wheat Marquis and one of the best selections of the cross No. 11 (Rieti × Red Fife) gives very promising results.

Of the 20 and more hybrids originally created, only some 5 or 6 have proved really resistant to rust, and at the same time fair croppers of good milling grain.

The following is a list of selections from the most satisfactory hybrids thus obtained:

1) Selections from hybrid No. 4 (Rieti × Thew).
2) » » » No. 10 (Early Rieti × Thew).
3) » » » No. 11 (Rieti × Red Fife).
4) » » » No. 12 (Egyptian No. 3 × Yellow Fife).
5) » » » No. 13 (Egyptian No. 3 × Nut Cut).

Some of these hybrids have already been grown on a large scale and with success in a considerable number of districts: Machakos (Athi River) Nyeri, Thika, Nairobi, Nakuru, Molo, Uasin Gishu and Trans-Nzoia.

734 – **Inheritance of Waxy Endosperm Aleurone Colour, and the Correlation between Endosperm Texture and Aleurone Colour of Maize.** — KEMPTON, J. H., in the *U. S. Department of Agriculture Bulletin of Plant Industry, Bulletin* No. 754, pp. 1-9, figs. 14, bibliogr. of 16 works. Washington, D. C., June 26, 1919.

In 1908 Mr. G. G. COLLINS found in a variety of maize imported from China, a new type of endosperm which was entirely different from any others previously known.

The 3 types already recognised are horny, starchy, and sweet. The cut surface of the endosperm of the Chinese variety resembled a hard wax, and the texture was therefore designated cereous (waxy).

This waxy endosperm was found to be alternative to horny endosperm, behaving as a definite recessive character, no blending or intermediate stages having been found, which simplifies the observations and studies on inheritance and the behaviour of Mendelian characters.

This bulletin reports the results of a series of investigations on ; (1) The inheritance of waxy endosperm ; (2) the inheritance of aleurone colour ; (3) the correlation between endosperm texture and aleurone ; (4) the correlation between endosperm texture and aleurone colour. Crosses were made between the waxy maize and an Algerian variety of maize with a horny endosperm.

INHERITANCE OF WAXY ENDOSPERM. — In 1911, crosses were made between the Algerian var (horny) ♀ × Chinese var. (waxy) ♂ giving the hybrid Dh 237, and between the Chinese var. (waxy) ♀ × Algerian var. (horny) ♂, giving the hybrid Dh 234.

In each case, in the F_1 it was evident that the horny character was dominant. The F_2, resulted in a monohybrid, in the ratio horny : waxy = 3 : 1. A fact of considerable importance should be observed, namely, that the deficiency in the waxy character, although negligible is constant, and could not be considered as due to chance or to calculative error. In the F_2, for example, instead of 25 % with waxy endosperm, the mean percentage for F_1 and F_2 is 23.9, showing a deviation of 1.1 %.

The reciprocal crosses clearly indicated that, in some cases, the percentage of male gametes bearing the waxy character was below that expected. It has not been possible so far to determine whether this observed deficiency is due to a higher death rate, reduced vigour, or a failure of equal segregation.

INHERITANCE OF ALEURONE COLOUR. — The Chinese variety possesses white aleurone, and the African variety coloured aleurone. Two and possibly more factors are concerned in the production of the latter character. The percentage of white seeds obtained in the F_2 of the hybrid Dh 234 showed that the aleurone colour of this hybrid behaved as a unit character ; approximating 25 % white. The F_2 of hybrid Dh 237 on the contrary, fell into two individual groups ; approximately half the plants having a monohybrid and the other half a dihybrid ratio.

To explain these phenomena, it is necessary to assume that aleurone colour is the result of 2 factors, which may be designated by the letters C and R. In the first cross (Dh 237), the Chinese parent had the gametic

combination **cR cR** and the African **CR CR**. When **cR**♂ fertilised **CR**♀, a coloured seed would result, and this when sown would produce the gametes **CR** and **cR**, which would give a ratio of 3 coloured to 1 white when self-pollinated. If, however, **cR**♂ is fertilised with **Cr**♀, a coloured seed would result, which when sown would produce 4 kinds of gametes, viz.; **CR**, **Cr**, **cR**, **cr**, and these when self-pollinated would result in 16 different combinations in a dihybrid ratio of 9 coloured to 7 white.

In the second cross (Dh 234) it is assumed that the Chinese parent had the gametic composition of **Cr Cr**, and the African **CR CR**. When **CR**♂ fertilised **CR**♀, a couloured seed would result, which when planted would produce the gametes **CR** and **Cr**, resulting 3 coloured to 1 white. There was deviation from this rule: F_2 gives in every case the monohybrid ratio.

An F_1 plant of the hybrd Dh 237 was pollinated with the Chinese variety, and the resulting ear had 54.17 % white, while another ear of the Dh 237 plant when self pollinated gave 25.2 % white seeds. Assuming that Dh 237 (segregating 3 coloured to 1 white) has the composition **CR cR**, a Chinese plant producing only **c R** gametes would be expected to give 50 % white when crossed with Dh 237.

The hybrid Dh 237 (**CR cR**) when self-pollinated, would give theoretically 25 % white seed (25.2 % was observed).

The Chinese hybrid (**cR**♀) would give theoretically 50 % white seed (54.17 was observed).

The white seed can therefore be classified theoretically according to the percentages, 25, 43, 75 and 50; but in reality deviations are not only constant, but although small, always, in excess of the probable error which excludes the possibility of attributing them to chance.

The 163 ears had a total of 81 366 seeds with 25 % white instead of 25.5 %; the difference of 0.5 % being given the number of the seeds involved, is almost 5 times the probable error.

For 110 ears with 47 872 seeds, 49.2 % were white instead of the expected 50 %. The deviation of 8 % is 5.10 times the probable error.

For 15 ears with 6519 seeds with 43 % white, there was a deviation of 0.75 % from the expected percentage.

The experiments confirm results previously obtained concerning the aleurone colour special. Attention should be drawn, however, to the deviation of the percentages of white seed, deviations which undonbtedly exist and which cannot be attributed to chance.

CORRELATION BETWEEN ENDOSPERM TEXTURE AND ALEURONE COLOUR. — Taking the symbol **H** for horny endosperm texture, and **h** for the waxy texture. The results of a series of analyses dealing with 17 15 seeds has led the author to discover that a correlation exists between the factor **C** (colour : see preceding paragraph) and the factor **H**. This degree of correlation has been found to be 0.762 ± 0.0057, and this may be explained by admitting that the gametes **CH** and **Ch**, instead of giving equal numbers, gave a ratio of 3 :1.

735 – **Selection of Strains of Dent Maize, Considering both Yield and Maturity, Adapted to New York State Conditions.** — MYERS, G. H., in the *Journal of the American Society Agronomy*, Vol. XII, No. 3, pp. 106-112. Washington, D. C., March, 1920.

The selection of dent maize was begun for the purpose of obtaining strains better adapted to the State of New York conditions, taking into account the qualities of yield and maturity, owing to the comparatively short growing season free from frost.

The experiments were carried out at Saratoga at an elevation of 400 ft. Here the growing season has an average length of 154 days, and the average date of the last spring frost falls on May 6, and the average date of the first autumn frost on October 7. Only the early strains of flint maize could be matured in this district in normal seasons.

Selection was made by the ear-to-row method, the seed from one ear being sown in a single row. The yielding capacity and maturity was determined for each row.

1) YIELD. — The total yield per row, as well as the individual yielding capacity were recorded. The latter was obtained by dividing the total weight in each row by the total number of eared stalks.

2) MATURITY. — At the beginning of the harvest season and at the end of the growing season, the ears were divided into two lots, ripe and unripe. The number of ripe ears was divided by the total number of ears, to give the expression which is called the "percentage of maturity."

Having determined the yield and the maturity, it was thought desirable to combine both of these expressions into a single one which should serve as a basis for selection. The author multiplied the average yield per plant by the percentage of maturity. This gave the "selection coefficient." Using the yield per row instead of the average yield per plant gave another coefficient, and this was not markedly different from the first.

The higher the selection coefficient, the greater will be the value of the corresponding line. In 1909, data from 50 rows were obtained showing a variation in the value of the selection coefficient ranging from 0.008 to 0.494.

From each row, 6 to 10 seed ears were reserved for further examination.

The following data from the comparison plot in 1911 and dealing with both selected and original seed from Illinois, are given :

Table I shows the results of 3 years' selection. The difference as shown by the yield is not striking, the average for the selected seed being 0.621 lb., while that for the original in 0.650 lb. With regard, however, to the percentage of maturity, there is a marked difference in favour of selected seed, for which the average is 71.9 while that for the original is only 13.2.

It has been found possible, therefore, to obtain a strain of dent maize which gives a good yield, and at the same time ripens sufficiently early to respond to the climatic exigences in New York State, with better success than the original variety.

TABLE I.

Row No.	Selected Seed			Row No.	Original Seed		
	Yeld per stalk	Percentage of maturity	Selection coefficient		Yield per stalk	Percentage of maturity	Selection coefficient
11	0.673	66.7	0.449	12	0.643	21.6	0.139
13	0.656	73.2	0.480	14	0.708	4.8	0.034
15	0.690	77.5	0.535	16	0.738	12.8	0.094
17	0.640	73.2	0.468	18	0.677	9.7	0.066
19	0.690	77.3	0.533	20	0.670	13.2	0.088
11^a	0.649	65.2	0.423	12^a	0.655	29.7	0.194

19^a	0.600	77.5	0.465	20^a	0.594	5.1	0.030

736 – **Inheritable Characters of Maize: Pistillate Flowered Maize Plants.** — EMERSON, R. A. (New York State College of Agriculture), in *The Journal of Heredity*, Vol. XI, No. 2, pp. 65-76, figs. 8. Washington, D. C., Feb., 1920.

At the annual "Corn Show" held at Lincoln, Nebraska, in the winter of 1913-14, a maize plant was exhibited which had an inflorescence in the form of a tassel, but bore a heavy crop of seed like a sorghum panicle:

The seeds of this specimen were sown at the Nebraska Experiment Station in the spring of 1914. All the resulting plants were normal, which may be attributed to the fact that pollen was not obtained from abnormal plants and to the recessive character of the pistillate inflorescence. One of the plants was self-pollinated and the progeny grown at Ithaca, N. Y., in 1915 consisted of both normal and abnormal plants. The normal plants were typical representatives of the rather late white dent variety cultivated in the Middle West.

The abnormality is known as "tassel seed," and, apart from the arrangement of the seeds, the inflorescence resembles in appearance the normal male terminal inflorescences.

The "tassel seed" is designated by the symbol **ts**, its dominant normal allelmorph being **Ts**.

In 1914, several plants of the variety "Pride of the North" were self-pollinated, and one of these gave progeny consisting of both normal and abnormal plants, the latter having pistillate-flowered tassels. In this case, also similar to the preceding one, the abnormality is inherited as a recessive.

The abnormality of Pride of the North is called "tassel ear" because of the ear-like form of the tassel, and is designated by the genetic symbol **te**, the dominant allelmorph being **Te**.

These two examples, although apparently identical, are as will be seen later, extremely divergent in character.

The F_2 progenies of the tassel-seed specimen gave a total of 238 normal to 67 abnormal, which corresponds with the mendelian monohybrid

ratio 3 : 1. When F_1 individuals were crossed with the abnormal parent there resulted 368 normal and 381 abnormal (1 : 1). It is evident that the two types differentiated from normal by the single factor pair : **Ts ts**.

Tassel-ear plants crossed with normals gave 24 normal plants in F_1, and 260 normal to 36 abnormal in F_2. This is too great a deviation from a 3 : 1 ratio to be due to chance. The possibility is at once suggested that the two types differ by one factor pair, and in others by two pairs hence the 15 : 1 ratio. But the calculated numbers, should be 277.5 normal and 18.5 abnormal. Even such a deviation as this would very rarely occur by chance.

The author, after having obtained analytical data for numerous progeny, both in F_2 and F_3, returns to the theory of the 3 : 1 ratio, suggesting that the observed deficiences in the abnormal plants are probably due to the low germinating capacity of the seed, the general lack of vigour displayed, and the consequent failure of the abnormal plants to survive and become differentiated.

It has been stated above that tassel seed and tassel ear were at first supposed to be identical. But, if the two types were fundamentally identical, differing only in density of inflorescence, vigour of growth, etc., crosses between the two should give pistillate-flowered plants. This cross is of course impossible, owing to lack of pollen.

Conclusive evidence can, however, be obtained from crosses of normal plants, the one heterozygous for tassel seed and the other heterozygous for tassel ear.

If the two recessive types were the same, the cross of two heterozygotes should give 25 % of pistillate flowered plants in the progeny. But 69 normal plants were produced by the cross. The two pistillate-flowered types are therefore genetically distinct. What the double recessive will be like cannot be decided until another generation is evolved.

The two abnormalities show interesting linkage relations with certain other factors of the maize plant.

A back cross involving tassel seed, **Ts ts** (normal heterozygote of F_1) and a factor pair for pericarp colour, **Pp**, gave 81 normal plants, *all with red pericarp*, and 77 tassel seed plants *all with colourless pericarp*.

The colourless pericarp and the tassel seed characters will then, be linked, that is, connected with the same chromosome, and the normal and red pericarp characters will be united in a similar way.

In a similar back cross, but involving a tassel ear **Te te**, there appeared normals with red and colourless pericarp and tassel ears also with red and colourless pericarp. There were 50 plants of the parental combination, i. e., tassel ears with colourless pericarp and normal ears with red pericarp, and 56 of the other two combinations, i. e., tassel ears with red pericarp and normal ears, with colourless pericarp.

There is therefore a distinct difference in these two cases between the linkage relations. In the second case, according to the "crossing over" hypothesis (the exchange of characters between two paired chromosomes) the cross-over percentage will be 52.8 %. Apparently then in

more than 50 % of the cases, half of the chromosome possessing the character tassel ear, becomes detached and unites with half of the other chromosome possessing the red pericarp factor. It is known that a recessive leaf abnormality called "liguleless" (**Lg lg**) is linked with a dominant plant colour called sun-red, in which the factor pair **Bb** is involved.

A back cross involving **Bb**, **Lg lg** and tassel ear (**Te te**) produced 96 plants with 6 to 8 possible combinations of these 3 pairs of factors. The cross-over percentage for **Bb** and **Lg lg** was 29.2 for **Bb** and **Te te** 20.8, and for **Lg lg** and **Te te** 45,8. In this last case, the percentage is so near 50 that, standing alone it affords no satisfactory evidence of linkage between the two characters "tassel-ear" and "liguleless."

The numbers of all the several classes were very close to expectation on the basis of the cross-over percentage observed. Of the 96 plants, 50 were non-cross-overs, 44 single cross-overs and 2 double cross-overs.

There are no data available at present with respect to the possible relations between **Ts ts**, **Bb** and **Lg lg**.

What would be the appearance of a plant with the double recessive tassel ear, and tassel seed is not yet known. However, the known linkage with other characters should make the solution of the problem less difficult. By introducing both **Pp** and **Bb** into the cross of tassel seed and tassel ear : (1) Any resulting pistillate flowered plant with colourless pericarp is almost certain to be **ts ts**, and (2) any pistillate flowered plant having the factor of the pair **Bb** present in the tassel ear parent of the tassel seed tassel ear cross will, 4 times out of 5, be **te te**.

737 – **Pure Line Selections of Rice in Burma.** — *The Tropical Agriculturist*, Vol. LIV, No. 3, pp. 133. Peradeniya, Ceylon, March, 1920.

Varietal selections of rice are being continued and "kalagyi" a strain improved at Mandalay has been tried at Hopin with good results.

At Yawnghwe the native varieties have been examined, and 3 selections made, and these are being multiplied for distribution.

The variety Ngasein 2104 continues to be a favourite with cultivators, especially in the Kyankse district where the area covered is gradually extending.

In the Southern Circle the pure strains Ngasein 8, Ngasein 10, Ngachima and Letywezin continue to hold their position.

Ngasein 10 as a heavy cropper is the premier variety and in spite of the fact that the season was unfavourable the yield was 3084 lb. per acre on an area of 22.74 acres.

738 – **A Mutating Blackberry-Dewberry Hybrid *Rubus caesius* × *R. fructicosus*.** — DETIEN, L. R., in *The Journal of Heredity*, Vol. XI, No. 2, pp. 92-94. Washington Feb., 1920.

The hybrid *Rubus caesius* × *R. fruticosus* (*lacinatus* Wild.) is very common in the vicinity of Raleigh, N. C. In the summer of 1915, the author discovered a specimen with a two canes, one normal, i. e., with entire leaflets, and one abnormal, i. e., with finely divided leaflets. The latter crown was taken up and planted in the station experimental vineyard.

By means of tip-layering, two distinct plants were secured, which continued to reproduce themselves, conserving the characteristics of the original mutation. In 1919 amongst the progeny, cases of atavism were noticed consisting of a complete or partial reversion of the leaflets to the undivided form.

AGRICULTURAL SEEDS

740 – **Distribution of Seeds for Sowing in France.** — HITIER, H., and J., in *L'Expansion Economique*, Year III, No. 8, pp. 13-14. Paris, 1919.

The export of French seed, which has more than doubled in quantity within 50 years from 1880 to 1913, represented before the war a value of 50 million francs.

At the head of the list of these export comes the leguminous seeds: alfalfas and clovers. In France there are two principal centres for the production of these seeds, i. e., Provence and Poitou situated on very fertile soil, where alfalafa seed is produced which is universally sought after throughout the world. In Poitou and in Brittany, clover seed is produced in large quantities.

Saint-Remy, in Provence, is one of the most important districts for the production of seeds of vegetables, such as beets carrots, celery cabbages, cucumbers, spinach, broad beans, kidney beans, lettuce, and onions. The principal seed warehouses, not only in France, but also in England, Russia, Denmark, Holland, the United States, and before the war Austria and Germany, arrange with the farmers at Saint-Rémy and in its vicinity to propagate a certain quantity of the best seeds from these plants.

It is the same in the Loire valley, between Saumur and Angers, where the cultivation for seed has developed considerably within the last 40 years. The farmers in this valley have found their soils to be an especially suitable medium for seeds. The better known seeds merchants in Paris have special seed plots there, which are superintended and worked by their agents, who visit frequently and have charge of the selection and cleaning of the produce. The principal crops included are : Cabbages, carrots, lettuce, beets, chicory, cucumbers, celery, kidney beans, turnips, leeks, sorrel, parsnips, parsley, pumpkins, radish, salsify, etc. Mignonettes, balsams, wallflowers, everlasting flowers, pansies, carnations, pinks, amaranths, etc., are also cultivated for seed purposes.

Even with the greatest care on the part of certain establishments and certain farmers, before the war, the production of beet seed was insufficient to meet French requirements, and permit of extensive exportation. But, since the war, in various parts of France, the crops have been increased and the most careful and perfected methods of selection used. Moreover, for some years now, in the experiment stations organised by the French syndicate of sugar manufacture, French seed carefully compared with German seed, has given excellent results, both in size of root and in sugar yield per hectare.

After the war the French production of beet seed should be able to cope with the demand both in France and abroad. In 1918, a Syndicate of French Beet Seedsmen was established. This Syndicate does not intend only to support the corporate interests of the profession, and to investigate and improve the beet seed, but also to see that the seed sold under cover of the Syndical Chamber, responds to certain guarantees. This is a commercial organisation which resembles the "douze marques" flour market. The syndicate sets a guarantee mark on the roots produced by each of its members, these agreeing in advance to submit mutually to this strict method of control.

CEREALS AND PULSE CROPS

741 – **Topping of Wheat Liable to Lodging.** — I. SCHRIBAUX, H. BACHELIER, in *Comptes rendus de l'Académie d'Agriculture de France*. Vol. VI, No. 14, pp. 360-365. Paris, April 14, 1920.

I. — M. SCHRIBAUX describes a definite means, not only of dealing with lodging, but for utilising the vigour of growth of wheat to increase the grain yield at the expense of the straw yield.

When the wheat shows signs of bearing and measures about 30 cm, it is sufficient to cut back to 15 cm, i. e., to half its normal height. When the plant again reaches a height of 20 cm., it is advisable to cut back a second time to 15 cm. if it still appears liable to lodging; this second treatment is hardly ever necessary. By this means, the entire wheat crop is rendered resistant to lodging, whatever the height, and 30 and 15 cm., are the recognised figures which it is wise to observe as nearly as possible. If the wheat obviously exceeded 20 cm. in height, one must take the risk of topping, anyhow to a small extent, the young ears, which are still enclosed in the sheath.

The practice of topping, first pointed out by M. HANICOTTE, farmer and former President of the Syndicate of Agricultural Distillers in the North, is at the present time a generally recognised procedure on the best farms in the north of France. On small areas, the wheat is cut with the scythe or sickle; in the neighbourhood of Paris, a header is employed, which is a kind of very light sickle with a blade which can be lifted to at least 15 cm. This same implement, manufactured by GARNIER, at Mormant (Seine-et-Marne), is also used for destroying weeds amongst the wheat.

Topping delays ripening for some days and somewhat reduces the straw yield, but, on the other hand, the quantity and quality of the grain yield is improved. A field thus treated gave the lowest proportion of dwarfed wheat. The cause is easily explicable: The topping which can be compared to the pinching practised by gardeners has the effect of equalising the development of the tillers. The more advanced are retarded in growth to the advantage of the smaller ones, not reached with the sickle; the latter which would have only given small tiller growths, take the same time to mature as the older ones.

In order to show the various advantages of topping, M. SCHRIBAUX gives a brief *résumé* of a paper read some time ago (1909) before

the National Agricultural society, by M. BACHELIER. M. BACHELIER had cut back wheat covering an area of 61.75 acres sown after alfalfa, leaving a control plot of 32.8 ft. untouched for comparison purposes. In the area treated, M. BACHELIER obtained an increased yield of 633 kg. of grain and a decreased yield of 700 kg. of straw per hectare.

What expenses are entailed by this operation? The machine used cost 450 fr. (pre-war prices). The cost of upkeep is negligible, as the blade is held too far away from the soil to encounter obstacles, (14 fr. for upkeep in 7 years. An area of 9.8 acres, can be covered in a day by a man and a horse. The cost per acre may be estimated thus:

Manual labour and horse	1.00 fr.
Depreciation and upkeep of machine	0.60 »
	1.60 fr.

This expense, plus the value of at least 13.7 cwt. of hay, is largely compensated for by the decrease in the cost of harvesting and the superior quality of the produce.

The idea of topping is almost as old as the cultivation of wheat, but M. HANICOTTE has the merit for having perfected it.

This method is equally successful with oats but the operation is not so easy as with wheat. As oats grow very quickly, the time allowed for performing this operation is very limited. By delaying the treatment there is a risk of a letting the plant get too tall, and of injuring the panicle, still enclosed in the sheath, and consequently of damaging the production of grain.

II. — M. BACHELIER considers that there is no reason to fear that, even in case of drought, topping will damage the crop yield.

In order to apply this process to hardy wheats, it is absolutely necessary to choose the right moment when the upper part of the leaves can be clipped without touching the stalk. The whole success of the operation depends on this precaution..

With the GARNIER, it is possible to cut back 9.8 acres per day. The machine consists of a kind of shears with a detachable blade which can be regulated to the height of the wheat. This blade is lighter than that of a mower. It is necessary to work quickly, as the period when it is possible to cut back wheat is very limited. Topping slightly reduces the height of the stalks and makes the plant resistant to lodging.

742 – **Phosphatic Fertilisers as a Means of Hastening the Maturity of Maize.** — RAYMOND, L. C., HARCOURT, R. and ELLIS, J. H., in *The Agricultural Gazette of Canada, Department of Agriculture, Ottawa, Canada*, Vol. 6, No. 6, pp. 550-552. June, 1919.

It is well known that phosphates are particularly valuable in inducing root development, and that later in the life of the plant the ripening processes are hastened by them. This has already been demonstrated in England, by Dr. F. J. RUSSEL, at the Rothamsted Experiment Station dealing with crops in general; in the United States by Prof. L. H. SMITH Agronomy department, Illinois; by Prof. G.E. CORSON, Iowa College

Station ; by Prof. J. D. HARPER at Indiana, and by Prof. R. A. MOORE, University of Wisconsin, with maize.

The stimulative action of phosphates on ripening, has the same effect as a deficiency of water, but to a minor degree ; nevertheless, as maize is deep rooted, there is not the same danger as with other crops (for example barley), that in case of drought the use of phosphatic fertilisers may add to detrimental effects of lack of water. It seems safe to conclude that this fertiliser will give invaluable aid in extending the northern limits of the maize area, both for grain and silage purposes, owing to its ripening effect on the crops. In Ontario, Mr. R. HARCOURT has noticed that the use of phosphatic fertiliser brought the maize to a stage of maturity a week in advance of the usual time. Further investigations will be necessary before it will be possible to ascertain to what extent phosphatic fertilisers may be used to hasten the maturity of various varieties in different localities.

743 – **Note on the Cultivation of Floating Rice in Cochin-China.** — TRAN-VAN-UN (Assistant at the Laboratory of Genetics of the Scientific Institute of Indo-China), in the *Bulletin agricole de l'Institut Scientifique de Saïgon*, Year II, No. 2, pp. 46-52. Saïgon, February, 1920.

The botanical name of floating rice is *Oryza Sativa* L. var. *utilissima* Kches, var. *mutica*(1) according to PIERRE or *O. Sativa* L. and var. *fluitans* according to CREVOST and LEMARIE.

CENTRES OF CULTIVATION. — This crop is important in the Cambodian provinces of Battambang, Kompong-Khom, and Preyveng. and, according to M. BRENIER, it constitutes the greatest part of the export from this region (50 000 to 60 000 metric tons.) Only recently introduced into Cochin-China, it occupies a preponderant place in the province of Chaudôc and is cultivated in certain cantons in the province of Longxuyen.

The first experiments on the cultivation of floating rice were made in Cochin-China in 1900 by PHAN-VAN-VANG, with seeds brought from the north of Kratie (Cambodia). The growers quickly saw the advantage to be gained, in a region subjected during 6 months of the year to heavy floods, by the cultivation of a rice capable of following the rising of the waters. Since then the cultivation of floating rice has increased steadily until at the present moment it covers from 70 to 80 % of the total cultivated area of the province of Chaudôc, i. e., 63 000 to 72 000 hectares ; the production amounts to from 115 000 to 130 000 metric tons.

GROWTH OF FLOATING RICE. — During the first two months of its growth, floating rice develops aerial roots like ordinary rice and puts out as many as 15 shoots per plant. When this stage is past, in order that it may prosper normally its stem must be completely submerged. This condition is realised in the low-lying plains, where it is grown thanks to the annual rising of the Mékong. As the waters rise the floating rice rises with them, keeping the tips of its leaves on the surface all the time. Its

(1) *Bulletin du Laboratoire d'Agronomie Coloniale*, edited by M. A. CHEVALIER, No. 1. Espèces et variétés de riz de l'Indo-China, par M.lle CAMUS, p. 18. (*Author's Note*)

roots then grow vertically and continue to lengthen out, forming fresh nodes. At the same time from each node spring rootlets which, in the marshy water, ensure the nourishment of the plant concurrently with the roots in the ground.

At Chaudôc the plain is constantly covered from July, to November with water varying in depth increasing towards the 15th and 30th of each lunar month and generally reaching its maximum in September or October. The depth of water varies on the average from 1.20 m. to 1.50 m. A heavy gradual flood is best for the growth of floating rice. It has been found that the water should not rise more than 10 or 12 cm. if the rice is to rise with it.

The water should subside gradually, for a sudden fall prevents the plant attaining its full development and deprives the grains of nourishment just as a rapid rise is unfavourable by submerging it, thereby weakening and sometimes destroying it. For instance, in 1917, a very favourable year for floating rice, at Chaudôc the rising waters were at first 2.15 m. deep (July 1) and finally attained a maximum of 4.82 m. in the first days of November.

When the water subsides, the floating rice gradually sinks until it lies flat, and from the nodes near the tip, branches shoot (one per node) which may, in turn, form one or two ramifications. There may be 3 to 5 branches per stem, each bearing a panicle. The tertiary ramifications, not having time to develop completely, do not bear grain. In a field of floating rice the branches, which all right themselves, slope in one direction so that the field presents a very different appearance from that of a field of ordinary rice which stands straight up, except in case of lodging. The lower part of the stalk which lies flat on the ground, rots and the healthy part obtains nourishment by striking roots from each node into the ground. From these nodes in contact with the soil there may spring secondary stalks which also take root and live a separate existence from the mother plant thus leading to propagation by shoots.

The stalk of the floating rice is thicker and harder than that of ordinary rice, but it is more brittle when dry. When it has finished growing, it may measure, so the growers say, from 2.50 to 5 metres in length.

The author, examining the stalks of the Nam-vian variety, has observed that the length varies from 3.50 to 3.70 metres. The internodes are very numerous : from 9 to 15 on each stalk. The internodes of the lower part of the parent stalk are the most developed (as much as 50 cm.), and become shorter as they reach the top (15 to 20 cm.) On the branches the author has noticed the contrary ; as they become more remote from the parent stalk the internodes are longer (6, 11, 12, 18, and 25 cm.). In ordinary rice the number of internodes is rarely more than 3 to 5. No noticeable difference exists between the leaf of the floating and ordinary rice, except that the parent stalk is bare for a considerable height and only has leaves on the upper part where the branches are given off. Floating rice, therefore, is very different from ordinary rice both morphologically

and physiologically and, according to the author, ought to be placed in the genus *oryza* as a distinct botanical variety.

VARIETIES. — In 1901 only one variety of floating rice was known in Cochin-China, but in 1906 M. PAUCHOUT (1) described 10 varieties several of which are no longer grown. The cultivated varieties all come from Cambodia and there are now 6 in the Chaudôc region. There is little difference between them from the point of view of vegetation, but they ripen at different dates covering a period of 30 days.

The period of growth of all these varieties varies between 8 and 9 months; sown in April or May they are harvested in December or January.

The seeds of all these varieties fall very easily, and they often contain a variable proportion of red seeds. There are also varieties of floating rice with entirely red grains. These red grains are sometimes in demand among Chinese buyers, probably for distilling purposes. There is also a glutinous variety of floating rice, but the grains, however, are less glutinous than those of the ordinary glutinous rice and have no smell.

CULTIVATION. — Towards the end of the first Annamite month, after the crops have been gathered in, the straw, which was left on the ground at the time of the harvest, is burnt. During the second month when the first rains fall the ploughing is done. According to the altitude the soil is exposed to the sun during a period ranging from 1 to 2 months, so that, in the low-lying districts sowing time falls in the third month and in the fourth month where the elevation is higher. Sowing is generally done by hand and harrowing is necessary to even the seeds.

Rice and maize are sometimes cultivated together, and are sown in alternate rows (2 of rice to 1 of maize) at a distance of 40 cm. or in pockets spaced at 20 cm. in every direction. The maize is sown 15 days before the rice. In any case the quantity of rice sown varies from 3 to 5 *gia* (2) per hectare; for ordinary rice that is to be transplanted 1 *gia* per hectare is sufficient. Floating rice requires no care; its growth is assisted by the floods and it flowers about November when the waters subside, and matures in December to January.

At this period the rice is cut with a sickle at a height of about 50 cm. as with ordinary rice; the rest of the straw, which is left in the ground, is burnt later on. The ground is dry at harvest time.

YIELD. — This varies from 80 to 150 *gia* per hectare according to the nature of the ground and the height of the floods. The average yield is from 80 to 100 *gia*.

COMMERCIAL GRADES OF FLOATING RICE. — Because of the way in which it is grown, floating rice is always more or less mud-stained and dirty But, yielding large and usually plump grains, it has the advantage of being heavy, giving 24 kg. per gia of 40 litres. Its weak point is that it often contains a rather large proportion of red grains which require a

(1) PAUCHOUT. Note on the cultivation of floating rice in the province of Chaudôc. *Revue Indochinoise* 1906. (*Ed.*)

(2) The Annamite *gia* = 40 litres. (*Ed.*)

longer polishing process, and yield more subsidiary products. Fortunately, this percentage of red grains has considerably decreased during the last years, thanks to the careful selection of seeds by the growers. At the Rice Competition organised in 1902 by the Saïgon Chamber of Commerce, floating immediately after its introduction into Cochin-China, was described as follows : — Round, well-developed grain, well adapted for polishing and blanching and on the whole possessing excellent commercial properties. More recently, at the exhibition of Rice Paddy and Maize organised by the Institut colonial de Marseille in 1911, a sample, submitted for examination to the Rizières Méridionales of that town was judged equal to the large grained Moulmein rice. For the native palate floating rice has not the same flavour as ordinary rice. It is considered that roasting makes it hard and insufficiently adhesive. Apart from this slight disadvantage, no complaint is made against it. At Chaudôc, the local trades do not differentiate between ordinary and floating rice if the latter is entirely white. For lots containing red grains the buyer varies his price according to the smaller or larger percentage of these grains and the cheapest quality generally, sold at 5 *piastres* per 100 *gia*, may, in certain cases, fetch up to 12 *piastres*. The market-price of the *picul* of paddy at Chaudôc is usually 0.50 less that at Cholon. Floating rice, owing to the size of its grains, which is over the average, is useful for export. With this object in view it is worth while for the growers to eliminate the red grains from their seeds. At the harvest they could put aside the panicles and sort them one by one. As the red grains are usually to be found on entire panicles it would be sufficient to decorticate one seed per panicle, setting aside the panicles which contain red grains. This simple operation could be entrusted to children, who, as it is well known, are to be found in respectable numbers in Annamite families.

Until the low-lying plains of the North-West of Cochin-China are raised, only floating rice can be grown in these districts. Requiring a minimum of care, it is sufficiently renumerative, thanks to its fairly, good and regular yield. It is to be hoped that this crop will extend over the low-lying lands where the rising of the Mékong leads to real floods. The utilisation of the vast plain of rushes will have every prospect of success if floating rice is grown.

744 – **Preliminary Experiments with Fertilisers in Rice growing in Indo-China.** — VERNET, G. and NGUYÊU-DUC LONG, in the *Bulletin Agricole de l'Institut Scientifique de Saïgon*. Year II, No. 2, pp. 52-53. Saigon, February, 1920.

The authors have made preliminary experiments on the use of fertilisers in rice growing. Unfortunately, the experiments are very incomplete because the rice fields belonged to natives who were not greatly interested in the question, and because they were made at a time when the rice was already transplanted therefore the observations could not apply to the entire harvest. The first conclusion to be drawn from these experiments is that, from an experimental point of view, it is useless to make them upon the native crops and more searching ones must, therefore, be made under different conditions.

Norwegian and Laos *nitrates* applied at the rate of 250 and 500 kg. per hectare gave good results, but it is impossible to make any comparison with the control plots for the reasons already given.

Lime applied at the rate of 1000 kg. per hectare had no visible effect upon rice already transplanted in the ricefields of Hocmon. The premature harvesting of the crops by the natives presented any comparison being made as regards the yield. *Calcium cyanamide* applied in the quantities indicated by the Congress of Rice Cultivation at Valencia as representing the nitrogen necessary for the whole crops, proved to be poisonous to the rice already planted in Indo-China.

When given at the rate of 500 kg. per hectare, in the low-lying parts of the field where the water accumulated most, the rice was literally burnt. But the poisonous effect was only temporary, for some of the rice plants, which were not completely killed, were able to resist and prosper.

But if calcium cyanamide, applied in such large quatities to rice already under cultivation proves poisonous it nevertheless appears to have a very different effect when applied in very small amounts. Cyanamide is a very fine powder and it is very difficult when speading to prevent the wind carrying some of the fertiliser on to the neighbouring plots. This is precisely what happened, and the authors show that where the wind carried a little of the cyanamide powder the growth of the rice showed excellent results. When the crops were gathered 10 panicles where no cyanamide was used only gave 754 grains weighing 16.87 gm. or an average weight per grain of paddy of 0.0223 gm. whereas 10 panicles with cyanamide gave 1428 grains weighing 32.158 gm., or an average weight per grain of paddy of 0.0225 gm. These results are interesting but the experiments need to be repeated and made more definite; for this reason M. MAGEN, Director of the Agricultural Department of the Scientific Institute of Indo-China, immediately arranged to send for a speader which could be regulated so as to permit the scattering the fertiliser evenly in small quantities on the growing rice.

745 - **Some Selected Rice Varieties in India.** — See No. 737 of this *Review*.

746 - **On the High Nitrogenous Content of Certain Cambodian Manioc.**— AMMANN, P.; in *Comptes rendus de l'Académie des Sciences*, Vol. 170, No. 22, pp. 1333-1334. Paris, May 31, 1920. SUGAR CROP

Manioc, whose roots constitute a source of much sought after food products (flour, starch, tapioca, etc.), is one of the principal food crops in the equatorial zone.

Many varieties are known, but in every case the extremely low nitrogen content of the roots is very noticeable; it has thus been usual to consider manioc simply as a source of starch.

PAYEN gives 3.51% as the content of nitrogenous matter; Theodore PEKELT gives 2.5 and 3%, respectively, for white and red manioc (these figures are calculated on the dry matter).

Source	Moisture	Matter Nitrogenous
Madagascar	16.05	0.74
»	13.87	0.82
»	13.55	1.17
Nossi-Bé	12.16	0.91
Réunion	12.61	0.64
Guinea	13.68	1.40
Dahomey	13.81	0.82
»	12.46	1.49
»	12.21	1.23
Annam	14.23	0.96

Several analyses of manioc made in the Laboratory of the Jardin Colonial from various sources have revealed still lower contents of nitrogenous matter.

In addition to this, the Economic Agency of Indo China sent, for analysis to the Jardin Colonial, roots of Cambodian manioc, which had a much higher nitrogenous content. The roots came from plants grown from seed at Pnom-Penh by Mr. DE FLACOURT, Director of the Agricultural Department of Cambodia, with a view of obtaining new varieties. The plants from these seeds were carefully studied and selected, and amongst the new varieties obtained, 5 showed outstanding qualities with regard to early maturity or good yield.

The chemical composition was found to be as follows :

	Register No al the Jardin Colonial					
	15.858 153 A 1 %	15.859 154 A 2 %	15.860 155 A 3 %	15.861 156 A 4 %	15.862 157 A 5 %	15.863 158 A 6 %
Moisture	11.58	11.02	11.16	11.06	11.00	10.72
Nitrogenous matter	2.93	4.33	4.33	4.33	6.93	7.43
Saccharifiable matter	74.00	75.30	76.00	77.60	70.00	75.60
Crude cellulose	2.70	2.65	2.73	2.10	2.55	2.13
Ash	2.48	2.80	2.50	2.74	2.88	2.74
Hydrocyanic acid (in mgm per 100 gm of matter)	3.7	4.7	2.2	7.8	6.0	2.4

These new varieties of manioc come under the heading of the sweet manioes, i. e., containing only slight traces of hydrocyanic acid (confirmed by analyses). However, in order to estimate only nitrogenous nutrients, the analyses were made after complete elimination of the hydrocyanic acid.

MEADOWS
AND PASTURES

747 – **Cultivation of Ghessab (*Pennisetum spicatum*) at Rome.** — PANTANELLI E., in *Stazioni sperimentali agrarie italiane*, Vol. LIII, Pts. 1-3, pp. 47-66, bibliogr. of 37 works. Modena, 1920.

Owing to the necessity of finding summer fodder crops adapted to arid countries and to soils that lack water, the author conducted experiments near Rome with several Gramineae of subtropical origin. The

good results obtained with *Sorghum halepense* have been described in a previous article (1); this time an account is given of the results obtained with ghessab (*Pennisetum spicatum*) which with its varieties *typhoideum* and *vulpinum* is grown in Abyssinia and Erithrea, under the name of "bultuc", chiefly as a cereal; in Central Africa as a cereal; in Tripoli, Cyrenaica, Fezzan, etc., it is called "gsab", "gassab" and "abora" and in Algeria "bescua" (cereal and fodder crop): in the Belgian Congo it is grown as a cereal and fodder crop; in India as a cereal and fodder crop, known as "bajre" or "cumbu." The fodder value of *P. spicatum* is recognised throughout East and North Africa. In Italy, *P. spicatum* has already been given a trial on the Bolgheri estate (Pisan Maremma) and in Florence; although in these two cases the sowings were made very late (May and June), there was an excellent yield of fodder in the autumn.

In the trials conducted by the author, the seed used was provided by the Agricultural Department of Tripoli; and sowings were made on April 16, 1919, on friable, poor land, without fertilisers, in rows 25 cm. apart. In spite of the very warm dry summer, *Pennisetum* remained swollen and green; flowering began in July and lasted until the advent of the September rains; only ¼ of the plants produced completely matured seeds. In September, the plants had reached a minimum height of 90 cm. and a maximum of 120 cm. The harvest on September 15, yielded 347.7 cwt. per acre of hay with an approximate moisture content of 75 %, so that the yield of hay with 15 % of moisture corresponded to 153.86 cwt. per acre. The yield would doubtless have been even higher if second cut had been taken in July.

In the United States, the yields have been much higher; for example Mr. GARRISON in South Carolina, obtained 840.15 cwt. per acre for 6 cwt, the first taking place 54 days after sowing, and in Kentucky 696.19 cwt. of green fodder, i. e., 291.8 cwt. of hay for 2 cuts.

The plant cut down whilst in flower, dried at 90°C. and powdered (containing only 12 % of moisture) had the following composition:

Crude protein (N × 6.25)	12 % (52.3 % digestible)
Crude fat (Ether extract)	3.91 %
Carbohydrates (sugar)	25.10 %
Cellulose	36.14 %
Ash	10.16 %

Cattle having shown a distinct liking for this plant, the author concludes that, if cultivated in Latium, it would prove a summer fodder crop of the first quality.

If the grain is allowed to ripen on the early flowering panicles, it is possible to obtain, even in Latium, a sufficient quantity of seed to ensure continuity to the crop without having recourse to African seed. In the arid regions of the Roman Campagna, 26.74 lb., per acre is sufficient, leaving 9.84 ins. between the rows, to give a crop which can even be cut with a machine, and at the close of the summer, used as pasture, which

(1) See *R.* February, 1920, No. 202. (*Ed.*)

is tolerated well by *Pennisetum*. The plant grows with such vigour that all other plants are choked. It is extraordinarily bushy with an average of 12 stems per plant, and, when the seeds ripen, the green plant continues to send out shoots from the axils of all the leaves. It is advisable to remove the ears as soon as it is certain that the grain will ripen. In this way the other ears on the same stalk ripen more rapidly. The author briefly surveys the trials made in various countries with other varieties of *Pennisetum* proving that this genus provides a fodder crop of inestimable value for semi-arid regions, and he considers that " this species should be systematically tested in southern Italy and the adjoining islands.

748 - ***Lotus Corniculatus* in Seine et Oise, France.** — De Rotschild, H., in the *Comptes rendus des Sèances de l'Académie d'Agriculture de France*, Vol. VI, No. 20, pp 505-508. Paris, May 26, 1920.

As it was necessary to cultivate large areas of impermeable land in the Rambouillet district, Seine-et-Oise, the author kept the fact in mind that with a view to rational and economic improvement, it is important to give the first place to plants which are the best adapted to the soil fertility as it stands.

In January, 1919, having analysed the hay from the various natural meadow lands, and after carefully examining the natural flora, the author found that the lotus plant, particularly *Lotus corniculatus* was growing wild on the plateaux and slopes and in the valleys, and gave promise of success on the shallow, alluvial undrained upland territory, where alfalfa and sainfoin are only occasionally found.

In 1919, seeds were sown at the rate of 2.6 lb. per acre with evident success, the plants varying in height, according to the type of soil, from 3.9 to 15.7 in., and in exceptional cases to 23.6 in.

From the standpoint of food value, the lotus is at least equivalent in value to alfalfa and sainfoin. New shoots are sent out continuously when it is grazed with cattle and even during an exceptionally dry season. It is therefore a valuable leguminous plant for poor regions which have limited forage resources, with a view to its use as an improving crop.

M. Schribaux agrees with M. De Rotschild in recommending that the lotus should be grown either alone or mixed with *Dactylis glomerata* as a protection crop. *L. corniculatus* is without doubt a forage crop of the first order, and has been up till now too much overlooked, although it deserves to be classed in the same category as alfalfa or clover. This hardy plant can apparently adapt itself to practically all types of soil, and flourishes in all parts of France regardless of climate. It is resistant to disease, productive, of good fodder value, lends itself as readily to pasture as to hay production and continues growing indefinitely. A heavy top dressing of phosphatic and potassic fertilisers is necessary to ensure satisfactory results. The high price of the seeds, which are difficult to obtain, is the sole disadvantage attached to the plant.

749 – **The Australian Saltbush (*Atripplex semibaccata)* in the United States.** Mc Kee, R., in *U. S. Department of Agriculture, Bulletin* No. 617, pp. 1-11, figs. 4. Washington, D. C., September, 1919.

The Australian saltbush (*Atriplex semibaccata*) was introduced into the United States some 25 years ago, and was distributed throughout the arid and semi-arid regions. In practically all cases, the plantations resulted in failure, and only along the coast, in the San Joaquin and Imperial Valleys of California, and in the Salt River, Yuma, and Santa Cruz Valleys of Arizona has it become well established. The plant is a perennial and prostrate, forming a dense mass from 6 to 12 inches thick. The minimum temperature of the regions in which it is naturalised is 19° F ; the mean annual rainfall in regions where it is possible to cultivate without irrigation ranges from 9-16 in. While the Australian saltbush can grow on practically all types of soil, it is found in but few regions where the soil does not contain an appreciable amount of alkali. It is quite drought resistant, but apparently not to the extent of some other species of *Atriplex* and other desert plants.

The chemical composition of the leaves and stems of *A. semibaccata*, and of the hay therefrom shows respectively : Water, 78.03 and 7.05 % ; ash, 4.58 and 19.37 % ; crude protein, 2.75 and 11.64 % ; crude fibre, 3.75 and 15.83 % ; nitrogen-free extract, 10.41 and 44.05 % ; crude fat, 48 and 2.01 %. The stems and leaves have therefore an unusually high content of salt (especially sodium chloride) and comparatively high percentages of protein, nitrogen-free extract, and crude fat.

In regions which offer favourable conditions, *semibaccata* is quite aggressive, and this adds to its value as a range plant. On account of its high salt content it is not as palatable as most ordinary forage crops, but it is eaten readily by sheep, goats, cattle and horses when other feeds are scarce. To be of the greatest value it must be supplemented with other feeds.

The greatest value of this plant is to supply succulent feed in late summer and to furnish a reserve supply. It can be used as a soiling crop, but has little value as hay. Seed is produced freely, but harvesting is expensive. For range purposes *A. semibaccata* should be sown in the autumn, scattering the seeds broadcast in favourable locations and leaving it to take care of itself. In sowing with a view to cultivation, the best time is in the spring and care should be taken to cover the seed only enough to ensure moisture conditions favourable to germination.

750 – **Silage Crops other than Maize in Canada.** — Trueman, J. M., Summerby, R. Barton, H., Brother Athanase, Toole, W., Ellis, J. H., Bracken, J., McCaig, J. and Boving, P. A., in *The Agricultural Gazette of Canada*, Vol. VI, No. 6, pp. 538-544. tawa, June, 1919.

Information concerning silage crops other than maize from various parts of Canada, including alfalfa, rye, clover, soya, Sudan grass (*Sorgum exiguum*), millet, rape, buckwheat, sunflower, mixed cereals, peas, and vetches.

Experiments conducted during 5 successive years at the Nova Scotia Agricultural College show that a mixture of oats, peas, and vetches will produce, under the prevailing climatic conditions, a larger yield of ensilage than maize, which rarely ripens satisfactorily. The average analyses of this mixture and of immature maize are compared as follows : Water, 74.76 to 81.54 % ; ash, 1.72 to 1.24 % ; protein, 2.60 to 2.02 % ; carbohydrates, 19.96 to 14,25 % ; fat, 0.91 to 0.66 %. This mixture, therefore possesses a higher nutritive value. The seed is sown at the rate of 3 ½ bus. per acre, the mixture being composed of 2 ½ bus. oats; ¾ bus. peas, and ⅓ bus. of common vetch. This should be sown as early as possible on rich land ; the green crop is cut before the oats turn yellow and is put in the silo through a silage cutter, and care must be taken to tramp it well down.

Wherever maize has not been a complete success, a mixture of peas and oats appears to give the best results.

Peas, soya beans, common vetch, hairy vetch, clover, alfalfa, and wood vetch put separately in the silo were not liked by the cattle as much as when mixed with maize ; what is more, fodder prepared thus kept in good condition much longer.

Artichoke stems moistened with a little water and slightly packed when put into the silo, gave a feed, mixed with maize, of excellent quality. The same was noticied with a mixture of maize and sunflower heads.

At the Manitoba Agricultural Colleges 7 silos were filled in 1918 with different fodder crops, and the appended table shows the results obtained. It is suggested that when the maize crop does not succeed, the best substitute appears to be a mixture of cereals (wheat, barley and oats), with equal quantities of peas, or, preferably, with Sudan grass (*Sorghum exiguum.*) Alfalfa may be ensiled it owing to wet weather, it is difficult to cure for hay, but ensilage from this crop is rather dry. Buckwheat and rape both make a very succulent ensilage, but are difficult to harvest.

	Maize		Sudan grass		Millet		Alfalfa			Cereals and Peas		Rape		Buck-wheat

Sunflowers give very promising results as a silage crop ; the cattle ate the silage quite satisfactorily and produced rather more milk as a result It was however observed that it was more laxative than the oat silage. In Saskatoon (Saskatchewan,) the sunflower variety Giant Russian yielded twice as much green fodder as the corn.

In British Columbia relatively more red clover is made into silage than any other crop, except corn. Prof. BOVING recommends for this district a mixture of 1 bus. of oats + 1 bus of peas + ½ bus. of small horse beans + ½ bus. of vetches per acre.

751 - **Food and Fodder Plants.** — HOLLAND, J. H., in the *Royal Botanic Gardens, Kew. Bulletin of Miscellaneous Information*, Nos. 1 and 2, pp. 1-84. London, 1919.

Description of the most important food and fodder plants included in the Natural Orders : *Leguminosae, Gramineae, Cruciferae,* and *Rosaceae,* etc.

For each plant the author gives the chief countries of production, imports into the United Kingdom, the approximate production of some of the principal crops in the United Kingdom, brief details as to uses, and other notes of practical interest.

752 - **Cotton in Guiana** (1). — *Bulletin de l'Agence générale des Colonies* (formerly *Bulletin de l'Office Colonial*), Year XIII, No. 145, pp. 47-48. Paris-Melun, January, 1920. FIBRE CROPS

The cultivation of cotton was first stated in the Antilles, and the Caribs paid their annual tribute to the Spaniard in bales of cotton.

During the War of Secession the cultivation of cotton was developed in Guiana as well as in the other French Colonies, but unfortunately, was given up afterwards.

Today, however, more interest is taken in the crop. In Guadeloupe (2) and Martinique it is proposed to revive the abandoned industry. In the British Antilles the cultivation of cotton has been highly developed and there is an important production.

Guiana ought to follow this example, as it could compete successfully in the production of cotton (to which the future promises inde finite extension) with the other producing countries mentioned and even with the United States.

In Algeria drought is an obstacle to the cultivation of cotton ; this obstacle does not exist in the moist climate of Guiana, where cotton can be grown both in high and low-lying districts, in river and maritime alluvial soils as well as on mornes (3).

Between Oyapok and Vincent-Pinçon, all the low-lying ground is specially adapted for the production of excellent cotton. Cayenne cotton is particularly silky. The production of cotton requires relatively little labour and capital, and is suitable for small landowners ; it gives rapid results (cotton is obtained in 6 months) and yields 2 crops yearly, one in February,

(1) This article constitutes the 13th part of the Series entitled "La Culture du Cotonnier dans les Colonies françaises" *R.*, May, 1920, No. 522. (*Ed.*)

(2) See *R.*, May, 1920, No. 522, XI. (*Ed.*)

(3) Small isolated mountains. (*Ed.*)

the other in September. The cotton plant in Guiana has the peculiarity that it can be renewed indefinitely by cutting the stalk, when it becomes arborescent. Guiana cotton is one of the best in the world. Formerly, the market value had fallen so low that it was not worth while cultivating, and ceased to be produced in Guiana, but times have changed and the future is full of possibilities.

PLANTS YIELDING OILS, DYES, TANNINS ETC.

753 - **The "Betratra" a New Oil Plant of Madagascar.** — HEIM, F., GARRIGE, E. and HUSSON, M., in the *Bulletin de l'Agence générale des Colonies* (formerly *Bulletin de l'Office Colonial*, Year XII, No. 143, pp. 679-691. November, 1919; Year XIII, No. 145, pp. 14-21 Paris-Melun. January, 1920.

In the calcareous plateaux with a desert climate (or almost so) in the districts of Mahafaly and Bara (south-west of Madagascar) there grows a small tree called by the natives "Betratra," and whose oleaginous fruit is already, to some extent, utilised for local consumption. This plant is almost unknown botanically; we only possess some data concerning it furnished by JUMELLE and PERRIER DE LA BATHIE. JUMELLE sent the authors a case of fruit gathered in the Mahafaly district for the purpose of botanical, chemical and technical examination. The results of these studies are summarised in the present note. The plant, belonging to the Euphorbiaceae, is dioecious, it is a tree 16.4 to 19.6 ft. high, described at first by M. JUMELLE as belonging to the genus *Jatropha* under the name of *Jathropha mahafalensis* Jum., but the same author thinks that it would perhaps be better to exclude it from this genus and class it with the genus *Ricinodendron* under the name of *Ricinodendron mahafalense*.

The "Batratra" would appear to be a distinctly xerophilous plant adapted to the desert climate of its native country. The shell in which the fruit reaches the market is rather thin, but, on account of its adherence to the kernel, is difficult to remove.

Breaking up the fruit is of little practical value, as the oil cake must be regarded *a priori* as poisonous and useless as a cattle food, for which purpose the kernel alone, without the shell, must be used; 100 seeds yielded 81.4 % of kernels and 18.6 % of husks (to a total weight of 74.3 gm.). The yield of oil obtained by expression amounts to 40 % of the weight of the undecorticated nuts, which is very satisfactory. The yield obtained by extracting with ether in a SOXHLET apparatus is 44.64 % of the entire fruit and 57.68 % of the decorticated nuts.

Chemical examination of the oil (clear, without any characteristic odour, and of a pale golden yellow colour has shown that it is semi-drying; almost entirely formed of triglycerides of stearic and especially oleic acids with small amounts of these fatty acids in a free state, a small proportion of volatile fatty acids and a minute quantity of hydrolysed fatty acids in the form of triglycerides.

If "Betratra" oil is to be used in soap making it must, when saponified with potash, be worked with weak caustic solutions at the boil It makes an excellent summer soap which requires the addition of winter oil to resist a temperature below + 5° C. The oil yields an excellent hard soda soap when mixed with copra and lard.

The oil would be of special value in the manufacture of soap paste for the texile industry and that indeed is its sole utility.

A study has been made of the oil cake from the point of view of its use as a fertiliser. It has an average content of fertilising elements, somewhat similiar to those found in flax, exotic rape, black mustard, *Guizotia Oleifera* and nuts. Its composition is as follows : Nitrogen, 5.43 % ; potash (K_2 O), 1.236 % ; phosphoric acid (P_2 O_5), 1.589 %.

754 – **Dangers which may occur through the Close Vicinity of the Coco-Palm in Hevea Plantations and Precautions to be taken when applying Organic Manure to these Plantations.** — De Wildeman, E., in the *Bulletin Agricole de l'Institut Scientifique de Saïgon*, Year II, No. 2, pp. 53-54. Saigon, February, 1920.

An experiment recently carried out in the Federated Malay States has shown that the vicinity of the coco palm to Hevea may be injurious especially to the latter.

In one plantation, the Heveas had been planted in rows between pre-existent coco palms which had been felled. The stipes of the palms had been split and buried in trenches between the rows of Heveas.

In 1907, it was observed that a large number of Heveas were a more or less seriously diseased. On examination, the roots were found to be attacked by one or both of the two fungi ; *Hymenochaete noxia* and *Poria hypolateritia*.

It was observed that the roots of all the diseased plants had struck down into the trenches where the stipes of the coco palm had been buried.

In a certain number of cases where the main root had not yet been affected by the mycelial filaments, it was possible to save the trees by removing the infected roots, which were, naturally, immediately burnt. But when the tap-root was attacked the Hevea had to be destroyed. Examination of the rotting stipes revealed the presence of the two fungi mentioned above and also of *Fomes lucidus*, a common fungus of tropical regions (1). This experiment proves, not only that the parasites of the coco palm can pass to the hevea, but also that great care is needed when applying organic matter. Such matter, (rotting trunks and stipes, branches of all kinds and leaves) may certainly constitute, and do constitute, a valuable source of humus towards which the roots will be attracted and from which they will derive part of their nourishment ; but if this matter is infected by noxious organisms, it may cause serious diseases, often fatal to the plantation. It is therefore important to exercise great care in making up manure in the form of mould. If there is any doubt about their value from the point of view of fungus mycelium, insect eggs or larvae, it will be necessary to disinfect or even burn them.

In the same way, great care must be taken in the use of green manures on the value of which too great stress cannot be laid. The truth must never be lost sight of that the more intensive the cultivation the greater the need of care and hygiene the manager of the plantation must keep

(1) See *R.* September 1918, No. 1 56. (*Ed.*)

watch over the health of his plants ; the State, by means of a department of plant pathology, must enable the planters to fight against the diseases which attack and will and more attack plantations in the tropics.

STIMULANT, AROMATIC, NARCOTIC AND MEDICINAL PLANTS

755 – **Preparation of Cacao.** — TEISSONIER, P., in *Journal officiel de la Côte d'Ivoire*, Year XXV, No. 13. Bingerville, July 15, 1919.

The simplest process is to wash the cacao beans in order to remove the surrounding pulp, and then dry them in the sun. Beans thus treated are smooth to the touch, and of a light colour ; the inside is brownish, inclining somewhat to violet. Cacao prepared in this manner has a pronounced bitter taste and no special aroma, therefore the process is not only inadvisable, but should be forbidden, if the quality of the cacao is to be maintained.

A superior product is obtained by fermentation, and cacao so treated is of greater commercial value than that which is merely washed and dried. The beans are placed in boxes, tubs, or barrels, buried in soil with 15 or 20 cm. protruding. The bottoms of the receptacles are perforated with holes to allow of the liquid to escape. The size of the receptacles varies, but the larger the quantity they contain, the more regular and complete is the fermentation.

The cacao beans are packed in even layers, and the receptacles covered with sacks, mats, or simply banana-leaves ; this is done in the evening, and the beans are left until the morning of the third day, when they are removed to another receptacle, care being taken to place at the bottom those beans that were previously at the top, and to move those at the sides to the centre. This must be done every morning until the fermentation is complete ; in this manner, the fermentation is regular and the product perfect.

The length of the fermentation process varies according to the district and the air temperature, but it may last from 5 to 7 days. No precise directions can be given on the subject as the right time can only be learnt by practice. Some guidance may be afforded by the fact that fermentation at the Bingerville Agricultural Station takes 6 days.

The process is considered complete when the interior of the bean has assumed its characteristic red colour, and the beans are then placed in the sun until they are completely dried, for which purpose the cacao, is placed on mats, or better still, in rectangular boxes with sides not more than 10 cm. high. Very good drying-racks are made by nailing mats upon frames with raised edges and furnished with feet or placed on cross-bars of wood 20 cm. above the level of the ground. The cacao is spread out in thin layers ; it is frequently turned during the day, and taken indoors at night, so that it may not get damp. The drying process last from 4 to 6 days, according to the heat of the sun : it is complete when the beans crack on squeezing between the fingers.

After fermentation, there is always a larger or smaller amount of pulp still adhering to the beans ; in order to remove this, they are either rubbed on a table after being dried or shaken backwards and forwards in a bag. The cacao is then sifted, sorted and stored.

The skin of the fermented bean is dark-red and somewhat rough to the touch; the inside is light-chocolate colour, the centre being lighter than the periphery. The beans have a special flavour without the least trace of bitterness.

Even after drying, the cleaning of the cacao beans, which is effected in the above-mentioned manner, is not complete. In order entirely to remove the pulp adhering after fermentation, the beans should be washed immediately after taking them out of the receptacles, if this be possible. Washing does not improve the quality of the cacao, but it improves its appearance ; the colour of the skin is uniform, and smooth, like that of washed and unfermented beans ; drying takes place more rapidly, and all smell of fermentation is removed. The product thus treated, always fetches a higher price on the market.

Washing, however, should not be practised in order to conceal incomplete fermentation, which can easily be detected by the internal colour, and the taste of the beans, these being the same as in the case of fermented but unwashed cacao.

Now that cacao production in the Ivory Coast is making decided progress, it is necessary to induce the natives to adopt the best methods of preparation in order to maintain the quality that it has been reported to possess, by commercial and industrial experts, to obtain a uniform product for the whole colony by means of the adoption of the same method of preparation, and to ensure proper fermentation followed by washing the beans, whenever sufficient water is available.

756 - **Camomile Cultivation in Anjou, France.** — HITIER, H., in *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VI, No. 18, pp. 467-469. Paris, May 12, 1920.

In the Department of Maine-et-Loire, medicinal plants, of which the camomile is the chief, are grown over more than 300 hectares. The number of camomile growers is about a thousand, not counting some 4000 persons engaged in cultivating and gathering the flowers.

The camomile produced in this district has special qualities of fragance and aroma which are due to the climate and soil of Anjou, but unfortunately the falling prices during the last few years appear to have discouraged the growers, who show an inclination to replace camomile by other, more paying, crops.

Camomile-growing is, however, very important because it is specially suited to small holdings, and provides remunerative occupation for all the members of the family.

757 - **The Insecticidal Properties of Different Parts of *Pyrethrum cinerariaefolium*, and of its Flower-Heads at Various Stages of Development** (1). — PASSARINI, N.,, in *Nuovo Giornale botanico italiano*, New Series, Vol. XXVII, Part 1, pp. 1-6. Sancasciano, Val di Pesa, January, 1920.

The author has compared the insecticidal properties of feverfew (*Pyrethrum cinerariaefolium*) from Dalmatia, Florence (Forestry Institute), Scandicci (Agricultural Institute) and Palermo (Botanic Garden),

(1) See *R.*, October-December 1919, No. 1151. (*Ed.*)

as well as those of ordinary insect powder, and found that they were all practically the same. The insects used in the experiments were the housefly, (*Musca domestica*), dog-flea (*Ctenecephalus canis*) and the ant (*Crematogaster scutellaris.*)

He also discovered that, although some investigators deny all insecticidal properties to the stem of pyrethrum, the leaves, roots, and stem when properly dried and ground, have all considerable insecticidal properties though to a less degree than the flower-heads.

No particular differences were found as regards the various parts of the flower head (ligulate florets of the ray, tubular florets of the disk, tracts of the involucre, and receptacles). Previous investigators were all agreed that the flower-heads should be gathered while still young, and before the rays have opened. In order to test this the author gathered flowers at different stages of growth from the bud to the fructification and after drying and powdering them, he tested their efficacity in destroying insects, and demonstrated the very evident superiority of fully-developed flowers-heads, and of those with rays entirely expanded. Thus the idea that the flowers ought to be gathered at an early stage can only be explained from the commercial standpoint, as the more mature the flowers, the more easily do the petals become detached and fall.

The author also tried the effect on mosquitoes of the fumes liberated during the incomplete combustion of pyrethrum, and found that the insects were stupified, but not killed, so that after some hours, they regained their wonted activity.

VARIOUS CROPS

758 – **The Use of "Falasco" in Paper Making.** — PAVARINO, G. L. and CASTELLARI, G., in *Le Stazioni sperimentali agrarie italiane*, Vol. I,III, Pts. 1-3, pp. 32-46, tables 1. Modena, 1920.

In the neighbourhood of Pisa, the name "falasco" is applied to a bog plant, which is cut down and made into hay during the season when the marsh is dried up. The crop is generally gathered in July, before the fruiting stage. The falasco plants mainly belong to the natural orders Poaceae, Cyperaceae, Typhaceae, and Juncaceae as shown by the following list:

CHIEF SPECIES CONSTITUTING FALASCO HAY: Common reed (*Phragmites communis*); common sedge (*Carex riparia C. glauca, C. vulpina*); giant sedge (*C. maxima*); *C. pendula*; *C. stricta*; *C. paludosa*; *C. stellulata*; rush (*Scirpus lacustris*); *Sc. triqueter*; *Sc. Holoschoenus*; sea-rush (*Sc. maritimus*); *Cyperus textilis*; galingale (*C. longus*); *C. vegetus*; *C. Monti*; *Schoenus mariscus*; lesser reedmace (*Typha angustifolia*); great reedmace (*T. latifolia*); *Heleocharis palustris*; wood small reed (*Calamagrostis epigeios*); *Arundo Donax*; jointed rush (*Juncus articulatus*); thread rush (*J. filiformis*); common rush (*J. conglomeratus*); hard rush. (*J. effusus*); sea rush (*J. maritimus*); slender rush (*J. tenuis*); *J. obtusiflorus*; *J. tenageia*; branched bur-reed (*Sparganium ramosum*); *Glyceria aquatica*; arrowhead (*Sagittaria sagittaefolia*).

Plants intended for special use are collected separately when they have reached the required size. Usually the proprietors of the marsh sell the falasco as it stands ; the buyer pays a fixed sum per acre and himself takes the responsibility of the cutting, drying and transport. Only a part of the falasco is used in the manufacture of ropes, matting, baskets, or to cover chairs, wine flasks, etc., or as stable litter, manure etc. A considerable number of plants rot away during the rainy season. The marshes in the Pisa district give an average annual yield of 20.2 cwt. of falasco per acre. On account of the present shortage of material for paper making, the author investigated the marsh plants in the Pisa district, in order to find out if they could be utilised in the paper industry in the same way as rushes were utilised during the war in the United States, and the marsh plants round the Masurien Lakes in Germany, where various species of *Sphagnum* and *Eriophorum* abound.

Special attention is drawn to the botanical, physiological, microscopical and chemical characters of the following species : *Carex paludosa*, *Phragmites communis*, *Scirpus lacustris*, *Typha angustifolia*, and *Cyperus longus*. The cellulose content was determined by chopping up and heating in a 6 % solution of caustic soda under a pressure of 3 atmospheres for over 3 hours, pouring off the liquid, filtering of the sediment, washing and bleaching with chloride of lime at the rate of 10 % of the vegetable material, pressing, and dryng. The data obtained are quoted in the appended table :

Name or Plant	Amount of material treated	Weight after treatment	Yield of Cellulose
Carex paludosa	200 g.	86 g.	43.0 %
Phragmites communis	200	95	47,5
Scirpus lacustris	200	91	45,5
Typha angustifolia	200	88	44,0
Cyperus longus	200	50	25,0

It will be seen that, with the exception of *Cyperus*, these marsh plants give a high yield of cellulose.

Bleaching the fibre with sulphur dioxide and permanganate of potash did not given as favourable results as with chloride of lime. It may be concluded that the principal falasco plants will furnish long, even fibres suitable for filtering. As the cellulose content does not notably differ from that of good paper-making plants, all the members of the falasco group may be considered as material especially adapted for paper-making. Experiments made in the laboratory on these same plants confirm these results.

759 – ***Muscari comosum*** **and** ***Hyacinthus ciliatus*** **as Forage and Economic Plants.** — See No. 795 of this *Review*.

FRUIT GROWING

760 - **An Account of the *Amygdaleae* and Apple Trees of the Cold Regions of Indo-China and South China** (1).—CHEVALIER, A., in *Comptes rendus de l'Académie des Scien-ces*, Vol. CLXX, No. 19, pp. 1127-1129. Paris, May 10, 1920.

Indo-China includes in the upper regions of Tonking, and Laos, and in the mountains of Annam, several million hectares of land capable of cultivation, where most of the plants of temperate and sub-temperate countries, viz., wheat, barley, hemp, flax, poppy, and nearly all the European fruit trees, can be grown.

The fruit-trees are already represented by species, or varieties, differing from those cultivated in France, and the author undertook his investigations with a view to improving the native trees or using them as stocks upon which to graft choice French varieties or for the purpose of obtaining hybrids by crossing them with these varieties. He was assisted in his researches by M. MIÉVILLE of the Agricultural Service of Indo-China. The plants were identified at the Museum Herbarium, and much help was afforded by M. J. CARDOTS, recent revision of the Asiatic Rosaceae.

The peach (*Persica vulgaris* Mill) is to be found almost every where in Tonking, but its numerous, ungrafted varieties are different from those cultivated in Europe. The species is said to be indigenous in China; it is very common in Yunnan, and the author has found it apparently wild among the brush wood on the Chapa massif in Tonking at altitudes varying from 1000 m. to 1500 m. A dwarf variety with pink double flowers (*P. nana* Mill.) is grown as an ornamental plant in gardens in China and Annam. Another variety with small spherical fruits with little pulp (*P. Davidiana* Carrière), which the author formerly met with in China, was frequently seen by him in the gardens of Tonking.

The author did not come across the almond tree, (*Amygdalus communis* L.) in Tonking and *Amygdalus cochin chinensis* Loureiro is a mystery to him. Very probably the tree was not an almond at all, for LOUREIRO frequently made similar mistakes with regard to other genera.

Plum-trees (*Prunus* spp.) are cultivated in may gardens in Tonking Laos, and in North Annam. They belong to the Himalayan and Chinese species, *Prunus triflora* Roxb. The author knows a farly large number of varieties which reproduce themselves from seed, some of which have violet, others pinkish white fruits, whilst some bear yellowish plums the size of a small *mirabelle*, or even smaller. These plums have a bitter favour, and need improving.

The Japanese plum (*Prunus Mume* Sieb. and Zucc.) is sometimes grown in gardens at Tonking mereby for the sake of its pretty double blossoms.

The apricot (*Armeniaca vulgaris* Lamk.) which was imported long ago from China, is also cultivated in Tonking gardens but it is a variety bearing small fruits with little pulp. It ripens in April in the Delta.

An indigenous cherry (*Cerasus Puddum* [Roxb] Wall) is found in the forests on the mountains in Tonking, at an altitude of about 800 m. near

(1) See *R.*, July-September, 1919, Nos. 908 and 909, and *R.*, February, 1920, No. 58: (*Ed*)

Langson, and at 1200 to 2400 m. at Traninh. It is a large tree with red flowers, the fruits are blackish red, very little pulp, and a bitter taste, being almost uneatable. The European cherries, however, graft very well on this stock.

The European apple-tree does not exist in China. Its place is taken by *Malus prunifolia* (*Willd.*) Borkh, an autonomous species, and not a hybrid (REHDER). It is farly commonly cultivated in Yunnan where it bears fruits resemble the Api apple, which ripen in May and June. These apple-trees have been introduced into some parts of Tonkin, and seem to have become acclimatised.

Two very interesting species of apple grow wild on the high plateaux of Indo-China. One is *Malus Doumeri* A. Chev. (*Pyrus Doumeri* Bois), which grows on Langbian and its spurs, at heights varying from 800 to 2000 m.; the other is *Malus laosensis* A. Chev. (= *Pyrus laosensis* Cardot), and is found at Traninh at an altitude of 1500 m., and therefore should grow also on certain mountains in Tonkin.

These two species form large trees producing fruit that resembles some of the Normandy cider apples, in shape, flavour, and colour. From these Tonking apples, M. MÉVILLE has made a beverage very like Normandy perry in colour. Although these two species grow in the depth of the forest and receive no care from the present mountain population, the author thinks it is very possible that at some distant date, they were cultivated and improved. Colour is given to this supposition by the presence of *M. Doumeri* and *M. laosensis* round some of the pagodas of Laos, where they are tended by the bonzes as sacred trees.

761 – **A Description of the Pear, Walnut, and Chestnut Trees of the Cold Districts of Indo-China and South China.** — CHEVALIER, A., in *Comptes rendus de l'Académie des Sciences*, Vol. 170, No. 22, pp. 1335-1336. Paris, May 31, 1920.

The pear is represented in South China and Tonking by various cultivated species differing from *Pyrus communis*, and known under the collective name of Chinese pear-trees. Their fruit is full of stone-cells, contains but little juice, and is only fit for compotes, to this group belongs *Pyrus Semoni* Carrière, a variety of *P. ussuriensis* Max., which the author saw in a native garden at Thanh-Ba (Tonking); it is also to be found here and there in the central region. This pear is not grafted by the natives, but is propagated by slips or layering.

Two species of *Pyrus* occur wild in the mountainous regions of Indo-China, and can be used as stocks for cultivated pear-trees; one is *P. Pashia* Ham (includes *P. Kumaone* Done), remarkable for the polymorphism of its leaves, and the other is *P. granulosa* Bertol. The latter was found by the author in the experimental farm of the Pasteur Institute at Homba, in the Annam mountains, at an altitude of 1500 m., and its habit of growth is worthy of mention.

P. granulosa grows in the moist, virgin forests, it develops first in the humus in the forks of trees, like an epiphytic orchid, and sometimes at a height of 10 m. Gradually, the principal roots descend the supporting trunk, and finally reach the soil into which they penetrate. From this

time, the branches of the tree develop, bear flowers and fruit, the tree mingling its crown, which often has a diameter of 8 to 10 m., with that of its support.

In Yunnan, a very remarkable variety of the walnut is cultivated (*Juglans Duclouxiana* Dode). Its shells are very thin and fragile, but it is worth growing and has recently been planted at different places in Tonking and Laos. Another variety with very hard nut-shells (*J. sagittata* Dode) grows in the same region. Both these varieties yield an excellent wood that can replace common walnut in the manufacture of the butt-ends of rifles. In 1917, there was a stock of 10 000 tons of this wood at Yannanfou. During the war, the idea had been entertained of exploiting it for the purpose of supplying France, but eventually the wood of a genus of *Lager stroemia*, known under the native name of "Banlang," was chosen. Almost pure stands of this tree are to be seen in certain forests of Cochin-China and Cambodia.

Castanea Duclouxii Dode, a species regarded by the author as akin to *Castanea vulgaris* Lank. var. *yunammenis* Franchet, is an arborescent chestnut very common in Yunnan, bearing average sized fruits and reproducing itself from seed without there being any need of grafting. It should be known by its older name of *C. mollissima* Blume.

In November, 1909, M. Miéville sowed some chestnuts at Chapa (Tonking), and, by 1917 the seedlings had become trees bearing large fruit of good quality that ripened about October 10.

Quite recently, commandant Eon discovered in the mountainous region of the second military district of Tonking, a chestnut tree with very spiky fruits and hairy leaves of which the lower surface was quite silvery This seems to be a variety (*C. Eonii* Chev.) of the preceding species.

In Indo-China there are a dozen species of *Castanopsis*, some of which are closely related to the genus *Castanea*. One of them, *C. tribuloides* C. D. C., is cultivated in the middle region of Tonking (Pays de Détham), and from it, the natives obtain a nut much like hazel-nut in flavour.

762 - **The Mango in the Belgian Congo.** — Pynaert, L., in the *Bulletin agricole du Congo Belge*, Vol. X, Nos. 1-4, pp. 185-240, figs. 14. Brussels, March-December, 1919.

The mango (*Mangifera indica*) has been introduced into the Belgian Congo, but the fruits of the varieties found there are not to be compared with those usually eaten in India, the Antilles, and Central America. Those at present consumed in the Congo, with the exception of choicer kinds obtained in the Eastern Province and the Upper Kasai, are fibrous, have a very strong turpentine flavour, ripen unevenly and are only fit for cooking.

It is therefore necessary to introduce, and to propagate by means of grafting, good varieties with large fruits, containing few or no fibres, and with sweet and succulent pulp.

The mango is most suitable as a native crop in districts near the principal centres of the Colony. Anyone possessing a good variety could certainly sell the fruit for a high price.

The same attention should therefore be devoted to fruit tree cultivation in the Congo as in other Colonies. The mango is one of the most paying trees, and its fruit can be exported.

The author treats in detail the following questions: History, description, synonymy, distribution, and varieties of the mango (Florida, Ceylon, India, Java, Trinidad, Porto Rico and Cuba), the best varieties, methods of improvement, classification of the varieties, climate, propagation (seeds, inarching, layering, shield-grafting, cleft-grafting crown-grafting, the Goa system of grafting, etc.), soil cultivation, pruning, gathering, diseases, methods of using mangoes, packing and transport, exportation, market.

763 - **The Possibility of Cultivating *Feijoa Sellowiana* in Italy.** — PELLEGRINI, M., in *Rassegna della Produzione italiana, Numero specialmente dedicato all'Agricoltura, all'Alimentazione, ed alle Industrie derivanti*, Year IV, Sect. D., No. 6, p. 25, figs. 2 Milan, June, 1920.

This *Myrtacea* is a native of Estarn Brazil, and was introduced for the first time into Europe about 1890 by ANDRÉ, who tried to popularise it in South France, but without success. In 1901, it was introduced into California, where it spread rapidly. In Italy, *Feijoa Sellowiana* is sold by all large seedsmen, and it grows in the South of the Peninsula, the islands, and even in the North in very sheltered spots, such as the Ligurian Riviera.

It is a shrub 4 to 5 m. high; it is not particular as to soil, resists drought and winds, and bears cold better than the lemon (the author found it could resist as much as —5° C). *F. Sellowiana* may be propagated by seeds or cuttings but the former soon lose their germinating power. The seed lings come up in 4 to 6 weeks after sowing, and the shrub flowers after 3 or 4 years at the latest. Experiments in grafting it on other *Myrtaceae* (*Eugenia* and *Psidium*) have, so far, proved unsuccessful.

The author considers that this species should be widely cultivated in Italy. The fruit is excellent, the shrub needs little care, and hitherto has not been attacked by special parasites.

764 - **The Vine in Madagascar.** — *Bulletin de l'Agence Générale des Colonies*, Ministère des Colonies, Year XIII, No. 146, p. 162. Paris-Melun, February, 1920. HORTICULTURE

The vine bears fruit in various regions in Madagascar. It is found in Imérina, Ambositra, and Bétsiléo, where it produces very good fruit. The grapes, when ripe, have an excellent flavour, and many colonial vine-growers have succeeded in obtaining very fine table-grapes. The vine, however, has a low alcohol content, and is of somewhat inferior quality.

Experiments have been carried on for a certain number of years in order to determine the best local conditions for growing this vine, and to study the wine-making processes. A new step has been taken in this direction.

Owing to the extension of wine-growing in the Province of Fianarantsoa, and the importance of investigating and determining methods of wine-making in this region, the Governor-General of the Colony has

passed a decree establishing an oenological laboratory which will be directed by a medical inspector of the native Medical-Assistance Service.

765 - **Lime and American Vines.** — De Angelis D'Ossat, in *Le Stazioni sperimentali agrarie italiane*, Vol. LIII, Nos. 1-3, pp. 97-100, 1 plate. Modena, 1920.

In a preceding article (Il calcare e le viti americane, *Le stazioni sperimentali agrarie italiane*, vol. XLVII, pp. 603-620, 1914), the author expressed grave doubts as to the truth of the common opinion regarding the lime resistance of American vines. In the present paper, he gives the results of his subsequent observations, which confirm his previous statement. The experiments were carried out in the agricultural garden of the Istituto Superiore Agrario at Perugia, and on the farm of Casalina which is attached to it. The data obtained reveal very evident contradictions between the theories based on the acidometric scale, and the facts observed by Prof. De Angelis, of which a summary is given in the following table :

Vines	Theoretical resistance	Percentage tolerated at Perugia
	Per cent.	Per cent.
Labrusca	5	30,02 — 40,35
Labrusca × aestivalis	5	27,81 — 35,43
Riparia tomentosa	17,5	32,83
Riparia vigorosissima	15	22,34 — 40,76
Riparia glabra	12	36,99
Rupestris of Velletri	17,5	38,88
Riparia vigorosissima of Avellino	17,5	42,20

766 - **Vine Growing Experiments on Calcareous Soil.** — Sagnier, H., in *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VI, No. 19, pp. 475-476. Paris, May 19, 1920.

The author communicated to the Académie a paper by MM. E. Zacharewicz and A. Tacussel dealing with the results obtained with American vines and their hybrids in an experiment field, planted in 1891, on an estate at Fontaine de Vaucluse (Department of Vaucluse).

The experiments lasted for 28 years, and bore upon 68 varieties of different origin.

The soil is extremely calcareous. From the physical standpoint it consists at a depth of 30 cm., of 57 % of fine earth, and 43 % of lime. Its fertility is very low and it is extremely dry in summer.

Most of these varieties have disappeared, owing to their being unsuited to the soil, and probably also to lack of cultivation and manure, as the experiment field was left unmanured, on account of scarcity of labour during the 5 years of the war. The vines that did well, therefore, showed great powers of resistance.

From observations made in November 1919, the authors classified the survivors as follows :

Fairly robust varieties. Pineaux × Rupestris 1305; Couderc No. 1325; 174^{25} Couderc.

Robust varieties: Chasselas × Berlandieri 41 B; Berlandieri Ecole; 74^{40}; Couderc 132^{9}; Hybrid Berlandieri Malègue No. 6.

Very robust varieties; Berlandieri × Dr Dawin's Alicante; Bouschet; Dr. Dawin's Berlandieri with compound bunches; Berlandieri Resseguier Nos. 1 and 2; Aramon × Rupestris Ganzin Nos 1. and 9, Mourvèdre × Rupestris 1202; Rupestris du Lot.

MM. ZACHAREWICZ and TACUSSEL conclude by stating that, by means of these last varieties, it would by possible to reconstitute a vineyard successfully on most soils.

767 – **Different Varieties of White Malvoisie.** — SANNINO, F. A., in the *Rivista di Ampelografia*, Year I, No. 10, pp. 141-142. Alba-Leghorn, May 15, 1920.

Some wine-manufacturers have spread the belief that malvoisie is a vine producing aromatic grapes, that is fruit with a special odour and flavour very similar to those of muscatel. Under the name of malvoisie, however, a large number of black and white grapes (few red) are cultivated, and only some of these possess the characteristic odour which causes malvoisie to resemble muscatel.

The white malvoisies of Piedmonte, Asti and Alexandria, are really aromatic, and have been described and figured in Volume I of the " Vignoble " by MAS and PULLIAT (p. 145, pl. 73), and by ROVASENDA, in whose classification they appear under Nos. 53 and 57 as vines with oval grapes of fine flavour with smooth pips, and 3 or 5 glabrous lobed leaves.

The above mentioned plate in " Le Vignoble " represent a fine bunch with large, oval, light-yellow grapes having all the appearance of choice table-fruit. PULLAT, however, draws attention to the fact that, owing to its soft pulp, this grape must be regarded as a wine-making variety, Formerly, it was used either alone, or mixed with muscat grapes in the manufacture of a sparkling muscatel, which PULLAT considers too aromatic for French taste.

The idea is that all malvoisies are aromatic grapes and must have originated from the character of this Piedmontese variety.

Certainly the Tuscan, or Long malvoisie, is also aromatic. It has been described and figured in *L'Ampelografia Italiana* (Part. I, p. 17, pl. IV) and in MOLON's *Ampelografia* (Vol. II, p. 747, fig. 57); it is the same as the white Bari malvoisie the white Zante, the " Cannilunga " malvoisie of Novoli (Lecce), etc. and the Conegliano Prosecco.

The Lipari malvoisie decribed and figured in MOLONS' *Ampelografia* (Vol. II, p. 747 fig. 56) is an aromatic grape as Mendola also said. At Catania, in 1910, a considerable number of vines from the Lipari isles and bearing magnificent white grapes of a golden colour were pointed out to the author as belonging to the Lipari malvoisie variety. If however, the true Lipari malvoisie is aromatic, these Catanian vines, must be of another kind. In any case, the Lipari malvoisie wine is always without aroma and has the strong alcoholic flavour of *vin de paille*. If it is made from an

aromatic grape, the loss of aroma must be due to evaporation while the grapes are drying in the sun, which happens in the case of muscatels also.

Count ROVASENDA in his *Saggio di un' Ampelografia universale* after having classified all the vines from "malvagea" to the violet malvoisie of Istria, adds: "I have only arranged in order, and under the supervision of the vine-growers of different countries, the numerous varieties of malvoisie mentioned by other writers. It was not possible in this catalogue to indicate their identity or diversity. To do so would have entailed much discussion, and, further, given the present state of the knowledge of the subject, we feared that, assisted by our own experience alone, it would by impossible to evolve any order out of this chaos. In our opinion, the name malvoisie should only be given to aromatic grapes with the special flavour ot a slightly bitter muscatel. There are, however, so many grapes of ordinary flavour bearing the name of malvoisie, that it is hopeless to try and deprive them of it, even though they have no right to the title."

In order to prevent all confusion in the future, the word aromatic should be added in the case of all malvoisies with an aroma like the Piedmontese variety. Those grapes that are not classified as aromatic, should be understood to be grapes of ordinary flavour. In ROVASENDA's classification, all the numbers from 1 to 50 are such varieties, whereas numbers 51 to 110 include all varieties with the flavour of the muscatel, or of the Piedmontese aromatic malvoisie.

768 **"Duranthon", a Good Direct Bearer.** — STEVANO, A., in the *Rivista di Ampegilografia*. — Year I, Nos. 7-8, pp. 99-103. Alba-Leghorn, April 15, 1920.

During the last twenty years, the author has been testing, in his vineyard at Savigliano (Province of Cuneo) various hybrid direct bearers. The variety known as Capitaine Duranthon proved itself superior to all the others. It is in the first place distinguished by exceptional vegetative growth, its shoots attaining the length of from 6-7 m. after the third year, so that they can be trained, either in festoons, or on pergolas. The following characters of the hybrid were also observed: (1) Almost complete resistance to plylloxera; vines grown for 19 years on soil infected with phylloxera are still immune; (2) great resistance to fungoid disease; at the flowering season; it, however, requires one or two preventive sprayings; (3) abundant yield; from a single adult vine about 71 to 75 kg. of grapes, or half a hectolitre of wine, is obtained; the bunches, of which 3 are borne on a branch, are fairly closely-set, much winged, conical, and from 20 to 25 cm. long; the grapes are of medium size, and round; if hung in an uninfected room, they keep as long as one year without rotting; hence they can be used for liqueur wines (*vino santo*); (5) it produces much must; 1 hectolitre of must can be obtained from 140 to 146 kg. of fresh grapes or 120 kg. of grapes that have been kept for 20 days; (6) high sugar content; usually from 19 to 21 %; in 1919, it was as much as 31 %, which corresponds to 20 % of alcohol; (7) acidity, 8 per thousand; (8) wine with a pure smell and flavour; colour rather a dark-red, clear; it ages easily if left slightly in contact with the air; (9) it is not a table-grape, for the berries are

somewhat small, but the skim is thin, and the pulp detached ; (10) it ripens early (September 15-20,) but it begins vegetative growth equally early, which is a serious defect, as it is thus exposed to frosts. However, in 1919, after the frost of April 23 had destroyed $^9/_{10}$ of the normal ones, the new buds already contained young bunches, and yielded a crop almost as large as that of 1918 ; (11) " Duranthon " suffers from drought and therefore, is not suited to cultivation on hill slopes.

769 – **Good Vine-Stocks of the Trentino** (1). — ZANOTTI, L., in the *Rivista di Ampelografia* Year I, Nos. 7-8, pp. 113. Alba-Leghorn, April 15, 1920.

The vine, *Rupestris Göthe* No. 9, is characterised by well developed shoots that are proof against the rigours of the winter, and by large leaves which are, however, less glossy than those of *Rupestris metallica*. It is largely cultivated in Styria, where its good qualities make it preferred to other vines of the *Rupestris* variety. Its wood reaches complete maturity. This vine grafts well, and is easily propagated by slips. The graft grows luxuriantly, and the grapes ripen at the normal time. This *Rupestris* will grow in poor, dry, and stony soils, provided they do not contain above 25 % of soluble calcium carbonate. According to Zweifler, it appears to give excellent results, especially when the vines are grown low and pruned close.

Riparia × *Rupestris Schwarzmann* has recently become a favourite with vine-growers, who prefer it to *Riparia*. It much resembles the latter, but is superior on account of its harder, more compact wood, which is more resistant to the cold in winter, and to the alternations of frost and thawing. The long shoots of the hybrid assume a dark brown colour and ripen perfectly ; its large leaves recall those of *Riparia*, whereas it resembles *Rupestris* in the colour of the leaf-veins which are more or less red. The hybrid is generally very robust and grows luxuriantly. It cuttings strike easily, and it grafts well, the stock giving strength to the scion, which becomes almost as large as the stock, so that at the crown of these vines, there are none of the special constrictions peculiar to the *Riparia* variety. *Riparia* × *Rupestris* Sch. grows well in all soils suited to *Riparia*, and can adapt itself to those light, or heavy, soils where *Riparia* would suffer. It has, however,, the defect of being little tolerant of lime, only being able to resist 12 % of this substance. It hastens the ripening of the grapes and improves their quality.

770 – **Hybrid Vine-Stocks for Sicily** (2). — GRIMALDI, L., in *Italia vinicola ed agraria*, Year X, No. 11, p. 118. Casale Monferrato, March 14, 1920.

The following Italo-American hybrid vines have been specially recommended by Dr. PAULSEN for use in the reconstitution of vineyards in the centre of Sicily, taking into account the conditions prevalent in that part of the island.

FOR DRY CALCAREOUS, SANDY LOAM SOIL WITH HEAVY CALCAREOUS SUBSOIL. — *Paulsen hybrids* : Catarratto × Berlandieri 2 No. 779 and

(2) See *R.* June, 1919, N. 663. (*Ed.*)
(1) See *R.* June, 1920, No. 662. (*Ed.*)

Berlandieri × Aramon Rup. 1043; *Ruggeri Hybrids*: Berlandieri × Rup du Lot 131 and 140.

FOR CALCAREOUS, CLAY LOAM SOILS WITH MARLY, FAIRLY DAMP SUBSOIL — *Paulsen hybrids*: Berlandieri × Rupestris Martin 1381 and 1417; Ber landieri 2 × Riparia Rupestris 2 A 1119; Berlandieri 2 × Riparia Rupestri 3309 No. 1776; *Ruggeri hybrids*: Albanello × Berlandieri 8 and 1

FOR DAMP, CALCAREOUS CLAY SOILS. — *Paulsen hybrids*: Cataratto × Berlandieri 2, No. 779; Berlandieri 2 × Mourvèdre Rupestris 120 No. 1322; *Ruggeri hybrids*: Berlandieri × Rupestris du Lot Nos. 13 and 142; *Grimaldi hybrids*: Troia × Rupestris 1132.

FOR SLIGHT CALCAREOUS, DAMP, SANDY LOAM SOILS. — *Paulsen hybrids* Berlandieri 2 × Aramon Rupestris 1045; Berlandieri × Rupestris Mon ticola 782; *Ruggeri hybrids*: Berlandieri × Rupestris du Lot; Ber landieri × Rupestris Metallica 122; Berlandieri × Riparia, 188, 20 225, 267.

A few years, however, are not long enough in order to judge of a ne hybrid. It must be studied on its own roots, and also grafted, for mar years. In hot districts vigorous development in the first few season not always a good sign for the future. The affinity of the graft does n reveal itself at once, sometimes only after 8 or 9 years have elapsed. T preparation of the soil has much influence upon the growth of the hybri

FORESTRY

771 – **Investigations into the Effect of Forest upon Water Courses.** — ENGLER, (Director der Eidgen forstlichen Versuchsanstalt), in *Mitteilungen der Schweizerisch Zentralanstalt für das forstliche Versuchswesen*, Vol. XII, pp. XV + 526, figs. Zurich, 1919.

It has long been supposed that forests increase the water supp of streams (SURELL, DEMOUTZEY), but some doubt has recently been ca upon this theory, because it was not founded upon careful, reliable obse vation.

The late Prof. C. BOURGEOIS, Director of the Federal Forestry R search Station of Zurich, assisted by M. ZÜRCHER, the Forest Inspect had already undertaken some direct experiments with a view to determi ing the effect of forests upon the flow of streams. For this purpose selected in the Bernese Emmenthal, two valleys much resembling one a other, with the exception that one was entirely wooded, while only or third of the other was covered by forest. He measured the water flowi from each of these valleys.

The author continued this work, and has just published the resu of this 15 years (1903-1917) researches. On the one hand these confi certain statements that had been previously made while, on the oth they reveal some new facts.

The memoir contains numerous graphs and summaries of observatio

The two valleys in question are excavated in a conglomerate co posed of crystalline and calcareous rocks derived from different sourc and rendered impermeable by layers of marl, which is an indispensa condition for such investigations. The climate is severe, the rain

eavy (about 1550 mm.), the average temperature of the air is only 6° C, nd westerly winds are the most prevalent.

The first of these valleys, the Sperbelgraben, situated at an altitude f from 912 to 1082 m., has an area of 56 hectares, of which 97 % is woods; contains 9 streams. The second valley, known as the Rappengraen, lies at an altitude of between 830 and 1060, its area is 70 hectares nd 35 % of it is wooded. Its waters are collected by 7 streams.

Pluviometers and recorders were set up in both valleys and the amount f water carried away by the streams was measured by means of a gauge, r calculated by the help of BAZIN'S formula.

It was found by careful investigation that the Sperbelgraben lost % of the water received while, on the other hand, the Rappengraben ad an additional amount, of 3 %, and this has been taken into account n all the calculations.

From 1903 to 1915, however, more rain fell by turns in one valley han in the other, with an average of 3 % in the favour of the thinly-vooded one. This result was in contradiction to what had been stated n other countries, namely that forests increase the rainfall. During the rowing season, that is to say, from May to October, 58 % of the total ain fell, in each valley and from November to April only 42 % of the vhole amount.

The forest soil is 5 % more porous than the agricultural soil to a lepth of 10 cm., and 1.1 % more at a depth varying from 40 to 50 cm., his increases its permeability.

As a result of experiments made in these two valleys, as well as at Swiss and foreign Forestry Stations, it has been found that the annual oss of water by evaporation amounts to :

123	mm.,	or	1230	cu.	m.	per	hectare	for wooded land
369	»	»	3690	»	»	»	»	land without woods
300	»	»	3000	»	»	»	»	trees
130	»	»	1300	»	»	»	»	field and meadow plants
65	»	»	650	»	»	»	»	pasture

The author compares the amount of the rainfall with that carried ff by the streams, after the rapid melting of the snow, during storms nd long rainy seasons, during periods of drought at different seasons, nd on wooded and unwooded land.

After the rapid melting of the snow, the averages for Rappengraben, vhich is thinly wooded, are 11, 12, and 30 % higher than those for the ther well-wooded valley.

After 6 storms, the average amount of water carried off from the Rappengraben was 3 % above that from the other valley. When the rain ad been continuous or in rainy seasons, the streams of first one valley, nd then the other carried off more water.

The graphic curves, although of different values, are parallel, which hows the regulating effect exercised by the forest upon the streams, ven during periods of drought in summer and winter.

During the summer, that is to say, from April 16 to November 30, the Sperbelgraben valley gave up 69 % of the rainwater it received, and the Rappengraben did the same as against 31 % in winter. Since the water-flow is the same for both valleys, it must be admitted that the amount of water evaporating per season and per year is the same for land under forest and unwooded land.

Taking into account the observations made in the Emmenthal, it may be stated that, speaking generally, the rainwater is distributed as follows :

	In % of rainfall	
	Wooded land	Unwooded land
Water carried off by streams	60 %	60 %
Water adhering to plants, evaporated immediately . . .	15	10
Water absorbed by plant transpiration.	20	6
Water evaporated directly from the soil	5	24
Total	**100**	**100**

It therefore appears that, throughout the year in the Swiss pre-Alpine regions at altitudes up to 2000 m., the rainwater finds its way by surface drainage and infiltration directly into the streams, and that 40 % is evaporated by the soil and by plants.

The soil of wooded land, on account of its greated porosity, is more permeable than that of land bare of trees ; it absorbs a great quantity of water which percolates from it, whereas where there are no trees, this water collects and forms streams.

The matter derived from the erosion of rocks and from the detritus of water-satured land has a volume per hectare per annum of 0.85 cu. m. in the case of the Sperbelgraben (wooded), and 2.22 cu. m. in that of the Rappengraben (partly wooded).

To sum up, the forest regulates the flow of the streams without, however, increasing the amount of water. The first fact was already known, but it is of the utmost importance in the utilisation of great water power; therefore, foresters and engineers should consult together with a view to planting and maintaining forests for selection-felling. The second fact is quite new, and we should be very grateful to Prof. ENGLER for having proved it so decisively.

772 – **The Experimental Cultivation of Foreign Trees in Austria.** — ZEDERBAUER, E. (Mitteilung der deutschösterreichischer forstlichen Versuchsanstalt in Mariabrünn), in the *Centralblatt für das gesamte Forstwesen*, Year XLV. Parts 7-8, pp. 153-169. Vienna, 1919.

The first report on the experimental cultivation of foreign trees in Austria was drawn up in 1901. The present report deals with the plantations and experiments made by the Mariabrunn Forestry Experiment

Institute in the State forests, or in collaboration with other public or private establishments.

In 1901, the total number of experiment plots was 372 ; 266 for conifers and 106 for deciduous trees. In 1916, the total number had increased to 640 ; 513 for conifers and 127 for deciduous trees. The conifers chiefly cultivated, as being in most request, were: Douglas pine (*Pseudotsuga Douglasii*), Sitka spruce (*Picea sitchensis*), Weymouth pine (*Pinus Strobus*) and Japanese larch (*Larix leptolepis.*) The red oak (*Quercus rubra*) was the most commonly-grown deciduous tree.

From the results of the experiments so far carried out, the following trees seem worthy of recommendation :

(*a*) For the *Castanetum* : *Juglans nigra, Quercus rubra, Q. palustris, Fraxinus americana,* and *Pinus excelsa.*

(*b*) For the *Fagetum,* according to the locality : *Pseudotsuga Douglasii and P. glauca, Pinus Strobus, Picea Sitchensis, Chamaecyparis Lawsoniana, Thuja gigantea, Larix leptolepsis;* and for the lower *Fagetum* alone, *Juglans nigra, Quercus rubra, Carya alba* and *Fraxinus americana.*

(*c*) For the lower (*Picetum* : *Pseudotsuga glauca* and *P. Douglasii, Picea sitchensis.*

Picea pungens and *P. sitchensis* are fairly resistant to the attacks of large game ; they are both suitable for the *Picetum* and the *Fagetum.*

The number of foreign trees worth growing is limited, especially from the point view of timber, which must be better than, or different from, that of the native species, or else produced in larger quantities. The only trees presenting these advantages are : Douglas fir, Weymouth pine, Lawson cypress, giant Thuja, white hickory, and black walnut. The principal object lies in the utilisation of the timber ;otherwise, from an aesthetic point of view, many other trees could be recommended for gardens and parks.

In planting new experiment plots with foreign trees, a space of at least, 0.25 hectares should be allotted to each species, if a good return is to be obtained. With regard to trees of which the qualities have not yet been sufficiently tested, only a few hundred individuals ought to be planted per plot.

Further, as M. CIESLAR has suggested, it would be advisable to plant from 2 to 3, or even more, hectares in different climatic zones, where trees suitable to the zone could first be raised, and then planted in 0.25 hectare experiment plots at the maximum most suited to each kind of tree. Indigenous trees should be grown for purposes of comparision with the foreign species.

X. XI. — Brazil possesses certain advantages which give promise of a brilliant future as a timber exporting country. The forests are often traversed by water courses that can be used for transport purposes to the port, of shipment. In the State of Amazonas, whose tropical climate also permits of speedy re-afforestation, specially favoured in this respect, and the evident possibilities of the exportation of timber from the States of Amazonas and Para will afford distinct compensation for the present stagnation in the rubber trade. Already in Para, the local timber has begun to be used in ship building. The timber exported does not only include that used for building but also for making sleepers, and for furniture etc.

II. III. VI. — Table I shows the exports of timber in the 6 years between 1913 and 1918.

TABLE I. — *Timber Export from Brazil,* 1913 *to* 1918 (*Metric tons*).

8 tanning, 6 colouring, 30 officinal, 6 gum and resin plants and 8 of distinct economic importance.

I. IV. — Besides the States of Amazonas and Para, those of Matto, Grosso, Bahia, Espirito Santo, Rio de Janeiro, Minas Geraes and Parana are also well stocked with valuable timber.

The most important are as follows :

Angico (*Piptadenia rigida* Benth.): wood solid, compact ; heartwood red with dark spots : used for interior work, as it develops with a rapidity equal or even superior to that of eucalyptus, it is decidedly suitable for afforestation purposes.

Cedro (*Cedrela* sp.) female mahogany ; well known.

Canella (*Nectandra* spp.) compact, yellowish brown heartwood according to species ; used for building purposes.

Copaiba (*Copaifera officinalis* L.) heartwood deep red, very compact ; excellent for building and submerged constructions.

Jequitiba (rosa) (*Couratari legalis* Mart.) : heartwood rose red ; soft ; used for casing and boxes, one of the most beautiful species as regard shape, etc.

Jaca andá (*Dalbergia nigra* Fr. All), rosewood.

Páo Brasil (*Caesalpina* spp.) : Brazil or red wood ; used for hydraulic constructions ; dyewood.

Peroba (*Aspidosperma* spp.) : heartwood golden colour, compact and hard ; building, hydraulic and shipping : furniture.

Sapucaia (mirim) (*Lecythis minor* Vell.) : heartwood deep red and dark-veined ; very durable and excellent for sleepers.

Massaranduba (*Mimusops elata* Fr. All.) : heartwood red, very compact ; used for construction purposes ; homonymous similar to *Lucama procera*, Mart. ; the former indigenous to northern Brazil.

Sebastião di arruda (*Physocalymma floridum* Pohl) : compact ; very valuable for costly furniture ; price varies from 50 to 60 *milreis* per cu. metre.

V. VII. — The export of "pinho do Paranà" (*Araucaria brasiliensis* Loud) greatly increased during the war ; it replaces admirably the soft

coniferous wood framework cases, matches and ordinary forniture. It has been exported to Argentina and Uruguay since the cessation of the export of coniferous timber from other countries. The exports. to Argentina and Uruguay were as follows :

	Argentina	Uruguay
	metric tons	metric tons
1910	1 222	1 192
1914	4 884	1 953
1918	102 680	49 341

Attention should also be drawn to the export of worked wood which amounted to 6568 and 9996 metric tons in 1917 and 1918 respectively ; the total export of wood was therefore 64 265 and 179 794 metric tons,

IV. — The area covered with forests in Brazil is 5 000 696 sq. km.. representing 58.63 % of the total area.

Brazil is second in the world, coming next to Finland with regard to the area of forest land. The states which have the greatest extent of forests are Amazonas with 1 683 427 sq. km. (91.85 %), and Para with 921 954 sq. km. (65.57 %).

In 1913, the exports were, in order of value sent to the following countries : Argentina, Uruguay, United States, Portugal, France, and Great Britain. The total value of the exports increased from 1 358 730 paper milreis in 1913 to 6 330 514 in 1916. (1 paper *milreis* = 2*s* 3*d* at par).

VIII. IX. — Brazil owes its remarkable fertility to its ranifall (rain, dew, humidity), which is closely connected with the forest territory. It is judged necessary for Brazil to have a proportion of forest territory at the rate of 50 to 60 % in the equatorial zone, and 40 to 50 % in the tropical and sub-tropical zones.

XII. — Besides the control of forest utilisation re-afforestation and plantation schemes should be carried out, and in his last message to the national congress, Dr. E. Pessõa, President of the Brazilian Republic, emphasised the importance of preserving and re-establishing the woodland area of the Republic. Forest economy has proved that there exists in Brazil extraordinary wealth which can be utilised : Paper, resins, dyeing and tanning materials, furniture, building, posts, sleepers, and firewood. Moreover the export of timber for building and cabinets is a branch of commerce that requires development and re-ordination. There is an evident need for legislation with a view to the protection of this wealth by the establishment not only of forest rules and regulations, but also exploitation, extraction of medicinal plants and rubber, carefully avoiding unnecessary felling. What remains is to carry out the legislative measures already proposed as soon as possible, and thus provide Brazil with forest laws, similar to other civilised countries richly endowed with forest territory.

LIVE STOCK AND BREEDING

HYGIENE

774 – **The Toxic Effect of Peanut Cakes Containing Small Quantities of Castor Seeds.** — BRIOUX CH. and GUERBERT, M. in the *Comptes rendus des Séances de l'Academie d'Agriculture de France* Vol. VI, No. 17, pp. 449-454. Paris, May 5, 1920.

The Académie d'Agriculture has had its attention drawn, on several occasions to cakes containing *Ricinus*, which are responsible almost every year for producing very serious poisoning in cattle. In 1913, M. LE CONTE, a member of the Animal Husbandry Section, reported that a consignment of peanut cakes fed at the rate of 0.5 kg. per day to milch cows produced in his herd a number of abortions, one of which terminated fatally. On examining the suspected cakes, they were found to contain sufficient *Ricinus* to account for these misfortunes.

One of the authors had examined at the Rouen Agricultural Station, several samples of peanut cakes which had caused more or less serious cases of poisoning. In one case, some horses and cows were affected after a single meal; there was one fatal case among the horses, and lactation was suspended in one of the cows.

Microscopic examination of the suspected cake revealed the presence of *Ricinus* to the extent of 1.52 %.

A second sample, which was supposed to have poisoned 3 horses (one of them fatally) after being fed to them once in the proportion 800 to 900 gm. per head, was found to contain 2 % of *Ricinus*.

Some months later, a third sample which had produced more or less serious toxic symptoms in several horses, was found to contain about 1 % of *Ricinus*.

Thus very small quantities of *Ricinus* are sufficient to make a cake dangerous. The authors, quoting KOBERT, estimate that 3 gm of castor cake per 100 kg. live weight is sufficient to kill a calf.

In poisonous cakes containing *Ricinus* (which are almost exclusively peanut cakes) there is as a rule only a small percentage; the addition of so small an amount could be of no use from the point of view of adulteration. The presence of this dangerous substance, therefore, can only be regarded as accidental and due, in most cases, to carelessness, either in the cleaning of the apparatus (crusher or press), after using it for castor-seeds, or in the handling and transport of the peanuts and castor-seeds, which are often carried on the same vessels, as they frequently come from the same places.

Laboratory workers entrusted with the examination of suspected if cakes generally find that the samples only contain a minute proportion of castor cake.

Chemical analysis cannot reveal the presence of small quantities of ricine, the active principle of the castor-oil seed; therefore it is necessary to have recourse to microscopic examination. This gives good results, the work is done by an expert, provided the *Ricinus* accidentally introduced comes from undecorticated seeds, and if the cakes examined do not contain too large an amount of thick highly coloured cellulose which may more or less mask the fragments of castor seed shells, which together

with the cuticle, are the only characteristic portions of the seed that are easily distinguished in the mixture.

If 10 gm of suspected cake reduced to flour, is boiled for some minutes with a 2 % solution of caustic potash, it is possible by means of successive decantations, to concentrate into a small volume, the black angular fragments of the castor seed shells which are hard and very dense, and can be identified under the microscope. In a well decorticated peanut cake, it is easy to find by this method, 0.5 % of undecorticated castor cake, but it is imposible to detect even larger amounts, if the *Ricinus* has been accidentally introduced in the form of seeds or decorticated cake, for the kernel of the castor seed contains no tissues that are easily recognised in a mixture.

In such a case, recourse must be had to KOBERTS' useful biological method, which is based on the fact, that even infinitesimal amounts of ricine dissolved in a physiological salt solution have the power of agglutinating the red blood-corpuscles of mammals and birds.

There are a certain number of substances which, on being introduced into the blood are capable of producing the formation of an agglutinant substance causing the globules to adhere to one another. If the experiment is carried out *in vitro* upon globules in suspension in a salt solution the globules unite, adhere together, and soon form a clotted mass on the walls and at the bottom of the vessel and this is the phenomenon of agglunation. Ricine is an excellent agglutinin.

KOBERT, in his later works, suggested the use of blood corpuscles from the pigeon or guinea-pig, and the concentration of the ricine in suspected cakes by precipitating with alcohol the product obtained by macerating in water.

The authors, however, like KOBERT, have found that the agglutinant properties of ricine are rapidly altered, when left in contact with alcohol, therefore they also tried to find another simple method of concentration which is free from this disadvantage.

They found that ammonium sulphate, a substance that in concentrated solutions precipitates albumens, has also the power of precipitating ricine, without apparently alterating its agglutinating power, even after contact-lasting 24 hours. Instead of using like KOBERT, the red corpuscles of pigeons or guinea-pigs, the authors chose those of the rabbit. These corpuscles also agglutinate very easily, and the rabbit is an excellent animal for the experiment in question. It is enough to prick one of the superficial veins of its ear, in order to obtain without trouble, and without killing the animal, the minimum amount of blood (1 to 2 cc.) required.

The following are the outlines of the biological method suggested by the authors for the detection of castor seeds in suspected cakes :

A given quantity of the cake flour is macerated at 30° to 40° C in 5 times its weight of a 9 per 1000 salt solution, a few cc. of xylol being added to prevent any fermentation. After about 15 hours, it is filtered, and a portion of the filtrate (an amount corresponding to at least 10 gm. of

cake) is heated for an hour in a water-bath at 70° C, in order to destroy certain slightly resistant agglutinins that may be present in the peanuts. The mixture is again filtered to separate the coagulated albumens, and to the liquid thus obtainted, is added 50 % of its weight of pure, crystallised ammonium sulphate, which must be entirely dissolved, without raising the temperature above 40° C.

When the precipitate is formed, it is collected on a small smooth filter, thoroughly drained, and washed with just a few drops of distilled water to remove most of the ammonium sulphate ; then the precipitate is removed with a spatula from the filter, put into a small glass containing 5 cc. of physiological salt solution, stirred for a few moments, and re-filtered. The filtrate thus obtained, which is used in the final experiment, contains about 10 times more ricine than that from the first maceration. The rabbit corpuscles are prepared, after defibrination, by being washed, centrifuged and placed in 4 times their volume of a physiological salt solution.

The agglutination experiment is carried out as follows : The above-mentioned filtrate is mixed with a few drops of the corpuscle suspension in a small test-tube, and the tube is put into an autoclave kept at 37° C, which is a temperature favourable for agglutination. This takes place more rapidly the larger, the amount of *Ricinus* present in the groundnut cake. In the case of a cake with 2 % of *Ricinus*, agglutination is very clearly seen (using the authors' method) in 5 or 10 minutes, and the process is compete before the end of the first hour. With 0.5 % of *Ricinus*, agglutination is already perceptible after half an hour, but if the percentage is lower, it often does not take place until one hour has elapsed, but the method is sufficiently exact to allow of the detection of at least 0.2 % of castor oil seed cake.

It is a good plan to have a control tube filled with liquid from some macerated pure peanut cake that has been treated in exactly the same manner as the suspected sample.

This method of detecting ricine can apparently be easily and profitably used on all agricultural laboratories. It is a useful supplement to microscopic examination, which is frequently at fault, when it is a question of decorticated seeds, or when the histological interpretation is doubtful.

The method can only be employed with certainty in the case of peanuts but these are almost the only cakes in which the accidental presence of castor seeds occurs.

The authors, however, mention that KOBERT found in the common bean an agglutin which resists like that of *Ricinus* a temperature of 70°, C, and they themselves discovered a very active agglutin of the same kind in soya cakes. Therefore in the presence of a suspected cake sold in the form of flour, it is well to take into account these possible sources of error, although it is a very rare occurrence to find beans, or soya in peanut cake flour.

775 - **Myositis Produced in Cattle by Serious Attacks of Aphthic Fever, and Sanitary Measures Dealing with the Consumption of the Meat of Animals Affected by this Disease.** — I. RONCA, V. (*Istituto di Anatomia patologica veterinaria della R. Università di Modena*). Alterazioni e calcificazione nel miocardio dei bovini nelle epizoozie gravi di afta. *La clinica veterinaria*, Year XLIII, Nos. 5-6, pp. 145-163, figs. 2 bibliography of 22 publications . Milan, March, 1 and 31, 1920. — II. SQUADRINI, G. (Direttore del macello di Modena), Miosite aftosa con infiltrazione calcare, *Ibid.*, pp. 163-171, figs. 2.

I. ALTERATIONS AND CALCIFICATION IN THE MYOCARDIUM OF CATTLE IN CASES OF SERIOUS OUTBREAKS OF EPIZOOTIC APHTHIC FEVER. — During two epizootic outbreaks of exceptional severity that raged in 1912-1913 and in 1919, the author had occasion to examine numerous infected cattle, and found that, as regards affections of the feast, the most prevalent were parenchymatous alterations, that is to say, retrogressive processes taking place in the fibro-cells of the myocardium. Those most frequently observed in the muscle-cells were opaque degeneration, hyaline degeneration, and necrosis due to coagulation. All these heart affections were usually present at the same time . The more or less pronounced atrophy and disintegration of the contractile fibres were aso observed. The striation of the fibres, especially the transverse strial, either disappeared entirely, was little apparent, or incomplete. Very aften the heart showed yellowish or yellowish-white, dry, hard, and granular patches, or striations frequently containing large quantities of calcium salts, the product of calcareous infiltration and consisting, as far as can be determined by microchemical reactions, of calcium phosphate.

II. APHTHIC MYOSITIS WITH CALCAREOUS INFILTRATION. — In the case of 4.97 % of the cattle that have succumbed to malignant aphthic fever, a larger or smaller area of the striated muscles in the neighbourhood of the skeleton are found to be pathologically afiected. This is moie clearly seen in young than in old animals. The microscope reveals the presence of striae, or zones, differing in aspect and position according to their situation, and of a colour varying from yellowish to red. These symptoms reveal a form of myositis with vitreous, or waxy degeneration of the sarcoplasm, necrosis due to coagulation, and the subsequent infiltration of calcium salts, with more or less interstitial phlogistic infiltration.

According to the author, the possibility that aphthic fever may be accompanied by such serious symptoms of degeneration does not imply the necessity of modifying the sanitary measures now controlling the consumption of meat of animals affected by this disease (1). Before allowing such meat to be used for food, all the pathological and anatomical symptoms must be taken into account in each particular case. Muscles showing any degree of alteration of the above-described type will be condemned. Whether the other masses of muscle that have undergone no changes in appearance or organoleptic characters are to be condemned or put on the market at a low price, is a matter that will be decided according to the regulations hitherto in force.

(1) Regulations on this subject were issued by the Director-General of Public Health (Prof. LUTRARIO) iu Circular No. 24310 of March 19, 1919. (*Ed*)

776 – **The Chicken Sticktight Flea (*Sarcopsylla gallinacea*.** — SANBORN, C. E., in *Oklahoma Agricultural and Mechanical College, Agricultural Experiment Station, Stillwater, Oklahoma, Bulletin* No. 123, pp. 3-8, figs 3, bibliogr. of 9 works. Stillwater, Feb. 1919.

Observations made for the use of farmers on the chicken sticktight flea (*Sarcopsylla gallinacea*) found in all the southern part of the United States. The parasite thrives best in an arid or semi-arid mild climate.

As a control measure the following are commended: (1) 5 or 10 % mixture of creosote with vaseline or lard; (2) 1 part carbolic acid + 5 parts vaseline; (3) 1 part kerosene + 2 parts lard. These 3 preparations should be applied to the infested parts. Four parts of zenolium in 100 parts water, sprayed in the poultry houses and yard, is also quite effective.

CATTLE

777 – **Cattle Fattening Experiment in South Africa.** — NOBBS, E. A. in *From Breeder to Butcher, Beef Feeding Experiment No. 6, Government Experiment Farm Gwebi, Bulletin* No. 338, pp. 1-12 Dept. of Agriculture. Salisbury, Dec., 1919

Previous experiments at the Government Farm, Gwebi, South Africa, have established the following facts:

(1) It is not profitable to fatten artificially the unimproved native cattle; only grade stock are worth feeding, and the higher graded they are the more profitable does the process appear.

(2) It is not profitable to stall feed cattle whilst pasture is abundant; it is better to let the stock graze until about May.

(3) Artificial fattening is only feasible between May and February.

(4) Complete stalling is preferable to grazing by day and stall feeding at night.

(5) The more quickly the animals are fattened the better; the duration of the fattening process should not in any case exceed 5 months; to this end feeding with concentrates is essential, but all the fodder crops should be grown on the farm.

(6) Under present conditions, it only pays to convert the cheaper forms of fodder and cheaper grades of grain into beef, as the finished article has to compete with pasture-fed meat, and the markets are not highly discriminating. Such comparatively costly products as oatcake, teff (*Eragrostis abyssinica*) and linseed are therefore to be avoided, and others such as beans, groundnuts, or mangels should be used sparingly as is consistent with securing a properly balanced diet.

(7) It does not appear advantageous to feed the class of grade stock now available till over 3 years of age. Younger stock is apt to suffer from teething troubles, and incline when forced, to grow in size and frame instead of adding flesh and fat. Possibly, high grade stock of early-maturing breeds may in time be profitably fattened at an earlier age than the grade now generally available.

(8) The relative advantages have yet to be tested of stall-feeding animals loose in a kraal or tied up individually in cribs, but experience points to the former as the better system.

(9) About 2 tons of well tramped manure, consisting of dung and litter may be reckoned upon from each beast during the process of fattening.

(10) To eliminate waste, it is advantageous to feed pigs with cattle (1 pig to 4 beasts), but if maize meal is used, not whole maize, then extra feed must be provided for the pigs.

After due consideration of these points if becomes a question between rapid forcing to fatten quickly on the one hand, and the use of the most economical foodstuffs which entails shower fattening, on the other hand. At the same time, only animals of suitable age to benefit by feeding, and yet not so young as to be wasteful feeders, should be selected. The principal aim of these experiments was to work out rations adapted to local conditions as regards seasons, foodstuffs available, class of stock obtainable, and markets ; the relative advantages of 3 aged and 4 year cattle for fattening purposes was also tested.

The stock used in these experiments consisted in 10 Shorthorns reared under ranching conditions, 5 of 3 years old and 5 aged 4. The fattening process covered a period of 133 days, divided into 3 stages during which the following daily rations were given per 1000 lb. live weight : (1) 9 lb. maize + 9 lb. of radisk, mangolds, pumpkin or majorda + 18 lb. of hay + 18 lb. silage ; (2) 7.5 lb. maize + 1 lb. groundnut meal + 1 lb. dhal meal (*Cajanus indicus*) + 7.5 lb. of succulents + 10 lb. velvet bean hay + 15 lb. each of silage and hay (these always fed *ad lb.*) ; (3) 6 lb. maize + 2 lb. dhal meal + 2 lb. groundnut meal + 1 lb. sunflower meal + 7.5 succulents + 15 lb. velvet bean hay + 15 lb pasture hay.

For the 2 groups respectively the following results were obtained : Initial live weight : 970 and 1097 lb. ; final live weights at Gwebi, 1243 and 1353 lb. ; (2) after transport to Johannesburg 1175 and 1277 lb. ; dressed weight 686 and 786 lb. ; percentage dressing on Gwebi weight 55.1 and 58.1 %, on Joannesburg weight 58.3 and 61.3 %.

The figures for the 2 groups seem to be similar with regard to the daily average increase in live weight ; but the older animals, however, dressed on the average better than the others. All the animals were praised for their prime quality by the butchers. They were sold at Johannesburg at £25 each, and had been bought before fattening at £8 per head.

778 – **Comparison between Different Rations for Wintering Breeding Ewes.** — Russel, S. F., in *Oklahoma Agricultural and Mechanical College, Agricultural Experiment Station Bulletin* No. 125. pp. 2-8, figs. 2. Stillwater, July, 1919. SHEEP

The objects of the experiments reported in this Bulletin were : (1) To determine the comparative value of some Oklahoma feeds for wintering breeding ewes ; (2) to find the cost of wintering breeding ewes ; (3) to compare rations which contain silage with others that contain no silage ; (4) to compare cottonseed meal with alfalfa hay as a protein supplement ; (5) to compare ground kafir (sorghum variety) with kafir heads when combined with cottonseed meal and Sudan hay (*Sorghum exiguum*), Five lots of 20 ewes each were fed during 90 days, starting on January 4, 1918, to test the value of 5 different rations.

In two of these lots receiving 0.5 lb. of cottonseed meal per head and wheat straw with kafir silage (Lot II) and in another lot receiving cane fodder (Lot III), symptoms of cottonseed poisoining were noticed,

and 3 ewes died before the cottonseed meal could be replaced by bran. The effects on those fed with silage fodder were somewhat less serious. Two lots which had received half the quantity of cotton seed meal fed to the preceding lots, plus more kafir heads (Lot IV) or ground kafir grain, plus 2.03 lb. Sudan hay (Lot V) showed no ill effects and gave the maximum gain in size. The ground kafir seemed rather more satisfactory than the kafir heads. But, from the point of view of cost and health, the most economical ration proved to be that given to Lot I, in which 1.97 lb., of alfalfa per head furnished the necessary protein supplement to the kafir silage plus wheat straw. The following table summarises the results obtained:

Winter rations for breeding ewes.

	Lot I	Lot II	Lot III	Lot IV	Lot V

PIGS

779 – **Pig Breeding in Italy.** — STANGA, I., in *Giornale di Agricoltura della Domenica*, Year XXX, No. 20, pp. 155 and 158. Piacenza, May 16, 1920.

The three possible methods which can be employed in pig breeding are domestic, rural (i. e., transformation of farm by products), and industrial (i.e., transformation industrial of by products or rather constituting a distinct industry such as the raising of herds on pasture or on semi-housing lines). The first is much developed, the second has practically died out and the third could be very much improved and developed.

It can be said that, in Italy, the only improved breed used has been the large white Yorkshire, which produces a large amount of fat, but is difficult to breed in a country much warmer than its native land — the north of England. For this reason, the improvement of domestic stock

by the introduction of this breed has had no chance of developing on rural and industrial farms and these are much more important from the national and economic standpoint. The half breeds are weak, withs tand only with difficulty the sun from March to October, and are very subject to epidemic diseases.

The author agrees with the statements made by Prof. BALDASSARE to the effect that preference should especially be given to Berkshire pigs as stock for improving Italian breeds for industrial and rural purposes, and though the Berkshire admittedly gives less meat, that meat is proportionately, of better quality. Moreover, they are more hardy and easier to rear.

The author closes by remarking on the active steps taken by the U. S. Department of Agriculture with regard to agricultural propaganda, particularly as regards the development of pig breeding.

780 – **The Effect of Feeding with Peanuts on the Quality of Pork; Experiments in Oklahoma, U. S. A.** — DOWELL, C. T. and FRIEDEMANN, W. G., in *Oklahoma Agricultural and Mechanical College, Agricultural Experiment Station, Stillwater, Oklahoma, Bulletin* No. 124, Bibliogr. of 17 works. Stillwater, May, 1919.

The cultivation of peanuts has become quite general in the Southern United States, as has the pratice of fattening hogs on peanut pasture and cake (1). This method of fattening is more economical than using the common feed-stuffs, but the chief objection is that it is claimed that pork thus produced possesses a lower melting point (1) is soft and shows an excessive shrinkage. For this reason, prices for animals coming from districts where this form of foodstuff is used, are usually considerably reduced. The authors started their experiments with the object of finding some way by which the bad effects of feeding with groundnuts alone could be overcome. The iodine number and melting point were determined for the kidney and bacon fats of hogs weighing about 100 lb. each, used for experimental purposes in 1916 and 1918.

In 1916, 5 lots of hogs were fed for 70 days, and 1 hog per lot was reserved for a chemical study of the fats. In addition to this, at the Experimental Station, the shrinkage data were taken, during cold storage of 4 hams and of the bellies of one hog of each lot. The maximum iodine number, the minimum melting point, and a higher shrinkage percentage was reached in Lot I fed on peanuts alone. Two lots fed on peanuts for 40 days, followed by maize and tankage in the ratio 23 : 2 (Lot II), and another on kafir (a sorghum variety), and tankage in the ration 23 : 2 (Lot III) gave high iodine numbers, relatively low melting points and evident shrinkage was noticed.

The 2 other lots received no peanuts, and Lot IV was fed on oats + shorts + barley + buttermilk (1 : 1 : 2 : 8) and Lot V on maize chop + kafir chop + cottonseed meal + tankage (11 : 11 : 2 : 1). Better quality pork and lesser shrinkage signified the advantages of using the

(1) See *R.* Febr. 1920, No. 236. (*Ed.*)

last mentioned ration in the 1916 experiments. Table I shows the results of these experiments.

TABLE I. — *Results of Experiments in* 1916.

Lot No.	Shrinkage %		Iodine No. of fats		Melting pint of fat	
	For 4 hams	of bellies	of kidney Fat	of bacon fat	of kidney fat	of bacon fat
1	8.40	10.34	86.6	89.2	29.7	26.8
2	—	6.62	79.2	78.2	36.5	35.3
3	3.59	9.03	73.5	78.8	36.2	33.4
4	1.33	6.80	51.8	60.6	46.0	39.6
5	1.29	6.09	48.4	50.6	47.1	45.5

The 1918 trials included 6 lots each containing 8 hogs. Each lot received a small amount of alfalfa ; self feeders were used and the feeds were distributed in the following manner : I. maize + tankage ; II. darso (sorghum) + tankage ; II. kafir + tankage ; IV. kafir + peanut meal ; V. kafir + cottonseed meal ; VI. kafir + tankage + peanut meal + cottonseed meal. These lots are classified in order according to the average iodine number of back or kidney fat, and according to the increase in melting point except in the case of ot IV, which comes last but one on the list. Lot IV received a larger amount of peanut meal than Lot VI. The results are given in Table II.

TABLE II. — *Results of Experiments in* 1918.

Lot No.	Iodine No. of : —		Melting point of : —	
	bacon fat	kidney fat	bacon fat	kidney fat
1	70.94	63.18	37.9	41.1

6	58.14	54.51	44.3	46.0

POULTRY

781 – **The Pigeon as a Means of Increasing the Food Supply.** — BENEDETTI, I. in the *Giornale degli Allevatori*, Year XVI, No. 14, p. 108. Catania, May 20, 1920.

The author recommends pigeon-rearing for the rapid production of meat. The ordinary breed of pigeons should be chosen, for it is the most profitable, as from 20 to 24 young are produced annually.

Taking his own experiences in pigeon-breeding as a basis he calculates the profits of one financial year as follows :

INSTALLATION EXPENSES. — In order to set up a small pigeon-breeding establishment, it is necessary to have 100 pigeons ready for breeding 50 suitable breeding boxes ; 100 glazed earthen-ware nests ; 4 zinc syphon drinking troughs ; 8 special feeding-boxes to prevent the food being scattered or soiled ; boxes for ashes, rubbish, straw, etc ; other objects such as perches, apparatus for disinfection, small ladders, etc. ; the transformation of a room with an area of 5 × 4 metres and 3.80 m. in height, including the external cage into a pigeon loft ; labour for putting in the boxes ; other expenses. At present prices, about 3000 francs would be necessary to cover the cost.

DEBIT ACCOUNT.

Repairs and renewal of material (5 % of capital)	150 fr
Rent of room used as pigeon-loft	50
Food of different kinds (grain and scraps from the table), 18 quintals, average cost 60 fr. per quintal	1 080
Cost of cleaning and disinfecting	300
Loss on sale breeders, 400 francs at the end of 4 years, or for the first year	100
Total	**1,680** fr

CREDIT ACCOUNT.

Sale of 1000 pigens at 2.50 fr. per pigeon	2 500 fr
Sale of 3 quintals of pigeon-dung at 15 fr	45
Total	**2,545** fr

PROFIT.

2545 — 1.680 fr. = **865** fr.

Which is at the rate of 28 % interest on the capital laid out.

If the pigeon-breeder had enough ground to permit of the pigeons going out of the loft every day, he could save about 500 francs on their food, and then the interest on the capital would amount to nearly 46 %.

782 – **Bee-Keeping in Corsica.** — BOURGEOIS, A., in *L'Apiculteur*, Year 62, Nos. 5-6, pp. 50-55, May-June, 1918 ; Nos. 9-10, pp. 102-105, September-October, 1918 ; Year 63, No. 1, pp. 19-21, January, 1919 ; No. 2, pp. 39-42, February, 1919 ; No 7. pp. 174-176 July, 1919 ; Year 64, No. 1, pp. 27-30, January, 1920. Paris. BEE-KEEPING

A description of the conditions of bee-keeping in Corsica together with information on the habits of bees, and methods of rearing them, founded upon the author's long experience of bee-keeping on a large scale.

THE CORSICAN BEE. — Bee-keeping in Corsica dates back to the most remote antiquity, but the methods employed there are still wholly empirical. There are a great number of hives (more than 15 000) on the mountains of the island, and 75 tons of honey, and 27 tons of wax are produced annually. Owing to natural selection, the Corsican bee is exceedingly hardy and active ; it answers all the requirements, of intensive breeding, and is superior to the selected bees on the market.

HONEY AND WAX. — Corsican honey is of very fine quality and aroma when it is collected in the spring ; the autumn honey has, however, a strong bitter taste, and is dark in colour.

The barbarous custom of suffocating the bees seems to be unknown in the island. The pre-war prices were from 1 fr. to 1.50 fr. per kg. for ordinary honey, and from 2 fr. to 2.50 fr. for choice kinds.

Corsican honey is in great commercial request, on account of its aroma and its whiteness. The pre-war price was from 3 fr. to 3.50 fr. per kg.

Resources of the Corsican Flora. — The bees can make honey for from 8 to 9 months of the year so that the season is very long. The honey- and pollen-producing plants of the various seasons include :

Winter and beginning of spring : Japanese medlar, hazel, willows, poplars, almond, apricot, peach, box, *rosemary*, mimosa, and maple.

Spring Cherry, wild plum, cultivated plum, quince, citrus, apple, pear, chestnut (this gives a reddish bitter honey, crystallising in large cristals), broad bean, kidney bean, lentil, peas, haricot bean, soya, cultivated aniseed, *sycamore*, *sainfoin* (abundant white honey, with a delicious flavour ; in good season, from 150 to 300 kg. of honey can be obtained annually from 1 hectare of sainfoins), black mulberry, white mulberry, asphodel, caper, evergreen oak, cork oak, Kermes oak, turnip, colza, cabbage, white mustard and nearly all the *wild Cruciferae* (the Cruciferae yield much honey which crystallises very quickly forming large crystals), lavender, and savory (a large quantity of very fine honey in some districts, none in others), banana, date-palm, Barbary fig (the fruit is used for making a bee-syrup), tamarisk, ash, wild geranium, orange tree, citron tree, lemon tree (these yield much honey where the soil is damp), *Trifolium pratense*, *T. incarnatum*, *white clover* (yields much white honey,) agave and aloe (a sweet syrup flows from their terminal bud, and is collected by the bees), vetch (all varieties of vetch, and especially the *hairy winter vetch*, yield large quantities of green honey which becomes white on keeping ; when the hairy vetch and sainfoin grow together, much very fine honey is obtained), cotton tree, dandelion (the pollen of this flower is believed to produce dysentery in bees, if they remain shut up for some days), and wild chicory.

Summer : Virginian sumach, still more the curriers' sumach, limes, especially the *silver lime* (yields much sweet honey with anodyne properties), ailanthus (much honey of an inferior quality) chestnut (honey of a common quality ; about 33 000 hectares are covered with chestnut in Corsica), tobacco (much honey of a brownish colour), lucerne (the last cutting give a little honey ; produces much honey on light irrigated soils, the honey is white, and has a delicate flavour), sage and viper's bugloss (much honey which crystallise slowly), *white melilot*, *Thymus vulgaris* and *T. Serpyllum* (a dark, very aromatic honey), bramble, spindletree, raspberry, whortleberry, eucalyptus and false pepper (much dark honey with a strong flavour), conifers (in addition to pollen and propolis, all conifers and the spruce in particular, produce in spring and especially in sum-

mer, so much nectar, that for 15 to 20 days, several kilograms of honey can be made daily by a colony of bees ; conifer honey is rich in glucose and resin, hence it is much used by doctors in treatment of affections of the bronchial tubes and lungs), Thuja, juniper, *Vitis Canadensis*, sorghum millet, maize, and reeds. At a height of about 1500 m., *Rhododendron ferrugineum* and *Rh. hirsutum* give much honey with a very delicate flavour.

Autumn : *Heather* (much light-coloured honey in summer, reddish and thick in autumn ; as it contains little, or no, saccharose, this honey never crystallises entirely), *buckwheat* (reddish honey, plantiful on argillaceo-calcareous soil, scarcely any or calcareous or heavy soil), mignonette, asclepia (much honey, but it may be injurious to the bees, as their legs adhere to it), *tree ivy* (white honey), *Arbutus*, *Japanese Sophora*, *carob-tree* (much reddish honey ; its fruit supplies a good bee-syrup), honeysuckle, and aster.

The plants whose names are printed in italics can, when numerous, supply sufficient honey to fill the hive in a few fine days. To do so, requires 2 or 3 hectares, of very melliferous plants per hive. The largest amount of nectar is produced on calcareous, or clay loam soils that are damp or irrigated.

NECTARS. — The herbaceous stalks of vetches, barley, and oats, the leaves and branches of the evergreen oak, willow, alder, aspen, ash, bramble, beech, hawthorn, juniper, orange, palm, maple, birch, agave, larch, eucalyptus, spruce, etc., secrete, under the influence of combined heat and cold, or as a result of the punctures of insects, a sugary matter which is at times very abundant. When hot days are followed by cold nights, or *vice-versa*, the plant nectar appears during the night and generally disappears in the early hours of the day. When they can obtain nothing better, the bees collect and store these nectars ; under favourable conditions, a colony of bees can collect 4 to 5 kg. daily and from 2 to 3 quintals in one season. There is always, in addition, a small amount of animal nectar due to the punctures and excrement of insect, which the bees sometimes collect. The presence of woods is therefore very advantageous to bees, especially in summer.

Extraction of Thick Honey. — Corsica produces some kinds of honey that are very thick and difficult to extract, in the centrifuge. This difficulty can be overcome to some extent by extracting the honey from the sections as soon as they are filled, and before they are entirely sealed up, but this is not always possible. The best plan is to prick both faces of the full cells to a depth of 8 mm. as soon as the combs are unsealed without, however, perforating the median wall of the cells, and then to have recourse to centrifugation; the operation should be performed, if possible, in a room heated to from 30-35°C.

URINE AND BEE-KEEPING. — The nitrogenous substances supplied by pollen are often insufficient for the requirements of the bees, hence they visit pits of liquid manure and urinals, where they find the diastases or salts necessary for themselves and their brood. It is expecially

at the height of the laying season that the bees use urine both as food and drink. The author gives them, as a strengthening food, 3 or 4 kg. of honey diluted and carefully mixed with 1 litre of urine. As a tonic drink, he gives them two spoonfuls of honey dissolved in 3 or 4 litres of boiling water to which has been added 2 litres of urine.

Urine which has been slightly fermented by the addition of a little honey, attracts scout bees and afterwards the swarms. The author made use of this by placing in the vicinity of the apiary small hives of which the interior and combs had been sprinkled with urine.

Shading the Colonies of Bees. — This increases the yield by 20 % but all damp must be guarded against, as it is very injurious to the health of the bees.

Hive Management in Bad Season. — In order to prevent scarcity of honey, treatises on beekeeping advise feeding the bees on sugar. The author, however, considers this is wrong, both from the hygienic and economic standpoint. He advises that as soon as the bee-keeper finds that the first spring harvest is deficient, he should stop increasing the apiary remove the store-houses already placed, and reduce the brood chamber to the number of combs that the bees can use for food. Later, it might be possible and wise to increase the apiary in time for the small summer and autumn harvests. This method obviates the necessity, in bad years of feeding the bees during the winter.

Extracting Honey without a Laboratory. —The honey should be collected during the day, and the full combs placed in well-fitting boxes provided with a door which opens only outwards. This permits of the escape of any bees that may be still in the combs. At nightfall, the honey is extracted at a certain distance from the apiary. It is filtered, placed in vessels, and carried immediately to the store-room. All the utensils must be well-washed, in order to remove every trace of honey, so that the bees when they return next morning, perceive nothing, and are not upset.

Economical Concentration of the Productive Forces. — The old fashioned-basket can still be of great use in bee-keeping, and is the best means of insuring the economical increase of the bees. The writer advises the following method:

Place 2 baskets, one to the right and one to the left of a hive provided with frames, and tenanted by active working bees. The 3 colonies will thus have one flight-board in common, and will be close together, which will facilitate later work. As soon as the bees show signs of having reached the height of their honey-making, transfer the contents of the hive with frames to a new box, with the exception of 5 or 6 combs, which should be left for the brood; this will prevent too early swarming, and will give rise to feverish activity. The same day or the day after, when many of the bees are out collecting honey, a second hive flanked by empty baskets should be placed on the top of the first one, the two first baskets being removed. The progress of the honey-making must be watched, the number of receptacles increased, if necessary, and finally the honey is taken. This system is better than any other, in countries where the honey har-

vest is large, and the season short, but does not succeed where there is little honey and the collecting season is long. The advantages of the method advocated by the author is shown by the following figures: One hive fitted with frames and treated in the usual manner produces on an average 15 kg. of honey the 2. baskets furnishing 10 kg., whereas by the systematic concentration of honey-makers, the production is doubled.

Hives fitted with frames can also be used for the economic increase of the bees; the most pratical are twin hives and the method to be employed is the following: As soon as a numbers of bees have gone out, take a swarm from the turn hive, and put it in another hive, replacing the swarm by honey-combs.

Purchase of Ordinary Hives. — The ordinary Corsican hive is usually made of the bark of the cork-oak, or else of plaited twigs, or straw. The author advises the bee-keeper to buy hives with a gross weight of from 20 to 25 kg., but never to purchase those weighing less than 15 kg. (10 kg. of honey and 5 kg. of bees). The price of natural swarms varies from 2.50 to 3 fr.; that of the mother-colonies from 6 to 12 fr. each.

The second part of this article, which is devoted to pastoral bee-keeping in Corsica, contains the following chapters: Pastoral apiculture; the advantages of pastoral apiculture; the situation of the apiary; places to be avoided; the aeration of hives during transport; packing hives transporting bees, unloading hives on arrival; opening the small door; orientation of the honey-gathering bees; treatment of colonies of which the combs have been broken; cost and yield of a Corsican pastoral apiary. This is calculated on the following manner.

Cost and Yield of Corsican Pastoral Apiary.

INSTALLATION EXPENSES

Purchase of 1000 pastoral hives at 14 fr.	14.000 fr.
Cost of bees	5.000
Cost of materials and wood-work	2.500
Cost of curtains and huts	2.500
Studies.	1.000
Total	**25.000** fr.

ANNUAL EXPENSES

Rent of ground for apiary.	1.000 fr.
Transport or change of place	2.000
Interest and depreciation	6.000
Payments to bee-keeper and assistants.	8.000
Total	**17.000** fr.

ANNUAL EXPENSES OF RETAIL SALES

Rent of shop	1.500 fr.
Management	1.800
Licence, lighting, insurance, various expenses	1.200
Advertising.	5.000
Total	**9.500** fr.

Sales of products	
1000 colonies at 30 kg. per hive, or 30.000 kg. of which 15.000 kg. are of superfine honey at 2 fr. per kg.	20.000 fr.
15.000 kg. of ordinary honey, or made into confectionery, at 1.50 fr. per kg.	22.500
500 kg. of wax at 3.50 fr. per kg.	17.500
Total	**24.250 fr.**
Balance	
Total sale of products	54.250 fr.
Cost of production and sale	26.500
Net annual profit	**27.750 fr.**

783 – **Bee-keeping in Macedonia and Chalcis.** — Tabusieau, H., in *L'Apiculteur*, Year 62, Nos. 3-4, pp. 35-38, 3 fig. Paris, March-April, 1918.

In Macedonia and Chalcis, bee-hives are seen everywhere, but there are no extensive bee-farms where bees are kept on a large scale. The peasant merely has, hidden behind the low wall of his garden, a few hives, and the honey produced is mainly intended for domestic consumption. The only large apiary in the country is that belonging to the Sédès Agricultural College. Bee-keeping however, is carried on in the numerous monasteries on mount Athos.

In the apiary of the Sédès Agricultural College, most of the hives are of the old Dadant type, but there are also some Dadan-Blatt, Layens, and Root hives. The hives with fixed combs are those generally used; they are cylindical, 50 cm. in height, and 25 cm. in diameter.

The black breed of bees is the one kept; it is very gentle, and a hive of these bees in full work can be uncovered without any risk of being stung.

The nectar is chiefly collected in spring and summer from the fine *Labiatae* growing on the mountains. If the nectar is rare, the honey, however, is delicious. White melilot grows plentifully in marshy localities. *Erica multiflora* abounds in many mountainous districts.

784 – **Bee-keeping in Ethiopia.** — Frère Julien de Mamers (Capucin, Apostolic Missionary), in *L'Apiculteur*, Year 61, Nos. 1-2, pp. 2-4, Jan.-Feb., 1917; Nos. 3-4, pp. 38-42, fig., 2 March-April, 1917; Nos. 7-8, pp. 101-103, July-August, 1917; Nos. 9-10, pp. 128-134, fig., 3 Sept.-Oct., 1917; Year 62, Nos 1-2, pp. 4-9, Feb., 1918; Nos. 7-8, pp. 74-80, 2 fig., Feb., 1918; Year 63, No. 1, Jan., 1919; No. 2, pp. 12-18, pp. 35-39, Feb., 1919; No. 4, pp. 82-89, April, 1919. Paris.

Swarms of bees are common in the forests of Ethiopia; the combs are taken in the most crude manner, not only by the natives, but also by hunters and explorers. Honey is one of the chief dues paid to landowners, administrators, and chiefs. It is much used as an article of food and the natives employ it as a medicine, as well as in the preparation of hydromel, their national beverage. About 90 % of the honey produced is made into hydromel.

The author estimates the number of hives in Ethiopia at about one million. Some 700 tons of wax are exported annually, and in addi-

tion, a certain amount is used in the country for lighting the houses of the rich, and in the churches, but it may be calculated that about half the wax obtained is thrown away by the natives, who are wholly ignorant of its value. The average annual honey yield may calculated at 10 kg. per hive ; no honey is exported. The Imperial Palace alone uses every year 210 tons of honey for the manufacture of hydromel.

The native hive is cylindrical, from 20 to 35 cm. in diameter, and from 50 to 120 cm. high. It is made of wood, wickerwork, bark, or sun-dried mud, and is always covered with straw, and provided with a movable bottom or with simple plugs of straw at the two extremities. The hive is suspended in such a manner that the long axis is horizontal (in this way, the combs are parallel to the cylindrical walls); the flight-holes are placed in the centre, or at one extremity of the cylinder. The hives are always hung some metres above the ground, usually at a height of from 6-8 metres, though sometimes at as much as 12 to 15 metres.

The apiaries near the houses only consist of a few hives, but in the woods on the mountains, there are sometimes as many as 40 or 50 per family, so that one may say for instance, that in the great virgin forest of the Gougou Chain, which covers from 20 000 to 25 000 sq. km., there is not a single tree without its hive. By suspending a hive to a tree, the bee-keeper becomes the exclusive possessor of the tree and no one may fell it, or attach another hive to it.

Natural swarms occur very frequently, for the natives gather the honey so rapaciously that the famished bees are obliged to seek a new home If an empty hive is suspended from a tree, 8 times out of 10 it will be occupied without further trouble by one of these swarms.

The author has found that wandering swarms are attracted by the buzzing of another swarm, and also by the smell of hot wax. A good way of enticing them is to place in the sun some light, small hives whose inner walls are covered with liquid wax ; this melts and emits a strong odour, which is soon perceived by the bees.

The domestic bee is *Apis fasciata*, the same species as that kept in Arabia and on the shores of the Rred Sea. It is somewhat smaller than *Apis mellifica*, and very productive, but so bad-tempered when in another country, that all breeders that have tried it have given it up. Smoke has no effect upon this bee, so the hives have to be handled at night, and the bee-keeper is obliged to use every means of protecting himself while at work. The domestic bees include 2 varieties, known respectively as the black bee, and the red bee ; the former predominates at altitudes varying from 1200 to 3000 metres, the latter in the low districts, and to the height of 1200 m. The maximum of production was attained by an early swarm, taken in September which, 6 months later, had filled a hive with a capacity of 189 cu dm. During this time, the bees had made 36 combs ; when the honey was taken, 18 of the combs yielded a total of 70 kg. of honey, the other 18 being still occupied by the larvae. The average production depends upon the usual size of the hive. In order to ensure

the development of the bees, and prevent swarming, 64 cu. dcm. are reserved for the brood, and 21 cu. dm. for the honey.

The author quotes same observations that he and his fellow bee-keepers have made upon the nuptial flight of bees. All the 4 queen bees observed made 3, 5 and even as many as 7 flights, and all the queens were fertilised twice. They left the hive at 2 p. m. (not at midday, as is generally reported). One of the queen bees only, began to lay 36 hours after fertilisation.

In addition to the domestic bee, there are several wild varieties that are stingless. One of these, a very small insect, belonging perhaps to the genus *Trigona*, produces a honey which is more liquid than that made by the ordinary bee, and is much prized for its medicinal qualities.

At Addis-Ababa, where the author has his apiary, there are 2 seasons: the rainy season lasting from May to September and the dry season, which comprises the rest of the year. During the rainy season, the temperature is warm, varying from a maximum of 25° C to a minimum of 14° C. At this time, the bees are out all day looking for flowers which, however, are non-existent. Their daily exit from the hive throught the year has several disadvantages, of which the chief is the larger consumption of honey, as this entails a diminished honey harvest. Throughout the dry season, the temperature varies during the day between —3° C and 25° C; it is about 14° C in the morning and evening. Given the lack of moisture, very little nectar is secreted, and little honey is made. There are, however, 3 kinds made from the flowers of the natural meadows the various species of eucalyptus, and as shrub of the genus *Eupatorium* known by the name of "garaivo".

The honey-collecting season usually lasts from the middle of September to the end of February. The average annual yield of a native hive situated in a fairly good honey district varies from 8 to 10 kg. The apiary belonging to the Catholic Mission (the only one in Abyssinia which has hives with movable frames) yields, on an average, 26 kg. of honey annually.

Bees in Ethiopia have numerous enemies, of which the most formidable is the ant-eater, known as "hama" (the "wicked one"). The natives, suspend their hives from trees for the express purpose of protecting them from the attacks of this greedy mammal, and this makes the operation of taking the honey a very difficult one, for on account of the bad temper of the Abyssinian bee, it has to be carried out at night.

Ants are other enemies of the bees. There are two kinds, the small red variety, similar to that found in Europe, which can easily be driven away by scattering a few ashes round the hives, and the large black variety, which does far more mischief. When the weather changes, these black ants come out of their nests in great swarms, invade houses and destroy insects, rats, and even fowls, young pigs, etc. It seems impossible to bar their progress by the use of the remedies used successfully in the case of the common ants (ashes, carbolic acid, a streak of oil, etc.). Naphthaline is the only thing which they dislike enough to refuse to face it.

A certain amount of destruction is wrought among the bees by birds. The honey-comb moth does as much damage in Abyssinia as in Europe.

In conclusion, the author describes the native method of making several kinds of hydromel.

785 – **Standard External Measurements and Rigidity of Bee-Hive Frames.** — E. and A. FROMENT, in *L'Apiculteur*, Year 64, No. 5, pp. 105-109, fig. 3. Paris, May, 1920.

I. — *Standard external measurement for bee-hive frames.* — If a hive with movable frames gives too much room for the passage of the working bees, the latter build; if there is too little space, they make propolis.

In order to prevent both these equally serious evils, the authors after comparing notes with other bee-keepers, decided to reduce the passages to a minimum, and to provide a way for the bees underneath the frames, by means of a strip of metal that raises the latter 5 mm., above the bottom of the rebate.

It would, however, be of general advantage if the same external measurements were adopted for all frames. This would make them interchangeable, and the same frames could be used for all types of hive, thereby greatly reducing the trouble of handling them. Therefore the authors urge bee-keepers to obtain, by means of propaganda and their united efforts the general adoption of standard external frame measurements.

II. — *The rigidity of the frames.* — The want of rigidity in bee-hive frames is a source of much inconvenience. In the case of a Dadant-Blatt frame 27 × 42 cm. with uprights 0.7 cm. thick, a slight pressure is sufficient to show that it has no lateral rigidity. The same may be said of all frames with uprights less than 1 cm. in thickness. With uprights of this thickness, however, the authors, obtained the required rigidity. Further, there was no necessity to fasten the frame above by means of *U* shaped nails, and it was possible, without bending the reprights, to attach the wires of the honey-comb wax, as M. DADANT recommends. The first can be fixed about 6 cm. from the top of the frame, the second at a distance of 14 cm., and the last at 24 cm. This arrangement obviates all risk of the wax losing its shape from the heat, or the weight of the bees (especially when new swarms are being introduced into the hive). The great difference in the thickness of the nails used in fixing a 1 cm. upright is also to be noticed. With frames of this type, the authors obtained perfect lateral rigidity.

According to this principle, the measurements of the frames (in mm.) would be respectively as follows:

For the LAYENS type: 330 × 370 interior; 330 + (2 × 10) = 350 by 370 + 15 + 10 = 395 exterior.

For the DADANT-BLATT type: 420 × 270 interior; 420 + (2 × 10) = 440 by 270 + 15 + 10 = 295 exterior.

For the VOIRNOT type: 330 × 330 interior; 330 + (2 × 10) = 350 by 330 + 15 + 10 = 355 exterior.

SERICULTURE

786 – **Eggs Intermediate in Type between the Summer and Winter Eggs Produced by *Bombyx mori*.** — LÉCAILLON, in *Comptes rendus de l'Académie des Sciences*, Vol. XLXX, No. 18, pp. 1085-1086. Paris, May 3, 1920.

As a general rule, the eggs laid each time by the different varieties of the mulberry Bombyx are either all summer eggs, or all winter eggs.

In exceptional cases, mentioned later in the article, a special type of egg is laid differing in various degrees from the two normal classes. Its colour, when first laid, is nearer that of the summer than of the winter egg. Some of these eggs, after assuming a pink colour, hatch out at the end of 10 days exactly like summer eggs. Others laid at the same time, become pink, but remain at a very rudimentary stage of development, not hatching out till the following spring that is to say, much later. The latter thus resemble summer eggs in some respects (initial colour and subsequent colour changes), whereas in another (duration of embryonic stage), they are more like winter eggs. It should be added that, in the same laying, some eggs are often found that are more highly coloured than summer eggs, both when first laid, and also at the time when they cease their development in order to prepare for wintering. These eggs very closely resemble the true winter eggs.

The larvae from this intermediate type of egg can sometimes be reared as easily as normal silkworms, but very often they die, in spite of all the care bestowed upon them. On the whole, they seem less well adapted to ordinary silkworm-breeding conditions than normal individuals.

It is well-known that the mulberry Bombyx manifests great variability in many of its specific (?) characters. That this depends upon difference in the chemical composition of eggs produced by the same ovary is clearly shown by the case of the intermediate eggs in question.

The author has previously drawn attention to the fact that the appearance of a supplementary generation in a hitherto univoltin breed is due to a change in the chemical composition of the egg (accidental bivoltism). The facts set forth in the present paper clearly support this theory, and, further, prove the truth of another conclusion arrived at by the author, who does not regard the appearance of accidental bivoltins in a univoltin Bombyx breed as due to a mutation in DE VRIES'S sense of the word. The composition of the intermediate eggs of the same laying is found to vary by imperceptible degrees.

The cases in which the author has seen intermediate eggs produced are as follows.

(1) Where the females were directly descended from accidental bivoltins (1).

(2) Where the females themselves came from intermediae eggs.

(3) Where the females were the descendants of hybrids of the first generation obtained by crossing a male univoltin with a female polyvoltin from China.

(1) For information on accidental bivoltins, see *R.*, Jan., 1918, No. 75. (*Ed.*)

787 – **Tussore Silk** (1). — FUSCHINI, C. (R. Istituto superiore agrario di Perugia), in I. I. I., *Rassegna della Produzione italiana, Numero specialmente dedicato alle Industrie tessili, manfatturiere, chimiche, minerarie ed edilizie*, Year IV, General Series, No. 24. Section C., No. 6, pp. 19-20, figs 3 Milan, June, 1920.

The silks sold under the name of « tussore » come from the cocoons of many kinds of silk-producing *Lepidoptera*, of which some Asiatic genera alone deserve mention, on account of the importance of their product, viz., *Philosamia*, *Antheraea* (the chief,) and *Theophila*. The species of *Theophila* which yields silk is *T. mandarina* (in Chinese " tién-seng-tsan "), which is considered by some persons to be the ancestor of *Bombyx mori* and, on account of its pale straw colour, is known by the name of " *tussah cloude* ". This silk is very rarely exported as the whole output is generally used locally. Among the Italian species, *Saturnia pyri*, or the " great peacock ", produces a large pyriform cocoon composed of coarse silk with little strength; it is of the same type as the cocoons supplying tussore silk.

The tussore silk of the Italian market is exclusively of Chinese origin, and is made from the cocoons of *Antheraea pernyi*. The silk-worm of this moth lives on several kinds of smooth-leaved oak, but will also eat the leaves of the apple-tree, hawthorn, chestnut, etc. In Manchuria and Shantung, it is also fed on the leaves of *Cudrania triloba*, and it appears that worms thus reared produce the finest silk.

The standard of the tussore silk made from the cocoons of *A. pernyi* is about double that made from the cocoons of the Italian mulberry Bombyx, its resistance is usually above 3.50 gr. per *denier* (a denier = 0,05 gr.); it loses from 17 to 18 ¼ when degummed. If special precautions are taken, the silk is easily wound off the cocoon.

A. yamamai (Japanese word meaning " worm of the mountains ") lives on oaks, preferably on *Quercus serrata*; it furnishes the Japanese " tussah " silk, which is of a pale green colour and very glossy. Little of this silk is exported, as most of it is consumed locally. The raw silk, like the product of nearly all silk-producing *Lepidoptera*, is much striated; its standard is nearly double that of the Italian silkworm, and its resistance is about 3 gm. per *denier*. It contains about 20 % of sericine; 1 kg. of dry cocoons contains about 700 gm. of chrysalides.

There are also other less important species, such as: *Philosamia arrindia*, which lives on the castor-oil plant; the cocoons, especially in Assam, are wound on the spot, and the silk is used locally; *Philosamia cynthia*, this species is also acclimatised in Italy and is sometimes found (especially in the district of Verbano), on *Ailanthus glandulosa*; its cocoon is smaller than those of the preceding species, and can be wound, though it is better carded. This silk furnishes a tussore of inferior quality to that obtained from the former species. Several attempts have been made to acclimatise these species in Europe and varying results have been obtained. Much of the lack of success was due to the fact that these insects,

(1) See *R.*, September, 1912, No. 1331. (*Ed.*)

which are a prey to many parasites, were regarded as more hardy than they really are. As the mulberry Bombyx flourishes nearly everywhere in Italy, and its silk is of superior quality, the rearing of the tussore silk species will be restricted to those limited zones where, as the Bombyx is a failure, some substitute for it must be found.

RURAL ECONOMICS

RURAL ECONOMICS

788 – **The Value of Fruit Trees.** — I. Delauny, L. in *La Vie à la Campagne*, Vol. XVI, No. 194, p. 181. Paris, August, 1920. — II. Breton-Bonnard, L., in *Le Jardin*, Year XXXIII, No. 720, p. 360. Paris, Sept. 20, 1919. — III. Lecolier, P., in *La Vie Agricole et Rurale*, Year IX, No. 47, pp. 384-386. Paris, Nov. 22, 1919.

The question of the valuation of fruit trees is of the first improtance, particularly at the present moment when so many people, ruined by the war, have to be compensated for the damage caused to their property by projectiles, poisonous gases, etc., and for the systematic destruction of orchards by the Germans during their retreat.

The following method of valuation was arrived at after a survey of the devastated regions of Northern France. In this method the tree must be considered from the time it was planted until it was destroyed, and its value fixed without taking as a principal basis the relation between the interest represented by the produce of the tree and the capital constituted by the tree itself, although these factors are taken into account to a certain extent; The value of the tree at the time of planting is represented by its cost price at the nursery, plus the cost of transport and planting, to which must be added the depreciation of the material necessary to the upkeep of the plantation and a percentage for insurance against unsuccessful planting.

During the year after it is planted the tree merely strikes its roots afresh. In the second year it begins to grow ; its branches lengthen and ramify ; it increases in strength and size, and acquires a plus-value which augments yearly. If, therefore, it is possible to determine exactly this annual plus-value with its various elements the problem can be solved.

Whether it be a question of young trees or trees in full bearing this plusvalue is divided as follows :

(1) The natural plus-value or plus-value of growth., (2) the plus value of maintenance, represented by the cost of cultivation, rent, ground occupied, material employed, etc., and (3) the future value. When once the tree is planted it grows in height and bulk even if it is not attended to ; it is this growth that the author designates as natural plus-value. Secondly, the cost of the cultivation of the ground, including tillage, hoeing, manuring, the care of the tree, pruning, staking, spraying, etc., can be estimated, and this annual estimate, added to the annual natural plus-value gives the approximate annual total plus-value. To the sum thus arrived at must be added a discount of so much per cent. representing the future value, or a kind of assurance premium against the risk of destruction of the capital represented by the tree in question. Calculating in this

manner rather than by the relationship between capital and interest, the field of discussion is narrowed and, consequently, it is easier to arrive rapidly at an understanding. This method will be adopted in every case that presents itself, whether orchards or pleasure gardens.

STANDARD FRUIT-TREES. — The most usual orchards are those stocked with standards:— pear, apple, cherry, plum, walnut trees, etc.

Let us suppose that a standard fruit-tree costs, together with the buying price and transport, the sum of 4 fr. (naturally the actual price of purchase is taken), and that it has been planted without further expense. To this figure should be added that of the percentage of assurance, which is valued at 10 %. The tree therefore is worth, before it is planted, 5.50 fr. The cost of planting consists of the preparation of the hole, the application of manure, the " dressing " (habillage) of the roots and top, " pralinage " (i. e., plunging the root system of the tree for a few seconds in a mixture made of clay, fertiliser and water), and the filling up of the hole; to this must be added the rent of the ground occupied, the reserve fund for tools necessary for the whole plantation and the cost of fertilisers. The whole, may be estimated at 5.50 fr. + 1.50 fr. = 7 fr., a figure which will remain unchanged until the end of the first year.

In the second year, it may be estimated that the annual plus-value of the tree will comprise: (1) The natural or growth plus-value fixed at 2 fr.; 2) the cost of up-keep of the ground and tree, hoeing, manuring, pruning staking, spraying, liming, to which must be added the cost of upkeep of tools and the rent of the ground; the cost of cultivation may vary, but it can be estimated at 2 fr.; (3) an insurance against any accident that might happen to the tree sufficient to cover its future value, either for instance, ¼ of the sum of the first two items or the sum of 1 fr. The annual plus-value is therefore 5 fr., and at the end of the second year the tree is worth 7 + 5 = 12 fr. This plus-value cannot be estimated in this way until the end of the tree's existence; at a given moment it should begin to decrease, finally disappearing.

PRODUCTIVE VALUE. — In arriving at these figures the real age of the tree is not taken into account, but is only the period that has elapsed since it was finally planted, the years spent in the nursery being included in the purchase price. The tree continues to grow vigorously until an age that may be fixed at 25 years, it is then worth the value of the first year, 7 fr. + 120 fr. (24 times the plus-value of 5 fr.).

At this period of its existence the tree does not remain stationary: it grows stronger, its branches ramify, and, consequently, its productive powers increase.

Its plus-value must then be lessened to the extent of the premium on its future value (which is no longer necessary, its full value bing attained), and, as it is now fully developed, and requires less care, the plus-value may be estimated at 2 fr., including the rent of the ground. It is admitted that a fruit-tree makes little progress after it has been planted for 40 years. The plus-value of 2 fr. can be estimated up to this point, the value of the tree being then computed as follows: Value at 25 years old, 127 fr.

+ 30 fr. (15 times the plus-value of 2 fr.) = 157 fr. Its productive powers, and, consequently, its value will be stabilised from this age onwards until its regularly decreasing yield shows that the period of deterioration has begun. It would then be necessary to estimate the tree at an annual minus-value were there not another factor to be considered, namely the industrial value of the wood. The tree has grown in height and bulk, its principal branches and trunk have attained a considerable diameter and the wood has hardened and is in demand for the wood industry. It is therefore logical to estimate the value of a tree that has been destroyed at its highest value, either industrial or productive as the case may be. Notaries, auctioneers and timber merchants whose business it is to buy and sell trees as they stand, are able to fix the exact industrial value of a tree in accordance with current prices. The figures indicated above, although varying in different districts according to the species and varieties of the trees and their production (fruit destined for the table or the press), may be regarded as average. It may be accepted that a tree which has been planted for 40 or more years, represents a productive value of from 150 to 160 fr., its industrial value varying with its size from that price onwards.

II. — The following, according to the author, is the value of fruit trees as estimated by State experts :

Standard apple, pear, plum, apricot, cherry and walnut trees :

Plantation, 2.50 fr. + 1 fr. yearly (including 4 years in the nursery) for 35 years.

From 36 to 60 years : 2 additional francs yearly, the tree being then in its prime if it has been attended to and the ground is good.

After 60 years the period of decay sets in, and the value of the tree decreases by 2 fr. yearly during 20 years for apple and pear trees.

After 80 years, pear and apple trees are of no value except as firewood.

The stone fruit trees (plum, cherry, apricot) only bear for 30 years. The produce of the walnut tree, however, may be counted for 100 years, at 2 fr. yearly from the 35th year, except in cases of accident. Anyone, therefore, who is concerned can easily, with these data, draw up a table and estimate the value of the damaged trees.

Trees whose bark has to any great extent been gnawed by horses are considered as destroyed.

For dessert apple and pear trees an increase in the value of 10 % is quite allowable.

For pruned garden trees each expert has his own tariff. The following one is for trees in good condition :

Pyramids, Standards, Bush, Cordons : value of saplings taken from the nursery, 1 fr.

Pyramids, Espaliers, Bush, already in cultivation : from 2 years, 2 fr. ; from 3 years 3,50 fr. ; from 4 years, 5 fr. ; add 1 fr. per tree for transport and planting. Pruning, labour, ground occupied, etc., add to its value.

In this way the following figures are arrived at, varying with the successful growth of the tree.

Years	Standard and Bush	Espaliers	Cordons
	fr.	fr.	fr.
2.	3.50	3.50	2.00
3.	5.00	5.00	3.00
4.	6.50	6.50	4.00
5.	7.75	7.50	5.00
6.	9.00	8.00	6.00
7.	10.50	10.00	7.00
8.	12.25	11.50	8.50
9.	14.00	12.00	10.00
10.	16.45	14.00	11.50

This applies to pear trees grafted on quince trees and to apple trees. Ungrafted pear trees which are very fine trees, may increase in value up to 20 years in the same proportions ; the beauty of the tree its fertility, the ground where it grows, may all affect its value more or less, but the commissioners will probably keep to the regular tariff which alone can enable them to work and justify their decision.

III. — According to the method described above, the value of a tree increases yearly by 1 fr. up to 35 years, then by 2 fr. from 36 to 60 years, afterwards decreasing yearly by 2 fr. up to 80 years, when the sole value of the tree consists in that of the wood. It is evident that, calculating thus, the matter is a simple one, but generally speaking this calculation is false, for the value is purely mathemical. The scale may be carefully graduated, but it applies to both productive and unproductive trees, and the latter cannot have the same value. A method of valuation cannot be precise or mathematical without creating errors. But factors of valuation exist, which serve as a basis for calculation, and enable us to reach an approximate figure. This has been investigated by the author for several years and the results constitute a further method. Every tree has its own individual value, according to the conditions of plantation in a given district, in a more or less suitable soil, in a form more or less variable. These factors must be estimated on the spot when taking into consideration the age of the tree and the "yield" which constitutes its value. Thus the examples given by the author cannot serve as a universal ready reckoner, but they illustrate his method, and the table given at the end of this article, are used for purposes of comparison. The use of given formula will always be easy in special cases and thus will be of great value to experts.

The fruit tree represents capital because it is a source of income. The income being variable the capital outlay represents the cost of the tree when purchased plus annual expenses such as rent, manuring, labour, etc. When the tree bears fruit the capital outlay becomes productive capital. The value of the tree is all the greater if it bears well and its fruit fetches a good price ; the basis of the method therefore is the yield, and if the tree is not productive its value is reduced to that of firewood. The author has worked out formulæ which can be applied to all conditions of production. V or value $= C\,O$ or capital outlay up to the period of pro-

duction. To discover the $C\,O$ the A or cost price must be ascertained plus the cost of planting, etc., B or annual expenses multiplied by the age from plantation. $C\,O = A + B$. The formula of valuation of a tree still in the period of capital outlay, will be: $V = C\,O$ or $A + B$. As soon as the tree becomes self supporting i. e., when its yield covers the annual expenses, it becomes productive capital, $P\,C$, and $V = P\,C$. To find this $P.\,C.$ we must ascertain: r or average value of the yield; f or average cost of production; R or net income from the crop which can be obtained by subtracting f from r. Capitalising at the rate t, say at 5 %. The net income obtained, the formula of valuation of a tree in the period of productive capital will be $V = P\,C$ or $\frac{100 \times R.}{t}$

We know that this productive capital does not last for ever; the tree is destined to disappear; its life is limited. It is therefore necessary to fix its longevity clearly so that with it will cease the productive capital which is based entirely upon the net income derived from the crop. Afterwards the period of deterioration must be determined and a portion of the productive capital (which will cease with the tree) must be reduced annually. If the period of dererioration is from the 60th to the 80th year i. e., 20 years, the productive capital is reduced by 1 per 20 (i. e. 5 %) each year from the 60th year onwards. According to the number of years which elapse during this period of deterioration until the time of valuation, we shall therefore have $\frac{X}{20}$ to reduce. D or deterioration, being equal to 20 years, the number of years elapsed during this period being T we shall have to reduce T. The value of the tree will be:

$$V = CP \text{ or } \frac{100 \times R}{t} - \frac{T}{D}.$$

The author selects a cider apple tree whose longevity will extend over 80 years and the period of deterioration from the 60 th to the 80th year, and thus establishes the data: Duration of capital outlay: 10 years from the time of plantation. A = cost price 6 fr. + expenses 1.50 fr. = 7.50 fr. B = rent 0.20 fr. + expenses (1 fr.), = 1.20 fr. multiplied by the age of the tree.

Value of the cider apple tree at 10 *years.* $V = C\,O$ or $A + B$, i. e. $V =$ 7.50 fr. + 1.20 fr. × 10) i. e., 19.50 fr.

Duration of productive capital 70 years.

Period of deterioration: 20 years.

The appended table examines the return of the yield.

From 10 to 15 years . . . . . 3 hl. of 54 kg. = 162 kg., average 32 kg. per annum = 3.20 fr. etc. etc.

As the average expenses vary from 2.20 to 3.50 fr., we obtain the net income from the yield, which when capitalised, gives the value at the different ages of the tree up to 60.

From 10 to 15 years . . .	3 hl of 54 kg.	=	162 kg;	average	32 kg	per annum	= fr.	3.20
» 15 to 20 » . . .	5 » of 54 »	=	270 »	»	54 »	» »	= »	5.40
» 20 to 25 » . . .	7 » of 54 »	=	378 »	»	74 »	» »	= »	7.50
» 25 to 30 » . . .	9 » of 54 »	=	486 »	»	97 »	» »	= »	9.70
» 30 to 40 » . . .	20 » of 54 »	=	1080 »	»	108 »	» »	= »	10.80
» 40 to 60 » . . .	50 » of 54 »	=	2700 »	»	135 »	» »	= »	13.50
» 60 to 80 » . . .	40 » of 54 »	=	2160 »	»	108 »	» »	= »	10.80
Total . . . **184**			**7236** kg. at 10 fr. per 100 kg = **723.60.** fr.					

From 10 to 15 years, $r - f$ =	3.20	− 2.20	= Net income =	1.00	fr.
» 15 to 20 years, $r - f$ =	5.40	— 2.20	= » » =	3.20	»
» 20 to 25 years, $r - f$ =	7.50	— 2.75	= » » =	4.75	»
» 25 to 30 years, $r - f$ =	9.70	— 3.30	= » » =	6.40	»
» 30 to 40 years, $r - f$ =	10.80	— 3.50	= » » =	7.30	»
» 40 to 60 years, $r - f$ =	13.50	— 3.50	= » » =	10.00	»

The value of the tree will be established as follows:

$$V = CP \text{ or } \frac{100 \times R}{t}$$

From 10 to 15 years . . . . . $\frac{100 \times 1}{5} = 20$

From 15 to 20 years . . . . . $\frac{100 \times 3.20}{5} = 64$

From 20 to 35 years . . . . . $\frac{100 \times 4.75}{5} = 95$

From 25 to 30 years . . . . . $\frac{100 \times 6.40}{5} = 128$

From 30 to 40 years . . . . . $\frac{100 \times 73}{5} = 146$

From 40 to 60 years . . . . . $\frac{100 \times 10}{5} = 200$

From 60 to 80 years $V = CP$. . . . . $\frac{(100 \times R)}{t} - \frac{T}{D}$

From 60 to 65 years $\frac{(100 \times 10)}{5} - \frac{5}{20} = 200 - 50$, i. e. 150 fr. at 65 years,

From 65 to 70 years $\frac{(100 \times 10)}{5} - \frac{10}{20} = 200 - 100$, i. e. 100 fr. at 70 years,

From 70 to 75 years $\frac{(100 \times 10)}{5} - \frac{15}{20} = 200 - 150$, i. e. 50 fr. at 75 years,

ending with zero, or rather, the value as fire wood at 80 years.

For trees whose wood is valuable, there must be added the further value " wood " to that of productive capital, especially for the walnut tree. It is simply a question of estimating the value of the wood at current prices and on the spot. In M. BRETON-BONNARD's method a smaller value is given to a tree (cider-apple tree) estimated at 26.50 fr., than the author who takes it at 64 fr.; at 40 years the former is valued at 51.50 fr., whereas the author,

taking into account its yield, estimates its value at 200 fr. The briefly summarised form of valuations of pruned trees given by the author does not allow him to discuss them at length, but his figures seem to fall short of the facts, especially for " palmettes " yielding choice fruit of greater value, sold separately, but necessitating the deduction of heavier expenses.

These figures are arbitrary, whereas those arrived at by the keep of the authors' general formula seem on the whole to be closer to the truth.

The method of M. DELANNOY (in *Vie à la Campagne*) does not seem any better to the author, because the plus-value of growth and labour added to the future plus-value makes the figures too high. Thus, according to the former, a cider tree will be worth 57 fr. at 10 years, whilst the author only calculates 19.50 fr.; at 20 years the former estimates its worth at 107 fr., but, according to the author it is only worth 64 fr. Finally between the age of 25 and 40 years the tree would be worth 157 fr., but

he does not clearly show the diminishing value from 40 to 80 years old., The author's method, which is based upon the yield or the income derived from the tree, without being absolute and purely mathematical is reasonable, for it comprises the chief elements constituting the value of the tree The same process that has been employed for the cider-apple tree could be used for any other kind of fruit tree.

In conclusion, the author gives a valuation table for the cider-apple tree, which has nothing absolute in its methods because it must vary according to the co-operating factors.

This table, given on pp. 904-405 reproduces the figures arrived at by the author's method and also by those of MM. BRETON-BONNARD and DELANNOY.

792 – **Exhibition of Wines from Direct Bearers (1) at Perpignan, France.** — SOURSAC L., in *Bulletin du Syndicat des Pyrénées-Orientales* reproduced in *Le Progrès agricole et viticole*, Year 37, No. 21, pp. 491-492. Montpellier, May 23, 1920.

On May 4, 1920, at Perpignan a comparison of wine from direct bearers was made, and the following marks given, taking into account both colour and taste. The samples tested came from the Pyrenées-Orientales, Aude, Lades, Rhône, Allier, Loiret, and Deux-Sèvres districts. The white wine from certain hybrids, such as Gaillard-Girerd No. 157, seemed to be generally appreciated, but the others were on the whole judged according to soil for ungrafted or grafted hybrids, stock, climate, etc.

Marks given to Wines from Direct Bearers.

793 – **The Action of Chloropicrin on Wine Yeast and Flowers of Wine.** — Bertrand G. and Mme Rosenblatt, in *Comptes rendus de l'Académie des Sciences*, Vol. CLXX. No. 22, pp. 1350-1352. Paris, May 31, 1920.

The authors have tested the action of chloropicrin (1) on 2 types of microscopic fungi, viz., yeast, when in a state of fermentation and completely submerged; and the flower of wine which lives on the surface of the nutritive medium.

The yeast experiments showed, that 1 mgm. of chloropicrin in one litre of sweetened must is sufficient to hinder fermentation, and that from 5 to 6 mgm. arrests the process completely.

The yeast, however, is not killed in 24 hours by the addition of sufficient chloropicrin to prevent fermentation. This small amount first paralyses the fungus, which gradually loses its reproductive power, but only succumbs after a much longer contact with the poison. In order to kill the yeast in 24 hours, at a temperature of 27° C, as much as from 30 to 40 mgm. of chloropicrin per litre must be added.

Flowers of wine are still more susceptible than yeast to the action of chloropicrin: 2 mgm. per litre entirely stop the growth of *Saccharomyces vini*. Even 1 mgm. per litre has proved sufficient to produce this result.

In the course of their experiments, the authors observed that, although flowers of wine grow so easily on the surface of common kinds of wine, only an excessively thin layer forms very slowly if the wine has been filtered through a Chamberland filter.

794 – **The Treatment of " Casse Bleue " in Wines.** — Piedallu, A., Malvezin, Ph. and Grandchamp, L., in *Comptes rendus de l'Académie des Sciences*, Vol. CLXX, No. 19, pp. 1129-1131. Paris, May 10, 1920.

One of the authors, in a previous article (2), described the action of hydrogen peroxide on wines affected by *casse bleue*. It is well-known that

(1) See also *R.*, July-Sept. 1919, Nos. 1049-1050; *R.*, Jan., 1920, Nos. 6 and 148; *R.* Feb., 1920, No. 274; *R.*, March, 1920, Nos. 374 and 375; *R.*, May, 1920, No. 595; *R.* June, 1920, No. 705. — (2) See *R.* Feb. 1920, No. 250; *R.* March, 1920, No. 359. (*Ed.*)

such wines contain ferrous salts. Though at first clear, they become cloudy through the action of the oxygen of the air, the ferrous salts, becoming ferric salts, are precipitated with the tannins and colouring matters; turbid wines deposit successive layers of these substances, but nevertheless remain thick. The operation of clarifying is useless, as the size, remains in solution.

Hydrogen peroxide precipitates a great deal of the iron (the wine becomes clear therefore, and there is no further formation of *casse bleue*), but it is illegal to add hydrogen peroxide to wine. Further, the very energetic action of the peroxide has a very bad effect upon the composition and organoleptic properties of wine. For this reason, the use of hydrogen peroxide was not recommended in the afore-mentioned article.

The authors have once more taken up the question and have investigated the action of gaseous oxygen obtained by the distillation of liquid air; it contained 99.9 % pure oxygen. When introduced by bubbling it directly into the wine, only unsatisfactory results were obtained. Large, bubbles were too rapidly evolved on the surface, and the oxidation was insufficient

On the other hand, most conclusive results were obtained by diffusing the oxygen by means of a Chamberland filter.

The oxygen, on leaving a " mano-détendeur ", enters the filter under a pressure of 4 kg. It leaves it, passing through the wall in small bubbles which form a sort of emulsion with the wine. The latter is now saturated with oxygen, and the ferrous salts become oxidised to ferric salts. In the presence of tannins, the ferric salts form insoluble tannates, and are precipitated, the albumens and gelatins becoming coagulated at the same time.

It has been observed that gelatin and albumens remain in solution when the iron is in a ferrous condition, hence the expression that the wine " ne prend pas la colle " i. e., will not clear.

The authors have found that a wine that will not clear, coagulates, after oxidation, 20 gm. of white refined gelatin per hl. becomes clear and remains so in spite of prolonged exposure to the air, and to changes of temperature.

In a white wine containing 160 mgm. of metallic iron per litre, the authors observed only a slight bluish reaction when tannin was added, and consequently a very slight precipitate. The same wine, under identical conditions, when oxidised by means of a Chamberland filter, gave a reaction of increasing intensity finally becoming bluish-black like ink. The reaction continued with the same intensity for 24 hours, and after 36 hours, the authors were able to see the beginning of defecation, clear patches appearing near the surface of the liquid. On the fourth day this wine had been clarified with refined white gelatin which was precipitated as a thick coagulum, leaving in suspension in the liquid small grey flakes, which on filtering, remained on the filter. The wine became clear after one filtering.

Analysis, after filtration, revealed the loss of 120 mgm. of iron per litre, viz. 75 % of the original amount. It would have been easy to have eliminated more of the iron.

Many red wines have been treated in the same way with identical results. Red wines attacked by " casse ", on being oxidised under the same conditions, but without the addition of tannin, lost iron in similar proportions, and finally became, after filtration, brilliant wines of a fine ruby colour, and perfectly stable.

To sum up : oxygen, when very finely divided by passing under pressure through the pores of a Chamberland filter, is capable of rapidly transforming into ferric salts the ferrous salts in a wine affected with *casse bleue*. This change removes the iron which produced the turbidity, and restores the wine to its normal clearness. Wines so treated become perfectly stable, and are not liable to relapse into their former condition.

795 – **The Use of the Bulbs of *Muscari comosum* and *Hyacinthus ciliatus* Used as Food and in the Manufacture of Alcohol in Italy.** — PANTANELLI, E., in *Le Stazioni Sperimentali agrarie italiane*, Vol. LIII, Nos. 1-3, pp. 101-112, bibliography of 6 works 1 plate. Modena, 1920.

In the Province of Foggia (Apulia), the bulbs of two wild plants which are much alike in appearance (*Muscari comosum* and *Hyacinthus ciliatus* are used as articles of food. The former plant, known in Apulia by the name of " lampascione ", has the larger bulb, is covered with red scales, and is more savoury than the bulb of *Hyacinthus ciliatus*, owing to its slightly bitter taste ; further, it is richer than the latter in laxative and diuretic substances, etc. It is exported to some extent to North America, where it is eaten by Apulian emigrants. The bulb of *H. ciliatus*, which is called " cipollaccio ", or " giacinto pugliese ", has white scales, is sweeter, and is less in request.

The author, having found that the bulbs of both these plants contained much sugar and were rich in saccharifiable carbohydrates (23.01 and 20.21 % respectively at the close of the vegetative period), tried to utilise them in the manufacture of alcohol.

Bulbs collected at the end of January, when the plants were already in leaf, and also at the beginning of June, immediately after flowering, were found on analysis, to have the composition given in the following table.

At the end of the growing period, the bulbs of the pink " lampascione " are rich in sugar, in soluble mucilage and in starch, whereas they contain little insoluble mucilage, less cellulose, and almost no hemicellulose.

The bulbs of the white " cipollacco " have a smaller sugar content, and more starch, hemicellulose and cellulose, the last-named substances rendering them less fit for human consumption. Although the bulbs of the " lampascione " contain more sugar at the beginning of summer, they are eaten by preference in winter.

By hydrolysing the sliced bulbs with sulphuric acid, 10.5 % by weight and 13 % by volume (the percentage refers to fresh bulbs) of anhydrous

Composition of the bulbs of Muscari comosum and Hyacinthus cilatus.

	January		June	
	Muscari comosum	*Hyacinthus ciliatus*	*Muscari comosum*	*Hyacinthus ciliatus*
Water	70.09 %	67.72 %	70.85 %	72.14 %
Crude protein (N × 6,25)	0.740	1.129	0.814	1.313
Reducing sugar	0.366	0.206	0.117	0.311
Non-reducing sugar	8.952	8.600	9.000	4.751
Soluble mucilage	11.240	4.630	6.743	2.384
Insoluble mucilage	2.004	2.085	1.030	2.008
Starch	0.372	5.100	6.041	7.106
Hemicellulose	0.212	3.014	0.080	3.650
Cellulose	3.412	4.300	3.038	4.211

alcohol is obtained from *Muscari comosum* and 8.4 and 10.5 % respectively from *Hyacinthus ciliatus*. The process is carried out as follows. The sliced bulbs are boiled for 90 minutes with an equal weight of 4 % sulphuric acid solution, then neutralised with calcium carbonate, pressed, and 1 % of ammonium phosphate added. Normal tartaric acid is then added until the precipitate of calcium phosphates is dissolved, and a little brewers yeast is introduced, and the mixture is fermented at 20° C for 4 days. The alcohol yield obtained is sufficient to employ a distillery satisfactorily.

The author is of opinion that the bulbs of *Muscari comosum*, which are preferred as an article of diet to those of *Hyacinthus ciliatus*, should be cultivated, for the manufacture of alcohol, since they contain as much as 23 % of saccharifiable carbohydrates which can be transformed into alcohol by fermentation. On the other hand, the bulbs of *H. ciliatus* would not pay for cultivation, but they are less common than those of *M. comosum*. The best season for collecting bulbs for the distillery is from June to December, because as soon as the growth begins they lose some of their sugar content. The bulbs should be used fresh, since on being dried, they lose part of their sugar through respiration, and the rest is condensed into carbohydrates which are difficult to convert into sugar.

796 – **The Use of Milk Powder in Bread-Making.** — LINDET, L., in *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VI, No. 18, pp. 465-417. Paris, May 12, 192

M. Lindet exhibited milk bread made with desiccated skim-milk. This bread has a good flavour, and rises very satisfactorily even when the quality of the flour used, leaves much to be desired. The skim-milk powder absorbs as much water as the flour, and this may be replaced weight by weight, by the milk powder. If 10, 15 or 20 % of the latter is added, and the consumer eats the same amount of bread, a saving of 10, 15, or 20 % of the flour is effected.

In flours, the proportion of the carbohydrates (starch, sugars,. etc. to the nitrogenous substances is as 100 is to 17 or 18; in skim-milk the proportion of lactose to casein is as 100 is to 70. In wheat bread with

the present flours extracted at 80 %, there is from 8 to 9 % of nitrogenous substances, while in a bread containing 15 % of milk powder, there will be from 15 to 16 %.

At the present time, milk powder costs 4,20 fr. per kg. but as milk bread is a luxury article, it finds customers, even at a high price.

It might be objected that skim milk itself could be used, instead of the milk powder, which would avoid the need for evaporation. This might be done, if the dairy were near the bakery, but skim-milk soon turns acid. It is true that it might be pasteurised or sterilised, but the coal used in these operations, and the transport of the water contained in skim-milk, would cost more than the coal needed for desiccating the milk.

In short. M. LINDET believes that the manufacture of milk bread might be encouraged without detriment to the general food supply, and that its use would economise the flour supply. However, he draws attention to the fact that such bread is article of luxury, and superfluous from the point of view of strict necessity.

797 – **The Italian Grape-pip Oil Industry.** — FACHINI, S. in the *Giornale di Chimica industriale ed applicata*, Year II, No. 5, pp. 246-250, 1 fig. Milan, May, 1920.

The production of grape-pip oil is an Italian industry dating back a great many years, for as early as 1770, this oil was already extracted at Bergamo, and, during the last 20 years, the industry has much developed. The distilleries usually supply the oil mills with the grape pips. These. are divided into 2 commercial varieties, undistilled pips (at represent worth about 60 lire per quintal (as against 6 lire before the war); and cooked, or distilled pips that have been separated from the marc after distillation. Such pips now fetch 40 lire per quintal (pre-war price 3 or 4 lire). The oil content of the former varies from 12 to 20 %; that of the latter smaller, and sometimes sinks as low as 8 %.

Some writers believe that there is a direct connection between the oil yield and the alcohol yield, but recent analytical results haw shown that the grape-pips of some regions of S. Italy have a much lower oil content than those of certain parts of N. Italy, where the grapes produce a wine containing but little alcohol.

The oil yield, however, depends in the first place upon the vine, and. in the second, in the case of white grapes, upon the age of the pips, etc. The pips most valued are those from Venetia, which have the highest oil content (20 %).

The most important factories using grape-pips are, according to the author, in Lombardy (Milan, Monza, Treviglio, Cologna, Bergamo and Lecce), and Piedmont.

Pressure is the usual method employed for extracting the oil. The pips after having been ground very finely in a mill or by rollers, are heated to from 50-60° C in desiccators by means of direct heat or steam, and after moistening, an indispensable operation for insuring a good oil yield, pressed in the ordinary presses used for oilseeds. Some makers prefer stave presses, or the types known respectively as " a vaso filtro ", or " a forata. "

For the pips, the best machine is the " tordoir ", with this, the work is automatic and simple.

The ground pips are heated by a double endless screw protected by a double wall and are carried slowly foward by this to the end of the upper cylinder (heater). From the cylinder, the hot oil meal falls to the bottom, where by means of a cone, and a truncated cone, it is crushed under very high pressure. The oil is thus expressed, and the residues are evacuated at the posterior part of the machine. According to the makers of this machine (FRANS SMULDER of Utrecht), all kinds of oil seeds and nuts can be crushed by it. It can grind from 150 to 200 kg. of seed per hour, according to the quality. It weighs 5 000 kg., needs no base and has the following measurements :— Length, 4.85 m. ; width 1.63 m. ; height 2.90 m. As this crusher does not require continual supervision, it saves labour to a great extent, and also has the advantage of rendering cloths unnecessary.

The first industrial use made of grape-pip oil was for burning, either alone, or specially mixed with rape oil. It is also used in soap-making, in paints and in the manufacture of substitutes, but for the last 5 years especially, the oil, when well purified, has chiefly been employed (either alone, or mixed with olive oil) as an article of food. Indeed, it can be said that all the grape-pip oil not made in Italy is used for this purpose.

If the annual average grape production of Italy is estimated at 60 million quintals, the pips produced per quintal of grapes at 3.7 kg., and the oil yield at 12%, the possible annual production of pip-oil in Italy would be 266 000 quintals. The manufacturing expenses may be reckoned at 15 lire per quintal. Commercial grape-pip oil is now sold at from 500 to 600 lire per quintal, and the edible oil at from 700 to 800 lire per quintal. From 100 kg. of grape-pips 88 kg. of cake may be made, which sells at 20 lire the quintal.

798 - **Contributions to the Microscopic Detection of Plant Substances that can be Used in the Adulteration of Certain Articles of Food, or as Their Substitutes.** — I. GRIEBEL, C., in *Zeitschrift für Untersuchung der Nahrungs und Genussmittel*, Vol. XXXVII, Nos. 5-6, pp. 129-141, figs. 15 Münster, September, 1919. — II. GRIEBEL, C. and SCHÄFER, A., *Ibid.*, pp. 141-145, figs.3.

I. — The author describes the characters of many substances that can be used to adulterate flour, jams and spice. In the case of flour, husks, straw, the germs of embryos can be used; in that of jams and similar articles, recourse can be had to the fleshy aril enclosing the seeds of the yew (*Taxus baccata*), the fruits of the crowberry (*Empetum nigrum*), and Irish moss (*Chondrus crispus*). The seeds of *Piper officinarum* are used as a substitute for black pepper, while the edible fungus *Boletus edulis*, when dried and ground, serves to adulterate spices in general. As new substances that are mixed with coffee, the author mentions the dregs of must, and the berries of the holly (*Ilex Aquifolium*) (1).

(1) In a preceding paper (*Zeitschrift für Untersuchung der Nahrungs und Genussmittel* Vol. XXXV, No. 6, pp. 233-235, 1918), the author described the microscopic characters of the seeds of *Ornithopus sativus*, which are used in Germany as a substitute for coffee. (*Ed.*)

In samples taken from dried leaves of commercial marjoram, dried ground leaves of *Thymus Serpyllum* have been found. The authors describe and illustrate by means of figures the microscopic differences serving to distinguish garden thyme (*Thymus vulgaris*) from wild thyme (*T. Serpyllum*) and from marjoram (*Origanum Majorana*).

799 – **The Utilisation of Sugar Cane Bagasse in Paper-Making.** — MAHEN, J. and MATROD, L., in the *Bulletin de l'Agence Générale des Colonies* (formerly *Bulletin de l'Office Colonial*), Year XIII, No. 146, pp. 139-154, figs. 19. Paris-Melun, February, 1920.

The idea of using bagasse in the manufacture of paper is so tempting that it is not surprising that attempts have been made to realise it. As long ago as 1835 a process was brought forward, but all experiments in this direction proved fruitless, or at least, unsatisfactory.

Recently, however, owing to the shortage of paper, the authors thought it opportune to resume the study of the question, and their experiments upon sugar-cane refuse from Guadeloupe have proved the paper-maching qualities of this raw material.

Chemical examination of sugar-cane refuse has shown that it contains 49 % of cellulose, as against 58 % of lignin, accompanied by small quantities of mineral and waxy substances.

In the technical experiments the theoretical yield fell to the 30 % of so-called paper cellulose, which represents the small loss of about 9 %. This is probably due to the fact that the fibre has already been exhausted by water under pressure, so that the nonfelting substances are largely removed during the extraction of the sugar. The yield obtained is sufficient to justify the use of sugar-cane bagasse in paper-making.

In the laboratory experiments a rough paper was made which had a pinkish yellow colour due to the presence of 7.64 % of lignin. It was rather granular to the touch, had a certain amount of consistency, was slightly resonant, offered a satisfactory resistance to pulling and crumpling, and was not easily torn. The coloration can be prevented by removing the 7.46% of lignin still present, which was reveled by the chemical analysis of the pulp.

Comparison between the paper-making cellulose yield of bagasse and that of other raw materials.

Bagasse		30
Lucerne		40 to 48
Bamboo		45
Straw		35 to 50
Dà (*Hibiscus cannabinus*) bast		50 to 60
Common hemp	straw	25 to 27
	spinning refuse	65 to 70
	fibre	85 to 87
Cotton rags		63 to 67
Flax fibre		70 to 80

Micrographic investigation shows why the cellulose pulp obtained is defective. Those fibres that had not been swollen or deformed by pre-

vious treatment, were such, owing to their fineness, suppleness, tenacity and felting capacity (0.007), that this pulp would be classed among those of superior quality, were it not accompanied by a large number of other elements greatly inferior morphologically, and therefore possessing but little binding power. The presence of these inferior fibres explains why it was found necessary in the commercial experiments made some years ago at Trinidad to incorporate a certain proportion of foreign fibres in the pulp.

On the other hand, the chemical analysis of the pulp proved that it would be easy to obtain, by means of a moderate amount of treatment a cellulose containing only 1 to 2 % of impurities, and that the oxycellulose present in fairly large quantities (4.30 %) in the raw fibre, disappear to a great extent in the course of these processes, so that there was no fear of the paper keeping badly, owing to subsequent alterations.

It should be mentioned that all the technical experiments carried out failed to reveal the presence of the gummy substances that are so detrimental to the paper, or any difficulty in bleaching, such as had been encountered by some experimenters.

The preparation of the cellulose, indeed, appeared to be quite simple. It is probable that the very special structure of the raw material in question, and the previous treatment it had received in the diffusers, facilitated the action of the caustic alkalis, and promoted delignification. Bleaching took place normally. The pulp further dried quickly on the sieves of the mould, which is another proof of the absence of gummy matters.

In short, Guadeloupe bagasse gives 30 % of cellulose suitable for paper-making, which is excellent for a by-product. The nature of this cellulose leads us to hope that it will find a ready market among paper manufacturers. Should this be the case, it would be necessary to replace the bagasse now used as fuel by the importation into the Colony of an equivalent amount of coal and perhaps also of fertilisers, for the ash of bagasse contains 2.5 % of mineral matter (silica, lime, iron, and traces of manganese), which must be replaced in the soil, in order to restore some of the substances of which it is annually deprived by the cultivation of sugar cane.

INDUSTRIES DEPENDING ON PLANT PRODUCTS

800 – **Milk and Milk Products.** — *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VI, No. 18, pp. 459-462. Paris, May 12, 1920.

Dr. E. Laur, Director of the Swiss Peasants' Union, and M. J. Raeci of the Central Prices Bureau of that Union forwarded to the Académie d'Agriculture de France the following letter addressed to the agricultural organisations of the various countries :

" The purchasers of milk and milk products are at the present time bringing unusual pressure upon the international market. Next summer it is proposed to pay for milk, prices that no longer at all correspond to the cost of production. Although salaries and wages have everywhere risen, and are still rising, an attempt is being made to reduce the profit

of the milk producer to such an extent, that the most hard-working and useful worker of the state will be the worst paid.

"The Swiss agriculturists are firmly resolved to oppose these efforts by every means, and they also request the Authorities to second their endeavours. The peasant was obliged, during the war, for the sake of the customers, to renounce taking full advantage of the condition of the market, and has thus every right to demand to be protected from the results of too sudden a return to ordinary prices.

"This end can, however, only be attained if the agriculturists of all milk producing States energetically oppose the efforts made by the purchasers to bring presure to bear upon the price of milk. It is inevitable that some fall in prices will occur in cases where they greatly inflated during the war. But, from information obtained from certain countries, such as the Netherlands and, in part, from France, it would appear that the producers in those regions are not inclined to concede too much to the purchasers.

"Swiss agriculturists demand for next summer a price of 35 centimes (Swiss) for each kg. of milk bought at the farm. This is 2 to 3 centimes, or 8 % less than the price in the winter of 1919-1920.

"Agricultural associations must see that milk sold for consumption fetches a price corresponding to the cost of producing it. By so doing, it will be easier to ensure fair prices being paid for milk products, as well as for the milk used in their manufacture. In Switzerland, the agriculturists together with the trade, have formed a large society with the object of purchasing all the cheese production of the country at a price corresponding to that of milk used for ordinary consumption. This will ensure uniform prices for all the producers.

"We would request all Agricultural Associations to explain the situation to agriculturists, and to induce them to resist all pressure appied to the international market of milk and milk products. A plan likely to yield good results would be to reduce milk production as much as possible, and increase the cultivation of cereals.

As long as the Russian political situation does not improve, and while that country does not take part in supplying Europe, the demand for cereals will doubtless remain very large. In spite of the precarious condition of their exchange, those States that are threatened with famine will buy cereals before everything else, and their demands will keep up the price of these products. It is, further, of the utmost importance, that the Governments should help one another to relieve the present pressure exerted upon the market of milk and its products by granting credit to the famine-threatened States, with a view to enabling them to purchase butter and cheese.

"The granting of this credit would soon obtain the sale required for these products. It is also necessary to promote the consumption of milk and milk products as much as possible."

The Permanent Secretary of the Académie adds that the Agricultural

Associations of France are unanimous in demanding the abolition of the controlled price of milk. The French Minister of Agriculture has promised, for his part, that no legal proceedings will be taken against milk producers, until the opinion of the Departmental Agricultural Office has been obtained as to the technical aspect of the case.

801 – **Plastic Materials with a Casein Basis: Galalith and Cornalith.** — DAUTREBANDE, J., in *Annales de Gembloux*, Year 26, Series 5, pp. 214-216. Brussels, May, 1920.

Galalith and cornalith, two substances made from casein that has been treated with formalin, are produced now in various countries, especially in France, where there are already several factories.

The process may be said to consist of three stages: (1) Preparation of the casein; (2) moulding the casein by means of pressure; (3) treatment with formaldehyde. If opaque articles are to be made, dried commercial casein powder is used, without any further treatment. Should transparent goods be required, the casein must be demineralised by being dissolved in soda and precipitated by an acid, for in this case, all the mineral salts, especially the phosphates, must be removed. The casein, whether it has undergone this preparation or not, is mixed with water into a consistent paste; this is put into suitable moulds, and subjected to great pressure at a high temperature in hydraulic presses, whose plates are heated by steam. In this manner, plastic masses are obtained, which have only to be put into a bath of formaldehyde in order to render the casein insoluble. The strength of the formaldehyde solution, and the length of the immersion vary according to the nature, and thickness of the articles made.

The masses of casein hardened in this way by formaldehyde, can be sawn, cut, perforated, and made into any object required. The original colour of the product is pinkish-white, but all kinds of tints can be obtained by the use of colouring matters. All articles that are made of celluloid can now be manufactured from casein coloured black, the latter is used as a substitute for ebonite; when white, it makes a good imitation of ivory, and has the advantage over celluloid of being free from all odour of camphor. Its great superiority over celluloid, however, consists in its not being inflammable on exposure to heat. A very high temperature, however, dries it up and blackens it.

Although celluloid still holds an important place in the industry of plastic materials, objects made of casein are becoming increasingly popular, and already show signs of supplanting those of celluloid. If a factory for the working of casein were attached to dairies, it would greatly assist the dairy industry.

In order to diminish the cost of opaque articles of casein treated with formaldehyde, various nitrogenous matters, such as the refuse of horns, hair, and horse-hair, are sometimes mixed with the raw materials. Attempts have also been made to use vegetable casein extracted from soya seed, instead of animal casein (that made from milk), which is more expensive.

802 - **New Contributions to the Study of Lactic Silages** (1). — GORINI, C., in *R. Istituto Lombardo di Science e Lettere*, Vol. LIII, Part. XI. Milan, May 20, 1920.

Investigations made in the United States and in England have confirmed the conclusions arrived at by the author as the result of a long series of experiments upon silaged fodder. He found that it was impossible to dispense with the action of bacteria, hence it was necessary that lactic ferments should preponderate, in order to preserve the silage against harmful and destructive fermentation.

In the present article, the author quotes the work of Swiss investigators, who have reached the same conclusion (*Schweizerische Milchzeitung*, 1917, Nos. 51 and 94 ; BURRI, R., *Ibidem*, 1918, Nos. 57, 58, and 61 ; 1919, Nos. 72 and 75 ; BURRI, R., STAUB, W. and HOHL, J., *Ibid.*, Nos. 78 to 83).

Of late years, there has been a strong movement in Switzerland, in favour of the silaging fodders. The "Herba" Co. has been established at Rapperswil for the object of exploiting a special patent mechanical pressure silo with cover, devised by MM. J. A. SONDEREGGER and A. MESMER (2). This system would ensure the success of sweet or as the author terms them) lactic silages by preventing the troubles arising from the use of acid silages, called butyric by the writer from the predominant bacterial flora.

The use of silage has, however, evoked the protests of cheese manufacturers, who complain, that it is impossible to make normal cheese from the milk of cows fed on these fodders (The same thing occurred in Italy, and it was these objections that have determined and guided the author's researches since 1903). The question was investigated by the Federal Dairy and Bacteriological Establishment at Liebefeld, near Berne, and the results otained coincided with those previously published by the author, namely : (1) Failure in making good cheese from the milk of cows fed on silaged fodders is not due to the ordinary gas-producing members of the *B. Coli aerogenes* group (the agents causing swelling in cheeses), but to the presence of butyric ferments ; in fact, these bacteria were found both in the silage and in the milk of the cows to which it was fed ; (2) these harmful micro-organisms (this according to the author is the most important result of his investigations) are not only to be found in spoilt or badly-made (that is to say abnormal) silage, or in acid (butyric) silage, but also in the best silage which appears perfectly normal and sweet. As the author has shown, the presence of butyric ferments may be prevented by half-drying the fodder, and by limiting the fermentation temperature. If this is below 50° C, lactic fermentation predominates, and if the temperature is raised to 70° C, as was formerly the custom, the silage is almost sterile; the most dangerous temperature is between 50° and 60° C, because it destroys the lactic ferments, but has no effect upon the butyric ones.

In his recent experiments, the author found butyric ferments even in masses of half-dried silage, when the fermentation temperature had

(1) See *R.*, January, 1916, No. 109 ; *R.*, February, 1916, No. 232 ; *R.*, February, 1918, No. 221 ; *R.*, February, 1919, No. 257 ; *R.* July-Sept., 1919, No. 1010. (*Ed.*)

(2) For a similar system devised by Prof. SAMAZINI, see *R.*, January, 1919, No. 105. (*Ed.*)

been between 30° and 40° C, and the silo provided with an impermeable cover. In this case, too much reliance had been placed in the perfect working of the cover, and in the antibacterial action of the carbonic acid produced by cellular respiration, and therefore a pressure of from 2-3 quintals per sq. metre had been considered sufficient, whereas it appears from the authors investigations, and from practical experience, that a pressure of 10 quintals per sq. m.is necessary. But even if every technical precaution is taken to promote natural lactic fermentation, it is not always possible to ensure a sufficient degree of it, or its permanence. Butyric ferments persist surreptitiously, and may become predominant if, for example, the silage is left for some time on carts, or piled up near the cow-shed. In order to avoid this hidden danger in cheese-making, it is advisable to use selected ferments, rather then antiseptics, or ordinary salt (which in given quantities hinders the growth of butyric ferments, but not that of the lactic ones). This has been advised and urged by the author since 1906, and is at present practised in France, Germany, the United States, and even in Switzerland, where the " Herba " Co. has patented a special method of inoculating with selected ferments.

With regard to the choice of the latter, it is necessary, in the first place, to use those lactic ferments, which do not attack lactose so readily as the sugars most commonly present in fodders (saccharose, pentose, etc.); in the second place, their proteolyptic properties must also be taken into consideration, in order at the same time to obtain a useful transformation of the albuminoids.

803 - **Handling and Transport of New Potatoes.** — GRIMES, A. M., in *U. S. Department of Agriculture, Farmers' Bulletin* 1050, 18 pp., figs. 18, Washington, 1919.

A study of the causes of the losses sustained during transport and sale by early potatoes sent from the Southern States of the North-American Union to the Northern States, together with a description of the methods of handling, packing, and loading, which would reduce these losses to a minimum.

Much loss is due to injuries caused by careless lifting, by the subsequent exposure of the potatoes to the sun, as well as by faulty methods of loading the trucks, owing to which some of the barrels slip, and get broken during transit. The best barrel to use is one with a double bottom. It is of the greatest importance that the trucks should be very well aerated during the journey, and that the barrels should be arranged in such a way that they cannot shift from their places.

804 - **Great Success of Meat-Canning Factories in Madagascar** (1). — *Bulletin de l'Agence Générale des Colonies*, Colonial Ministry, Year XXIII, No. 146, p. 178, February, 1920. Paris-Mélun, 1920.

Since January 1920, the meat-canning factories in Madagascar have paid a tax of 2 fr. and 3 fr. respectively on every pig and ox

(1) See *R.*, February, 1920, No. 258. (*Ed.*)

slaughtered. It has been calculated that this tax will being in more than one million fr. annually, which shows the rapid extension of these factories in the Colony.

Their success is to some extent due to the war, but other causes will soon promote their development. France, at the present time, imports American meat to the value of many million of francs. As soon as it is recognised that the Madagascar products are as good, or better, than those imported from South America, they will take the place of the latter on the French market.

DISEASES OF PLANTS

DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN

805 – **Topping Wheat to Prevent Lodging.** — See No. 741 of this *Review*.

806 – **Observations on the Nature and Control of Apple Scald.** — BROOKS, C., COOLEY J. S. and FISHER, D. F., in the *Journal of Agricultural Research*, Vol. XVIII, No. 4, pp. 211, 240, figs. 2. Washington, D. C., 1919.

Scald is typically a skin disease of the apple. In the early and more typical stages of the trouble, only the five or six surface layers of cells that form the colour-bearing tissue are affected. With long continued unfavourable conditions, the apple tissue may become dead, brown and rotted to a depth of $^1/_8$ to $^1/_4$ inch, and occasionally the disease spreads practically to the core.

The experiments undertaken have demonstrated that the occurrence of apple scald is determined by orchard, packing house, transportation, and storage conditions.

As has been shown by other investigators, mature fruit has in general scalded less than immature ; but it has also been found that the fruit surfaces just changing from green to yellow have scalded worse than those that were coloured leaf green, and worse than those that had more completely changed to yellow. Well-coloured red-fruit surfaces have been found practically immune to scald.

Apples from trees receiving heavy irrigation scalded worse than those from trees receiving lighter irrigation. This was found not to be due to the greater number of large apples in the former case, but to some forcing effect that increased the susceptibility to scald in both large and small apples.

Delayed storage increased or decreased apple scald according to the amount of aeration the apples received previous to packing.

Apples in ventilated barrels developed less than $^1/_3$ as much scald as those in commercial barrels, when both were held in a storage that received occasional ventilation, but where the storage room received little or no ventilation, the ventilated barrels caused but little decrease in scald.

The amount of scald developed in cold-storage plants varied greatly with the location of the room. Apples near the passage or near a door scalded less than those in the bottom of the stack. Boxed apples exposed

to a continuous air current of 0.88 mile per hour, in a commercial storage plant remained practically free from scald, while similar apples that did not receive constant fanning became badly scalded. Agitating the storage air had been found more important than its renewal, in the prevention of apple-scald.

The ordinary commercial apple wrappers caused but little decrease in scald, and paraffin wrappers were only slightly better ; but wrappers impregnated with various fats and oils either entirely prevented the disease or reduced it to a negligible quantity. In barrel experiments in which only part of the fruit was wrapped, scald was greatly reduced on the apples close to the wrapped ones, as well as on the latter themselves.

Typical scald has been artificially produced within a few days by exposing apples to the vapours of ethyl acetate, amyl acetate, or methyl butyrate.

The manner in which scald can be produced artificially, and the different methods of control indicate that the disease is due to the accumulation of esters or similar products of the apple, in the tissues of the fruit and in the surrounding air. The vapours of these substances can be dispersed by air currents or absorbed by fats and oils.

DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS

807 – **Wheat Varieties Resistant to Rust in British East Africa.** — See No. 733 of this *Review*. RESISTANT PLANTS

808 – **The "Duranthon" Vine. A Direct Bearer Resistant to Fungoid Diseases and to Phylloxera, in Piedmont, Italy.** — See No. 768 of this *Review*.

809 – **Formaldehyde Treatment of Seed Maize to Prevent the Growth of Fungi.** — See No. 729 of this *Review*. MEANS OF PREVENTION AND CONTROL

810 – ***Helminthosporium* sp., the Cause "Foot Rot" of Wheat, in Illinois U. S. A.** — STEVENS, F. L., in *Science*, New Series, Vol. LI, No. 1325, pp. 517-518. Lancaster, Pa., May 21, 1920. DISEASES OF VARIOUS CROPS

In the spring of 1919, attention was called to the occurrence of a foot rot of wheat in Madison Co., Illinois. From the first it appeared probable that a certain fungus was the cause of the disease, and as early as June, 1919, records show that this fungus was universally present, and that inoculations with pure cultures gave positive results.

These preliminary investigations were clearly and conclusively confirmed by subsequent research work.

The fungus in question is a typical member of the genus *Helminthosporium*.

This disease, while of the general type of foot rot known heretofore in Europe, Australia and elsewhere, is caused by on organism not hitherto designated as a cause of foot rot in any of the publications in the countries mentioned. The foot rot found in Illinois should therefore be recog-

nised as a disease quite distinct from all others of a similar type described previously. The experiments clearly proved that it is soil-borne, and it is probable also that it is also seed borne. How serious the disease may prove to be, and how far it is dependent upon local conditions of climate and soil, can only be decided after one or more years of additional observation.

811 – ***Bacterium glycineum* n. sp. Injurious to the Soya Bean *(Glycine hispida)* in U. S. A.** — COERPER, F. M. in the *Journal of Agricultural Research*, Vol. XVIII, No 4, pp. 179-193, figs. 1, pl. 8. Washington, D. C., 1919.

Description of bacterial blight of the soya bean (*Glycine hispida* Maxim), first observed some years ago, and since subject to investigation on the experimental plots at the University of Wisconsin, Madison. Subsequent observation proved the blight to be very prevalent throughout the soya bean fields of Wisconsin. A disease showing symptoms of the same type has been reported from various other localities in the United States.

It is characterised on the leaves, where it is most conspicuous, by small angular spots, either isolated, or confluent. The lesions are light-coloured and translucent in early stages and very dark-coloured in late stages. In the latter case also, the diseased tissue may become dry and detached from the rest of the leaf. Bacterial exudate occurs on the leaf spots in the form of small drops, but it is not very evident except under favourable moisture conditions. It is pale in colour and dries as granules or scales.

Petiole, stem and pod lesions accompany the disease on the leaves. Exudations have been observed on petioles and pods.

The blight is caused by a bacterium described by the author as a new species under the name of *Bacterium glycineum*. The organism is able to enter the tissues of the host plant without wounds. The organism has been isolated repeatedly, and pure cultures obtained.

Simply spraying water suspensions of the organism upon soya bean plants is sufficient to produce infection. It is advisable, however, to rub the tissue gently between the fingers to insure contact between inoculum and plant surface.

The best growth of the organism occurs between 24° and 26° C, the maximum at about 35°. The absolute minimum has not been determined, but growth is slow at 2°.

The organism is sensitive to desiccation, and there seems to be gradual loss in pathogenicity when it is grown in artificial culture. Razor sections of lesions in fresh leaves show the bacterial invasion to be in the parenchymatous tissue. Infection evidently takes place through the stomata.

Until further work on wintering and dissemination has been done, it is impossible to recommend any specific control measures aiming to check the development and spread of the disease in the field. At present the development of disease resistant varieties seems to offer the greatest promise.

812 – ***Spongospora subterranea*** **Affecting Potatoes in Switzerland.** — *Schweizerische Landswirtschaftliche Zeitschrift*, Year XLVIII, Part I, pp. 5-7, figs. 1 Zurich 1920.

The Agricultural Experiment Station at Ärlikon (Zurich) states that during 1919 the potato-disease known as "scab" (*Spongospora subterranea*), appeared in various parts of Switzerland.

This disease — for which the popular German name of Kartoffelräude has been suggested — seems to attack certain varieties of potatoes more than others. Thus, for instance, in the Cantons of Berne, Zurich, and Thurgau, the tubers of Bauernglück were affected, sometimes seriously, while other kinds were immune. The symptoms of the disease are given, and also the methods suggested for its control.

813 – **Two Destructive Rusts Ready to Invade the United States.** — ARTHUR, J.C., in *Science*, New series, vol. LI, No. 1314, pp. 246- 247 Lancaster, Pa., March 5, 1920.

The author calls attention to two rust fungi that seem to possess the possibilities of great harm, but which have not yet invaded the United States.

The peanut crop is a large and growing industry in the Southern States. There is a rust of peanuts widely distributed in South America, and becoming common in the West Indies. It is usually designated by the name of *Uredo Arachidis*, although a sample from Paraguay would indicate that it, should be called *Puccinia Arachidis*. It is has been known to mycologists since 1884, but has only very recently attracted the attention of cultivators. Specimens, of this rust were received by the author in September, 1916, from W. ROBSON of Montserrat (West Indies) ; every leaf was covered with the abundant brownish-yellow powder of the fungus. According to Mr. ROBSON, in some seasons, it is a serious menace to the peanut crop on that island. Attempts to control it with Bordeaux mixture did not prove satisfactory.

The life cycle of the rust has not been worked out, but with cultivated plants, only the uredospore is produced, as observed in 1913 in Porto Rico, and in 1915 in Cuba.

The second rust to which the author calls attention is *Puccinia Pittieriana*, which attacks potatoes and tomatoes. It was collected by H. PITTIER on the wild potato in 1903 and 1904, and again in 1916 by E. W. D. HOLWAY on the slopes of the volcano Irazù in Costa Rica. It has been mentioned also under the name of *Uredo Pittieri*. The author has examined specimens from Ambato, Ecuador, where it was found in 1918 both on potatoes and tomatoes. For this rust only one kind of spore, the teleutospore, is produced in the life cycle, and these germinate at once upon reaching maturity, requiring no resting stage.

814 – ***Rosellinia Pepo*****, an Ascomycete Injurious to Cacao in Trinidad, West Indies.** — NOWELL W., with introductory note by. FREEMAN W. B, in the *Bulletin of the Department of Agriculture, Trinidad and Tobago*, Vol. XVIII, Pt. 4, pp. 178-190, figs. 5. Port of Spain, 1920.

Several species of the genus *Rosellinia* give rise to a well-defined type of root disease in numerous countries in the world, both temperate and tropical. The fungus destroys cultivated trees and shrubs in patches,

and often infests the soil and destroys practically all the vegetation with which it comes in contact.

In the Lesser Antilles, *Rosellinia* diseases occur in Guadeloupe, Domenica, Martinique, St. Lucia, St. Vincent and Grenada; they are unknown in the remaining islands of the group, which have drier climates.

The range of hosts is extremely wide, including practically all the important cultivated and semi-cultivated plants, but the plants most affected are cacao (in all the islands), coffee (in Guadeloupe and Martinique), limes (*Citrus aurantifolia*; on new clearings in Domenica), and arrow root (*Maranta arundinacea* in the interior districts of St. Vincent.

The disease on cacao is usually caused by the species *R. Pepo*, and in most cases, is communicated from the roots of dead or dying shade trees, especially breadfruit (*Artocarpus incisa*), avocado (*Persea gratissima*), and pois-doux (*Inga* spp.). Another species of *Rosellinia*, as yet unidentified, is believed to attack cacao in certain localities.

The death of cacao trees from root disease has been known in Trinidad and Tobago for a long time, but the cause of death does not appear to have been specially investigated.

Although *Rosellinia* had not previously been recorded as a cause of root disease of cacao, etc., in Trinidad and Tobago, Mr. NOWELL, during his visit in 1918 to this Colony, expressed an opinion that this fungus was likely to be found on these two islands, considering its wide distribution in the West Indies and tropical America.

During a second visit in 1919, Mr. NOWELL, accompanied by Mr. FREEMAN visited an estate where trees in a particular area had died. An examination of the dead trees led to a diagnosis of the cause of the disease as *R. Pepo*.

The disease on *Citrus aurantifolia* and coffee is caused by *R. Pepo* and *R. bunodes* indifferently.

The first cases in new clearings are usually associated with forest stumps left to decay, especially those of certain trees. Subsequent cases arise from the spread of the fungus from tree to tree along the roots, or by infection from surface soil rich in decaying vegetable matter, which readily becomes infected in damp and shaded situations.

An infected tree may be killed gradually by the progressive investment of the roots, or rather quickly by the destruction of the bark around the collar. The fungus penetrates both bark and wood. Conidia are produced with great readiness wherever the mycelium emerges into the open; perithecia occur later, and, especially in the case of *R. Pepo*, their formation may be much delayed.

Much can be done to prevent outbreaks of the disease by exposing the soil, the bases of the trees, and other dead material lying about to the wind and sun. Cases which may arise may be retsricted by these measures and by the provision of a close system of trenches to prevent root contact.

Treatment by excision and exposure is successful in the early stage of infection, but in practice these are hardly ever detected. Periodical surveys would save many trees.

Infected trees should first be flamed and then promptly removed, all roots dug out and burnt, the soil limed, and the situation exposed as much as possible. All adjacent trees should be isolated from each other by trenches.

815 - ***Phytophthora Cactorum*, Injurious to Pears in Nova Scotia.** — *The, Agricultural Gazette of Canada*, Vol. VI, No. 11, pp. 951-952, figs. 1. Ottawa, November, 1919.

In September, 1919, specimens of pears were received from Kentville, Nova Scotia, which showed a rather unusual rot.

The nearly full grown pears showed one or more large, circular, dark-brown spots, resembling the common soft rots, but unusual, because the spots were not soft but quite firm. The pears of one tree only were affected, and on microscopic examination it was found to be due to the fungus *Phytophthora Cactorum* (Leb. and Cohn) Schr. This disease of pears is new to the continent of America. In the few cases where it has been observed, the fruit is affected only on low hanging branches. This fact suggests that the infection may originate from surrounding infected vegetation. In the early stages, the rot does not extent very deeply into the tissues, but soon a large number of other organisms appear — bacteria and fungi — and the pear becomes a soft rotten mass.

The fungus reproduces by zoospores and oospores.

As control measures, it is advised to prevent branches loaded with pears from hanging low and to prop them up. All fruits showing such or similar rots should be carefully collected and burnt, particularly any that may have fallen to the ground. The weeds should be kept down around the trees, so that the fungus may find no host plant near the trees. Fruits and other infected material allowed to fall to the ground are certain to perpetuate the disease.

WEEDS AND PARASITIC FLOWERING PLANTS

816 - **Undetermined Larvae Attacking the Orobanche of the Bean, in Italy.** — Sciacca N., in *La Propaganda Agricola*, Series 2, Year XII, Nos. 9-10, pp. 126-128, Bari, May, 1920.

The author noticed that, in the field of the Bari Agricultural Experiment Station, in some plots of beans, more or less attacked by Orobanche, there were some individuals which, although they were infested by the parasite, still looked healthy and did not shed their "jumping" fruits. On the other hand, certain beans, also hosts of the Orobanche, had already been much injured by this parasite. While, however, the Orobanche plants living on beans that had lost their flowers and fruit, were healthy and difficult to uproot, those infesting healthy-looking beans were wilted and were easily pulled up, the swollen portion of their stem being completely rotten.

On cutting sections through the stalk of one of these diseased Orobanche, one or more galleries were seen running its whole length. These were inhabited by a larger, or smaller, number of white, apodous larvae

from 5 to 8 mm. long, and very agile. The galleries begin in the swollen portion of the stem of the Orobanche, and present as many ramifications as there are flowers. Each ovary contains one or more larvae. The latter, after having destroyed all the ovules, remain in the flowers in the form of dark yellow nymphs from 2 to 3 mm. in length. So intense was the infestation, that not one flower of a diseased Orobanche was spared; the little enemy made its way from below, and never rested till it reached the flower which was always faded, and sometimes decomposed.

The author extended his investigations to other bean fields, and reached the district of Cassano. He found, that wherever the Orobanche grows, its parasite is found more or less plentifully. Many local agriculturists said that they had also seen these larvae in the past, but they attributed no importance to them, and never noticed that all the withered Orobanche were to be found on bean-plants that were little, or not at all, injured.

The parasite was also observed in 1905, by Prof. C. CAMPBELL, in the Cassino district, and the attention of entomologists was drawn to it as being a means of controlling Orobanche. Prof. G. LO PRIORE also found the parasite in Sicily, and published his discovery in 1914.

Of all the methods suggested for controlling Orobanche, the most certain and thorough is the systematic destruction of the flowers. If this does not save the bean crop of that year, it hinders the parasitic phanerogam from spreading and reproducing itself in subsequent seasons. If the work of destroying the flowers could be entrusted to the animal parasite in question, a very economical and generally applicable system of controlling the Orobanche would have been found, and at the same time, the propagation of the natural enemy of that plant would be encouraged, instead of impeded. It should be noted, that the larvae do not only destroy the haustoria and seeds of their host, but aso the little tubers that develop on the swollen part of the stem, thus depriving the plant of all means of reproduction.

Many southern, especially Sicilian, agriculturists plant their beans late, with a view to controlling the Orobanche. The author suggests that possibly one of the reasons for the success of this practice may be found in the fact that the late development of the beans, and consequently of the Orobanche, offers the most favourable conditions for the growth and attack of the larvae.

INJURIOUS INSECTS AND OTHER LOWER ANIMALS.

GENERAL

817 – **Insects Injurious to Economic Crops in the Zanzibar Protectorate.** — MANSFIELD-ADERS, W., in the *Bulletin of Entomological Research*, Vol. X, Pt. 2, pp. 145-155, pl. 3. London, Jan., 1920.

The injurious insects mentioned in this list attack the following crops: —

Eugenia caryophyllata. — A certain number of young clove trees have been killed by *Termes bellicosus*, in the isle of Pemba. The same insect attacks the bark of unhealthy full-grown trees.

COCONUTS. — The most serious pests throught the islands of Zanzibar and Pemba are *Oryctes monoceros* and *O. boas.* Trees from 2 ½ to 3 years old are most usually attacked, many are killed, others greatly delayed in reaching maturity. Trees in isolated positions and on bad soil are more often attacked. Fully matured trees harbour adult beetles, but are not seriously damaged. The most useful preventive measure is the trapping of larvae in pits filled with rotting coconut trunks, vegetable debris, and a little horse manure. No insect have been found preying on the eggs, larvae, pupae or adults of the two *Oryctes.* The larvae are destroyed by certain mammals, including *Rhynchocyon adersi, Petrodomus sultan, Pachyura murina,* and two species of crows, *Corvus scapulatus* and *C. splendens.*

The following are minor pests of coconut palm :— *Aspidiotus destructor, A. cyanophylli, A. lataniae, Hemichionaspis minor, Cerataphis lataniae, Rhina amplicollis, Diocalandra frumenti, Rhyncophorus phoenicis,* and *Termes bellicosus.*

COTTON . — Attacked by *Pectinophora* (*Gelechia*) *gossypiella, Pyroderces simplex, Earias insulana, Sylepta derogata, Prodenia litura, Acrocercops bifasciata, Bucculatrix loxoptila, Orgyia vetusta, Euproctis producta, Dysdercus fasciatus, D. superstitiosus, Oxycarenus albidipennis, Pseudococcus obtusus, Ps. virgatus,* and *Ps. citri.*

CEREALS. — Maize is attacked by *Cirphis loreyi, Sesamia calamistis, Chilo suppressalis* and *Peregrinus maydis ;* except the last, all the other insects quoted feed also on *Sorghum vulgare* which is also attacked by *Busseola fusca.*

VEGETABLES. — Cabbages are attacked by *Crocidolomia binotalis, Plutella maculipennis, Phytometra signata ;* egg-plants by *Acanthocoris fasciculatus ;* Cucurbitaceae by *Dacus vertebratus, D. brevistylus* and *D. punctatifrons ;* pigeon-peas (*Cajanus indicus*) by *Pseudococcus obtusus, Tragocephala variegata, Lyprops breviusculus, Mylabris dicincta, M. amplectens, Coryna ambigua, Marasmarcha atomosa, Deudorix antalus,* and *Agromyza* sp. ; *Hibiscus esculentus* by *Pectinophora gossypiella, Earias insulana, Sylepta derogata, Prodenia litura,* and *Nisotra weisei ;* sweet potato (*Ipomoea batatas*) by *Cylas formicarius* and *Aspidomorpha punticosta ;* and cassava (*Manihot utilissima*) by *Pseudococcus* (*Dactylopius*) *virgatus* var. *madagascariensis.*

FRUIT TREES. — Citrus plants are injured by *Lepidosaphes beckii, Icerya purchasi, I. seychellarum, Pseudococcus obtusus, Ps. citri, Ceroplastes rubens, Coccus viridis, Aspidiotus trilobitiformis, Cerataphis lataniae, Aphis tavaresi, Argyroploce leucotreta, Papilio demoleus, Tragocephala variegata, Porphyronota maculatissima, Gyponychus cervinus,* and *Ceratitis capitata ;* mangos by *Sternochetus* (*Cryptorrhynchus*) *mangiferae, Aspidiotus* (*Chrysomphalus*) *dictyospermi, A. destructor, Pseudococcus obtusus, Lecanium adersi, L.* (*Saissetia*) *nigrum, L.* (*Saissetia*) *punctuliferum ;* bananas by *A. destructor ;* and *Anona muricata* by *Ceratitis rosa.*

SHADE TREES. — The African almond (*Terminalia catappa,* is occasionally severely attacked by bag worms (*Psychidae*), and less severely

by *Miresa melanosticta ; Casuarina equisetifolia* by *Cirina forda* and *Pseudococcus obtusus ;* cinnamon trees by *Asura saginaria ; Ficus elastica* by *Aspidiotus* (*Pseudaonidia*) *trilobitiformis* ; silk cotton (*Eriodendron anfractuosum*) by *Dysdercus superstitiosus* and *D. fasciatus.*

TIMBER. — Various woods are damaged by *Macrotoma palmata, Dinoderus minutus* and *Termes bellicosus.*

MISCELLANEOUS PLANTS. — The castor plant is attacked by *Thalassoides digressa, Duomitus capensis, Eutyposis impressa* and *Chrotogonus hemipterus ; Amaryllis* sp. by *Brithys pancratii* and *Brachycerus atrox ; Ipomoea* sp. by *Euchromia formosa ;* gardenias by *Glyphodes sericea ,* roses by *Mausoleopis amabilis* and *Aspidiotus* (*Chrysomphalus*) *aonidum ,* and various ornamental creepers by *Pseudococcus virgatus.*

STORED PRODUCTS. — The following injurious insects are mentioned :— *Calandra oryzae* in rice, maize and sorghum ; *Laemophloeus pusillus* in maize ; *Tribolium castaneum* in maize and occasionally in rice ; *Silvanus surinamensis* in maize ; *Tenebriomaides uritanicus,* occasional pest in maize ; *Bruchus chinensis,* serious pest, especially of *Phaseolus Mungo,* and *Cajanus indicus ; Cossonus suturalis,* occasional pest of sweet potatoes ; *Latheticus oryzae* and *Rhizopertha dominica,* occasional pest of maize : *Necrobia rufipes* in dried copra ; and *Ephestia cautella* in rice and various flours.

818 – **Weevils Injurious to Certain Cultivated Plants in South Africa.** — MARSHALL, G. A. K., in the *Bulletin of Entomological Research,* Vol. X, Pt. 3, pp. 273-276, pl. 1. London, April, 1920.

A description of four hitherto undescribed species of *Curculionidae* sent to the Imperial Bureau of Entomology from the Division of Entomology, Pretoria :—

1) *Protostrophus planatus,* from East Rand, Transvaal, where it was recorded as injurious to the foliage of young orange trees.

2) *P. noxius,* from Clocolan, Orange Free State, found feeding on young wheat.

3) *P. instabilis,* from Nelspruit, Transvaal, also injurious to foliage of young orange trees.

4) *Eremnus horticola,* from Bloemfontein, Orange Free State, found feeding on dahlias and chrysanthemums.

MEANS OF PREVENTION AND CONTROL

819 – **Effect of Deleterious Gases on Insects.** — *Bulletin de la Société entomologique de France,* 1920, No. 5, p. 82. Paris, 1920.

CH. DEMAISON reports that, in the neighbourhood of Rheims, there was an apparent scarcity of insects during the year 1919. He imagines that the continuous distribution of gas in this district evidently has some effect and he calls attention to the interest of this question from the point of view of applied entomology.

820 – **The Insecticidal Properties of Different Parts of Pyrethrum *(Chrysanthemum cinerariaefolium).*** — See No. 757 of this *Review.*

821 – ***Chlorochroa sayi,*** **Grain Bug Injurious to Wheat and Other Crops in the United States.** — CAFFREY, D. J. and BARBER, G. W., in the *Department of Agriculture, Bulletin* 779, pp. 1-35 figs 13. Washington, D. C., 1919.

Since 1911, *Chlorochroa sayi*, Stål has caused serious damage to wheat and other crops in the inter-mountain and southwestern States. The most important damage is caused by the insect piercing the newly-formed heads of the cereals and feeding on the liquid content, which prevents the formation of the grain or greatly reduces its weight.

The reduction in yield from grain bug attack varies from 10 to 50 % of the crop. In extreme cases the entire crop may be destroyed.

The cultivation of large areas formerly devoted to grazing, eliminated the native food plants of the insect and caused it to attack cultivated plants, and resulted in an increase of the pest beyond its former abundance.

Wheat, barley, and rye are the cultivated crops most preferred by this bug. The species also feeds on other cereals, and on alfalfa, cotton peas, beans, cabbage, tomato, and lettuce, in addition to many wild native plants.

The first damage was recorded in 1903, and since that time serious attacks have been reported from most of the States west of the Great Plains area.

Weather and the work of parasites generally restrict destructive outbreaks in each locality to periodic intervals of two or three years.

Adults emerge from hibernation in the early spring and deposit eggs on the material composing the hibernating quarters. The resulting nymphs feed upon tender plants growing in their vicinity. Upon reaching maturity the adults migrate to cereal crops and feed upon the developing heads.

There are three distinct generations and sometimes a partial fourth generation annually. About 50 days are required to complete the life cycle of each generation. After midsummer, the numbers of the insects are greatly reduced by an egg parasite, *Telenomus ashmeadi*, and by two species *Gymnosoma fuliginosa* and *Ocypterodes euchenor* which parasitise the adults. Several kinds of predacious enemies contribute to the same result.

Hibernation occurs in the adult stage under weeds or rubbish. No nymphs or eggs survive the winter. Severe winters result in the death of a large number of hibernating adults and constitute one of the most important factors in restricting destructive outbreaks of this species. During normal winters, at least 95 % of the adults survive when hibernating in protected places.

The most effective and practical method of control is the destruction of the adults while concentrated in their winter quarters. This is best accomplished by turning under or burning all rubbish and weeds (particularly Russian thistle, *Salsola Tragus*) in and about cultivated fields.

Trap crops, hand picking and hopperdozers (1) might prove practical in the control of the insect under special conditions.

(1) For the apparatus, employed in America in the control of locust attacks, see « *La lutte contre les sauterelles dans les divers pays* », Inst. Internat. Agric., Rome, 1916, pp. 142-143. (*Ed.*)

822 – ***Lecerfia chitinipyga*** **n. gen., and n. sp., a Macrolepidopteron found on the Grass *Aristida pungens* on the Algerian Sahara.** — DUMONT, C. in the *Bulletin de la Société entomologique de France*, 1920, No. 6 pp. 102-104, figs. 1. Paris, 1920.

A morphological description of the adult, larva and pupa of a Macrolepidopteron (fam. *Noctuidae*) found in 1919 in the Algerian Sahara (Western Grand Erg, west of El Golea), and which the writer has designated by the name of *Lecerfia chitinipyga* n. gen. and n. sp.

The caterpillar lives on the panicles of *Aristida pungens* Desf. (the "drin" of the Arabs), and eats the caryopses of that plant.

823 – **Insects Injurious to Cotton in Porto Rico.** — SMYTH, E. GRAYWOOD, in *Entomological News*, Vol. XXXI, No. 5, pp. 121-125. Lancaster, Pa., May, 1920.

Pyroderces rileyi Wals, although frequently found, does no perceptible damage.

On the contrary, *Alabama argillacea* often becomes a serious menace to cotton production. As the use of arsenical insecticides is too expensive for the average cotton grower of the Island, he is advised to use a much cheaper but equally effective method of control, namely, to cut down and destroy the moth's wild food-plants growing between the cotton crops. The principal host plants of this moth are two weeds, *Urena lobata* and *Malachra rotundifolia*, both Malvaceae, the former much the more abundant and the more noxious, owing to its habit of attracting large numbers of the ant, *Solenopsis germinata* Fabr., because of the three small honey ducts on the underside of each leaf. Unfortunately, this weed is considered highly medicinal by the natives, and with difficulty can they be pursuaded to destroy it ; if left alone, *U. lobata* grows vigorously. On July 15, 1916, the author was able to collect as many as 52 larvae from four plants, showing how the weed may facilitate the spread of the moth.

Dysdercus andreae L. is sometimes abundant and at other times entirely absent, so that it cannot on the whole be considered as a serious cotton pest.

An occasional larva of the cutworm, *Xylomiges sunia* Guen. has been seen attacking cotton foliage.

The Greenhouse thrips, *Heliothrips haemorrhoidalis* Bouch., has done much damage according to the author, but it had not been previously reported as a cotton pest.

Another insect that is very common, and infests probably 30 % of the cotton bolls, is the mealybug, *Pseudococcus virgatus* (Ckll.), which occurs in all stages of its development. It is believed that this beetle is heavily parasitised by a Cecidomyid, probably *Karschomyia cocci* Felt.

A very few specimens of *Ps. citri* (Risso), one specimen of *Ps. longispinus* (Targ.) and a number of adults of a beetle very analagous to *Coccus mangiferae* (Green) were also found on the bolls.

Leaves of the Malvaceae have been occasionally found to be attacked by the lace-bug, *Corythuca gossypii* F.

More important than the last mentioned species is the cotton aphis, *Aphis gossypii* Glov., although the attack is light and scattered, thanks to the activity of its natural enemies, amongst which may be quoted, in

order of importance, *Cycloneda sanguinea* L., *Scymnus roscicollis* Muls., *Acrostalagmus albus*, a Braconid, a Chalcidid, a Chrysopid, and a species of Hyperaspis. In very wet weather, *A. albus* usually becomes the most efficient of the parasites. *C. sanguinea* is greatly hampered in its multiplication by the attack of a hyperparasite (*Homalotylus* sp).

The adults of *Diabrotica graminea* Balz. are often seen eating cotton blossoms or foliage, and the larvae doubtless attack the roots.

Occasional nymphs and adults of the species *Empoasca* have been found on foliage and bolls.

Two adults of *Antianthe expansa* (Germ.), one adult of the species *Agallia*, and a few adults of *Oliaris* sp. have been found on cotton stems.

The nymphs of the green bug *Nezara viridula* (Linn.) were noticed for the first time in 1919 on many cotton bolls.

Lepidopterous larvae of small size have been found also on the bolls; none of them, however, resemble the treacherous pink bollworm (*Pectinophora* (*Gelechia*) *gossypiella* Saund.

824 – ***Strategus quadrifoveatus*, a Coleoptoron Injurious to the Coco Palm in Porto Rico.** — Crespo, M. A., in *Revista de Agricultura de Puerto Rico*, Vol. IV, No. 3, pp. 47-48. San Juan, P. R., 1920.

Strategus quadrifoveatus ("escarabajo rinoceronte") is, at the present time, causing much havoc among young coconut palms in the island of Porto Rico. During the day, the adult beetle lies hidden in the soil surrounding the stem of the palms. The larvae are found hiding in the dead palms, on which they live, or in dry or rotten stakes, etc.

The insect undergoes complete metamorphosis, its life cycle lasting from twelve to thirteen months.

S. quadrifoveatus injuries the coco-palm by excavating a deep gallery in the stem while it is still young. The author has seen eight of these insects round a coco-palm a year and a half old, which was almost completely destroyed by the attacks of the pest. It has often been observed that sugar-canes growing in the neighbourhood of young coco-palms have also been injured.

The best way of killing these beetles is to attract them into piles of dry rotten stakes, heaps of coco-nut debris, or any similar places where they can find food. These traps should be visited at least once a month and the larvae destroyed.

When young coco-palms are attacked by *S. quadrifoveatus*, the leaves turn yellow, cease growing, and the plant finally dies. It is a good plan to dig round the palms to a certain depth, as soon as there is any suspicion of their having been infected.

All the beetles found must be collected and killed by sprinkling them with paraffin or paraffin emulsion. Further, all rubbish that might serve as a hiding-place for the insect must be removed from the plantation.

INJURIOUS VERTEBRATES

825 – ***Merops philippinus*, a Bird which Destroys Beneficial Insects in India.** — FLETCHER, T. B. and INGLIS, C. M. in *The Agricultural Journal of India*, Vol. XV., Pt. 2, pp. 121-123, pl 1. Calcutta, March, 1920.

Merops philippinus (blue-tailed bee-eater) is common throughout the plains of India, but is partially migratory, visiting Northern India in summer and Southern India in winter. In Bihar they are seen from March to October, and in the Duars have only been noticed during June and July.

It has only been encountered once in North Cachar, but is common in Pusa. C. W. MASON, after an examination of the stomachs of 13 birds between April and October, states that of the 83 insects taken by *M. philippinus*, 70 were beneficial, 3 injurious and 10 neutral. The beneficial insects included dragonflies (*Odonata*), bees and other Hymenoptera.

GENERAL INFORMATION

826 – **Forests, Stock Breeding and Agriculture in Upper Mesopotamia.** — NAAYEM, J. (Delegate for Chaldea), in La Haute Mésopotamie et ses richesses naturelles, *Chimie et Industrie*, Vol. III, No. 5, pp. 684-688, Maps 1. Paris, May, 1920.

DÉVELOPMENT OF AGRICULTURE IN DIFFERENT COUNTRIES

Upper Mesopotamia includes the two provinces, or vilayets, of Diarbekr and Mosul, which are situated between the Tigris and the Euphrates; adjoining Mosul, lies territory extending from the left bank of the Tigris to Persia.

Although the area of the country is about 200 000 sq. km., there are not more than 1 500 000 inhabitants or about 7 inhabitants per sq. km.

The numerous and magnificent forests that formerly clothed the banks of the Tigris in Upper Mesopotamia now no longer exist as they were distroyed owing to bad management. However, on the banks of both the large rivers, forests are still met with at intervals, and serve as a source of fuel for the neighbouring population. In the mountain of Karadjdagh, and in the neighbourhood of Souverek, there are still forests where charcoal is made; all the mountains extending from Mardin to Djezire are also completely covered with woods.

It was from these mountains, that the Naazem Bros. procured during the war, when coal was scarce, all the wood required by the Bagd.d Railway Co. for the construction and working of the l'ne running from Arrada to Demir-Kapon beyond Nisibin.

Upper Mesopotamia may be termed a cattle-breeding country *par excellence*. Its splendid pastures and vast prai ies covered with succulent grass serve as camping-grounds for the nomadic tribes that pitch

their tents there, and breed for export large flocks of sheep and goats and herds of camels. They also derive much profit from the butter, cheese and wool that are produced. In the summer when the "rahil" (journey) takes place, the natives leave the plains and drive their stock to the Kardjdagh and Zorane mountains, where the permanent and luxuriant vegetation provides them with ample food. By enlarging the irrigation works, and thus obtaining a sufficient water supply during the summer for the pastures, it would be possible to save the animals these long migrations, that only fatigue them and make them lose flesh.

Goats and sheep form the chief live stock; they are exported, and also supply the country with meat. In the departments of Ourfa alone, there are about 1 000 000 of these animals.

The Mesopotamian draught-oxen and milch-kine are, as a rule, smaller than the French varieties. The Arab horse is also bred in Mesopotamia, an active centre for trade in this breed, which has been kept very pure.

The production of horses could easily be increased, and the animals improved, by the creation of Stud Stations, and by importing European varieties for crossing with the native ones, interesting results from every point of view could be obtained. The mule and donkey are used to draw the plough and large numbers are exported.

Although the methods of cultivation adopted are rudimentary, and the agricultural processes and implements very primitive, yet the soil of Mesopotamia, consisting of fine, friable alluvium, produces splendid crops. The Arab peasant, who is a person of fixed and careless habits, after having put some of the seed apart for his own use, throws the rest on the field somewhat at random, covering it more or less with the plough, so that a certain amount is eaten by the birds.

As soon as the ear is formed, the horse, the farmer, and his oxen, etc., use the crop for food, and this continues until the theshing which lasts two months, and is carried out by beasts of burden that tread out the ears, or drag over it a plank weighted down with stones. During harvesting, which is done with a sickle, the reapers are obliged to leave the ears that fall to the gleaners, who are often as numerous as the reapers, and return home in the evening with 10 to 15 kg. of grain. Before dividing the crop between the landowner and himself, the agriculturist tries to steal as much of it as possible, and the landowner is obliged to resign himself to this. In spite of these losses, and of the Government tax, which amounts to $^1/_7$, and often to more, the grain that falls to the lot of the landowner is 5 times, and sometimes ten, or fifteen times, the amount of the seed-corn sown. The crops would be much larger if modern and improved agricultural implements were obtainable, and if scientific cultural methods were adopted under the direction and vigilant eye of an expert engineer. Careless and dishonest manual labour could be replaced by motor-cultivation the success of which is assured by the proximity of rich petroleum wells. Enormous tracts of land now lying incultivated, could then be turned to account, and would thus be-

nefit, not only the owner and the population, but also the capitalist, who ould find no better manner of rapidly increasing his wealth.

Everything grows and suceeds well on this soil, including crops such as, wheat barley, maize, rye, rice, lentils, chickpeas, sesame, tobacco, otton, etc. All the fruits and vegetables of both hot and temperate climates — pears, apples, figs, apricots, peaches, mulberries, olives, etc. — yield good crops in Mesopotamia. The pomegranates of Ourfa are without rivals, the cherries and plums of Mardin are exquisite, the melons and water-melons (the latter weigh sometimes as much as 50 kg.) are perfumed and their flavour and delicacy are unusual. Cucumbers, artichokes, asparagus, beans, haricots, cabbages, cauliflowers, " corne grecque," tomatoes, eggfruits, capsicums, carrots, turnips, beetrots, onions, and lettuces are abundant. Potatoes do well and may later become an important crop.

The vine, however, is of chief importance owing to its innumerable varieties ; much of the fruit is exported in the form of raisins. Well-cultivated vineyards with favourable exposures cover the temperate plains stretching between Ourfa and Diarbekr, and the mountains of Mardin, Djebel-el-Tour and Sindjar. There are thousands of hectares of uncleared land veéy suitable for vine-growing, and only requiring a little care in order to turn it into vineyards. Nothing is wanting for the establishment of a large wine industry, the products of which would find a sale on the markets of Aleppo. Mosul, Bagdad, Bassorah, and India.

The olive also grows in Mesopotamia, and might give rise to an important industry. The methods employed in the country are still very primitive ; it would be worth while to set up modern mills and apparatus for expressing all the oil from the cakes ; in this way a far larger yield of oil would be obtained than from the very rudimentary presses which are always used (1).

RURAL HYGIENE

27 - **Phosphorus Requirement for the Maintenance of Man.** — Sherman, C. with the Cooperation of Rose, A. R., Koch, M., Mathews, E. and Osterberg, E. in *The Journal of Biological Chemistry*, Vol. XLI, No. 2, pp. 173-176. Baltimore, M. D., Feb. 1920.

For convenience of comparison, the data of the six experiments made by the author and his collaborators, and of all available previously published experiments which seem to be quantitatively comparable, have been calculated to the uniform basis of phosphorus output per day per 70 kilos of body weight

Out of the 95 experiments taken as a whole, 34 were made with men and 61 with women. The quantity of phosphorus required per day ranges from a minimum of 0.52 to a maximum of 1.2 gm., with an average of 0.88 gm. per 70 kg. of body weight. The experiments upon men average 0.87 gm. and those upon women 0.89 gm. per 70 kg. per day. The author considers that the variations in the phosphorous output may be due to the function of the phosphates in the maintenance of neut-

(1) See also *R.*, 1919, No. 552. (*Ed.*)

rality in the body, and to the possible differences in quantitative efficiency in nutrition of the various phosphorus compounds.

The author considers that while several factors determining the phosphorus output remain for further quantitative investigation, we are probably justified in concluding that the phosphorus requirement is now known with about the same degree of accuracy as the protein requirement, and that about $^1/_5$ to $^1/_{10}$ as much phosphorus as of protein is required in the maintenance metabolism of man.

If the quantity actually required for maintenance, is compared with the quantity of food supplies of 224 families or other groups of people selected as typical of the population of different parts of the United States, only 8 showed less than 0.88 gm. of phosphorus per man per day, and in all but two of these cases the phosphorus would have reached this figure if the food had been sufficient in amount to adequately cover the energy requirement per day. These two cases which are typical of the Southern United States according to the author, confirm the results obtained by McCollum and others indicating that the diets which resulted in pellagra in the Southern States lacked phosphorus content.

With this exception, the author considers that the danger that a freely chosen American diet will be deficient in either protein or phosphorus does not appear serious so far as the maintenance requirements are concerned. What quantities of phosphorus in the food will best meet the requirements of growth, pregnancy and lactation, remains yet to be determined.

828 – **Digestibility of Certain Vegetable Fats.** — Holmes, A. D. and Deuel, H. J. in the *Journal of Biological Chemistry*. Vol. XLI, No. 2, pp. 227-235, bigliogr. of 5 works. Baltimore, M. D., Feb. 1920.

Results of experiments on the average digestibility of diet are shown in the appended Table.

The digestibility of the protein and carbohydrate of the entire ration was essentially the same as that in other experiments of a similar

Average Digestibility of Diet and Estimated Digestibility of Fats Studied.

King of Fat	Digestibility of Entire Ration				Estimated Digestibility of Fats
	Protein %	Fat %	Carbohydrates %	Ash %	%
Avocado (*Persea gratissima*)	85.8	90.0	97.0	74.9	87.9
Cohune Oil (*Attalea Cohune*)	63.5	94.6	95.8	73.3	99.1
Cupuassú (*Theobroma grandiflora*)	75.2	88.8	96.6	55.8	94.1
Hempseed Oil (*Cannabis sativa*)	67.1	94.4	97.0	68.2	98.5
Palm-Kernel Oil (*Elaeis guineensis*)	61.0	95.3	96.9	56.5	98.0
Poppy-seed Oil (*Papaver album* and *P. nigrum*)	49.1	91.3	96.5	50.2	96.3

nature, indicating that the fats exercised no unusual effect on the utilisation of these constituents.

These fats and oils, with the possible exception of cupuassú fat, produced no abnormal physiological effects and may be regarded as satisfactory for food purposes. Cohune, hempseed, palm kernel and poppy seed oils are very nourishing to the human body.

829 – **The Destruction of Anopheles Larvae by Means of Powdered Trioxymethylene.** — ROUBAUD, E., in *Comptes rendus de l'Académie des Sciences*, Vol. CLXX, p. 1521, and Vol. CLXXI, No. 1, pp. 51-52. Paris, 1920.

Trioxymethylene when powdered is very useful in destroying Anopheles larvae. It is the formaldehyde fumes given off by the particles of the powder that react on the insects, as, if the fumes are dissolved in water after an exposure of a few seconds the powder becomes inactive. Therefore, it is only possible to count upon the efficacy of the remedy at the very moment of its application.

If the powder is in an inactive condition, or is ingested in too small a quantity, it does not kill the larvae, but on the contrary, renders, them immune to trioxymethylene. This rapid immunisation does not, however, last longer than a week, if the insects are once more under normal conditions. The powder must not be applied too frequently, and an interval of at least a week should be allowed to elapse between each application.

Even small doses, in the end, destroy the larvae almost infallibly, for their power of resistance being weakened, they fall a prey to their natural enemies, carnivorous insects, etc.

The effects of trioxymethylene powder upon Anopheles larvae are as follows: (1) Neurotoxic action soon causing total paralysis; (2) the preservation of the dead tissues, which are able to resist the attacks of putrefactive bacteria for some weeks.

830 – **"Ecole Supérieure" of the Rural Engineering in Paris.** — PATRIX, L. (Assistant Director, of the "Ecole"), in *Journal d'Agriculture pratique*, Year LXXXIV, No. 25, pp. 476-477. Paris, June 17, 1920. AGRICULTURAL INSTITUTION

The "École supérieure de Génie rural" was founded at Paris by the Decree of August 5, 1919, and opened on October 1 last. Its objects are: (1) To obtain recruits for the Corps of Rural Engineers which is under the Direction Générale des Eaux et Forêts, and was created by the decrees of April 5, 1903, and December 26, 1918; (2) to provide technical instruction for French, or foreign unattached students desirous of obtaining the diploma of Rural Civil Engineer.

The engineering students of the State Service are drawn from the students leaving the Paris National Agricultural Institute according to their place on the lists, and subject to certain conditions regarding the marks gained in various subjects. The unattached students are admitted to a competitive examination based upon the subjects taught in the agricultural and mathematical courses in the above-mentioned Agricultural Institute.

The instruction given in this École supérieure greatly exceeds the limits of what is commonly understood as rural engineering, which merely deals with agricultural machines and buildings.

In fact, it includes all the technical knowledge required of the engineer in matters relating to agriculture, and the centres of rural population.

Among the duties entrusted to the corps of Rural Engineers the author mentions: The agricultural utilisation of water; the irrigation, drainage, and reclaiming of land; the re-adjustment and exchange of small scattered holdings; the improvement of uncultivated land, marshes, peat-moors, salt-marshes, etc.; making country roads, bridges, foot-bridges, acqueducts, etc.; farm roads; various agricultural buildings; the construction of cheap houses for agricultural labourers and small farmers; rural industries (carpentry, etc.); the installation of co-operative factories; agricultural cable-ways, agricultural bascule bridges; supplying water to villages; the utilisation of waterfalls for the requirements of farms; rural hydro-electric installations and rural networks for the distribution of electricity.

The engineering course lasts two years. The instruction consists in class-teaching, lectures, and practical work carried out at the Station of Agricultural Hydraulics and of Rural Engineering, and is completed by excursions, visits to industrial establishments and residence. The courses and the lectures deal with the following subjects:

I. — *Course.* — Theoretical Analyses and Mechanics, Applied Mechanics, Hydraulics, Electrotechnics, Topography, Building and Construction, Canals, Roads, Bridges, Rural Jurisprudence and Administration.

II. *Lectures.* — Drawing plans; Officer work and Book-Keeping, Practical Work, Testing Materials. The Value of Property; its Valuation. Re-adjustment of holdings. Study of water storage and making mountain reservoirs, Rural Buildings. Motorcultivation, Agricultural Industries. General Comparative Agriculture.

The practical work consists in testing materials and machines, electrical engineering, making drawings and plans, etc.

Electricity, which is of ever-increasing importance in the economic field, is called upon to render the greatest services to agriculture and to transform the conditions under which the rural population live. Therefore, in order that the Rural Engineers may be authorities in the matter of electric plant, it has been decided that, during their second year, the students shall attend courses at the College of Electrical Engineering (*École supérieure d'Electricité*) and take the diploma of Electrical Engineer.

EXPERIMENTAL AND ANALYTICAL WORK

831 – **The Relation of Size, Shape and Number of Replications of Plots to Probable Error in Field Experimentation.** — DAY, J. W. (Oklahoma Agricultural and Mechanical College, Stillwater, Okla.) in *Journal of the American Society of Agronomy*, Vol. 12, No. 3, pp. 100-105. Lancaster., Pa., March, 1920.

Results of experiments obtained at Missouri Agricultural Experiment Station on a plot of approximately ¼ acre in extent situated on silt loam and apparently very uniform throughout. In the autumn of 1916, wheat was sown in 100 rows, 8 inches apart, and 155 ft. in length.

The following June, the wheat was harvested in 5-ft. row segments, and the yield of grain and of straw was recorded for each unit. There were, therefore, 3 100 units available for study. A calculation was first made to determine the direction in which the greatest variation in yield existed, both in and between the various rows ; followed by a study of the relation of size of plot to variation in yield.

From the results obtained, it is evident that by increasing the size of the plot to at least $^1/_{20}$ acre and probably much beyond, variation is reduced. The shape of the plot has also an important effect on variation that up to the present has been overlooked or misunderstood. More accurate results are obtained from long and narrow plots and the longer the plot the more accurate the result. Square plots or approximately square are to be preferred to long narrow plots that have their greatest dimensions in the direction of least variation.

The results from single plots are usually not sufficiently accurate to determine small differences between varieties or between fertiliser or cultural treatments. The use of a unit of comparison composed of systematically distributed parts, gives results much less variable than those obtained from an equal area in a single plot.

An increase in the number of replications of a plot of given size increases the accuracy of the results. When the number of replications remains constant, but the size of the plot replicated is increased, variation is reduced. The most effective replicated group from the point of view of shape, is one that is long and narrow, and has its greatest dimension in the direction of greatest variations.

832 - **Horticultural Exibition and Garden Competitions.** — Mulford, F. L. (Office of Horticultural and Pomological Investigations), in *U. S. Department of Agriculture, Department Circular* No. 62, pp. 1-38, figs. 12 Washington, Oct. 1919. EXHIBITIONS

The author who is associated with the Bureau of Plant Industry, United States Department of Agriculture discusses horticultural exhibits from the following point of view: Organisation ; competitors; classification; various kinds of shows; arrangement of exhibits and methods of judging (score card method) ; prizes ; rules (example are quoted). The author concludes by a brief survey of garden competitions, and gives also an outline of the schedule system advised.

CROPS AND CULTIVATION

833 - **Temperature and Humidity Associated with the Sirocco in Palestine.** — Georgii, W., in *Monthly Weather Review*, Vol. XLVIII, No. 1, pp. 40. Washington, D. C., Jan. 1920. AGRICULTURAL METEOROLOGY

The sirocco winds of south-west Palestine originate in the desert of Arabia and are most frequent during the spring and autumn, especially during April, May, September and October. The period during which this very hot wind blows is from one to three days, and sometimes even longer and completely neutralises the effects of the sea breezes.

The unpleasantness of the sirocco is due to the extremely low relative humidity, and to the subsequent rise at the conclusion of the wind.

The following data on temperatures and humidity cover a period lasting from May 9 to 20, 1916.

		Shelter temperature °C			Psichrometre						Relative humidity			Extreme temperature °C	
					Dri bulb			Wet bulb							
		7 a. m.	9 p. m.	2 p. m.	7	2	9	7	2	9	7	2	6	maxima	minima
		°C	°C	°C	°C	°C	°C	°C	°C	°C	°C	°C	°C	°C	°C
May	9	16.2	26.4	16.6	—	—	—	—	—	—	—	—	—	27.5	10.0
»	10	21.8	26.8	17.2	—	—	—	—	—	—	—	—	—	28.0	10.2
»	11	17.4	29.6	18.3	—	—	—	—	—	—	—	—	—	30.3	13.2
»	12	19.6	33.6	22.6	—	—	—	—	—	—	—	—	—	34.5	12.0
»	13	22.3	35.4	25.5	—	—	—	—	—	—	—	—	—	37.8	15.2
»	14	29.4	39.5	26.5	—	—	—	—	—	—	—	—	—	39.6	21.2
»	15	25.2	39.5	28.6	24.6	39.0	26.0	13.0	20.5	14.8	18	12	23	40.1	19.2
»	16	34.3	40.3	30.0	34.2	41.2	29.0	16.9	17.9	16.2	9	2	20	41.6	23.1
»	17	35.5	42.0	33.7	35.8	41.0	33.1	16.2	19.0	16.1	2	5	7	43.1	25.0
»	18	36,1	37.6	22.4	36.2	38.0	22.7	17.0	22,2	21.2	3	20	88	42.1	25.6
»	19	22.7	25.0	18.4	20.8	25.2	18.1	19.1	20.2	16.5	85	63	85	28.8	20.0
»	20	18.6	24.9	18.2	18.4	2.44	18.2	16.9	17.8	15.2	86	52	72	26.4	16.5

During the early part of May the temperatures were practically normal; the maximum lay between 26° and 29° C, and the minimum between 10° and 15° C. On the 11th however, the maximum reached 30.2° C which may be regarded as the first symptom of the approach of the sirocoo The sudden rise of temperatures during the morning of the 12th, was followed by temperatures which gradually mounted higher and higher until the 17th, the highest point of the sirocco, and the temperature remained above 30° C from 5 a. m. until 11 p. m From the commencement of the sirocco the relative humidity was very low but on the 18th and 19th it mounted very rapidly.

The sudden change of temperature and humidity has an evident unfavourable effect on both animals and plants.

834 – **Cultivation does not Increase the Rainfall in the Great Plains States.** — Smith, J. W. in *Monthly Weather Review*, Vol. 47, No. 12, pp. 858-860, figs. 2 Washington, D. C., Dec. 1919.

It has been the general opinion amongst the farmers in the Great Plain States that the amount of land under cultivation influences the rainfall increase.

The author refutes this idea after taking note of numerous records.

The average precipitation in the northern Great Plains during the period 1868 to 1917 is recorded as follows:

1868-1877	19.8	in.
1878-1887	20.4	»
1888-1897	18.6	»
1898-1907	19.5	»
1908-1917	19.1	»

In the Central Great Plains:

1868-1877	16.3 in.
1878-1887	20.4 »
1888-1897	17.6 »
1898-1907	20.2 »
1909-1917	18.2 »

The data with reference the southern and western States are analogous. There are well defined sequences of dry and wet years, but there has been no progressive increase or decrease.

Thanks to the spread of dry farming and to the cultivation of varieties particularly resistant to drought, the acreage of certain grain crops in the Great Plains States is on the increase, as shown in the appending table, with reference to barley, maize, oats and wheat in the States of Kansas, Nebraska, Dakota, and Montana, during the years 1867, 1882, 1892 and 1917.

	1867	1882	1892	1917
	Acres	Acres	Acres	Acres
BARLEY				
Kansas	90	8 000	56 000	300 000
Nebraska	89	62 400	36 000	85 200
Dakota	—	11 200	128 000	1 148 000
Montana	—	740	2 012	360 000
MAIZE				
Kansas	2 622	188 000	628 800	3 662 000
Nebraska	4 591	160 000	646 000	3 696 000
Dakota	—	56 000	—	1 576 000
Montana	—	196	432	32 000
OATS				
Kansas	2 622	188 000	618 800	913 600
Nebraska	4 591	160 000	646 000	1 235 200
Dakota	—	56 000	469 000	1 800 000
Montana	—	11 200	25 529	272 000
WHEAT				
Kansas	35 600	629 200	1.628 800	1 494 800
Nebraska	4 000	662 800	501 200	39 880
Dakota	—	288 000	2 164 000	4 286 400
Montana	—	17 124	16 704	690 800

Comparison between the data referring to the cultivated areas and the temperatures, indicates that the effect of cultivation on the total precipitation must be negligible.

835 – **Influence of Sun-Spots and Rain-Fall upon the Growth of Annual Rings in Trees.** — DOUGLAS, A. E. in *Skogsvårds Föreningens Tidskrift*, Year XVIII, Parts. 5-6, pp. 165-168. Stockholm, June, 1920.

The author gives the results of a series of experiments carried out by him on different trees, with a view to ascertaining whether any cor-

relation exists between the growth and thickness of the annual rings of their wood, and periods of unusual solar activity (sun-spots) and other meteorological factors.

The first researches bore upon *Pinus ponderosa* growing in Arizona, where the dry climate would allow us to presuppose the existence of some connection between wood development and rainfall. The data collected during 43 years fully justified this expectation, and revealed a very high and positive correlation between the two values, the driest season being characterised by the reduced development of annual rings.

In making these researches, the total rainfall from one autumn to another was taken into account, so as to group together all the values corresponding to the vegetative period of the tree (winter rainfall + summer rainfall.)

The correlation would be still higher, if the accumulated moisture were reckoned (in the algebraic sum of the annual deviations) from the normal rainfall, beginning from the commencement of the growth period up to the year (inclusive) for which the correlation is to be determined.

The thickness curve of the annual rings is practically the same in regions very distant from one another, as for instance Prescott and Flagstaff in Arizona. The author suggests the possibility of distinguishing meteorological zones from these differences.

The results first having proved clearly positive, the experiments were extended to other trees and other countries: *Pinus douglasii*, *Sequoia*, *Abies canadensis* (in North America) and various species of *Pinus* and *Abies* (in Europe.)

From the comparative examination of very numerous growth curves, it was possible to determine periods of different length, of which the greater number seemed in direct connection with sun-spots:

Length of periods in years	Multiples of 11 (average duration of a period of sun-spots)
5-6	1/2
10-13	1
21-24	2
32-35	3
100-105	9

The last and longest period is especially show by sections of *Sequoia* trunks from the Sierra Nevada. These trees were 3000 years old (maximum 3077). The triple period (32-35 years, 3 times the period of the sun-spots), recurred with great exactitude (with a displacement of 3 years in 400), in a trunk from north of the Arctic circle in Norway, and in another from Arizona.

A double period of sun-spots was observed, not only in *Sequoia* from the Sierra Nevada, but also in sections from the centre of Norway. Single periods were met with most frequently and were seen in sections of *Pinus ponderosa* (500 years old) from Arizona, in those of *Sequoia* and were

very clearly marked in material (*Pinus Abies*) from the Baltic regions (Prussia and Sweden). Finally, periods of 5-6 years were also distinguishable in trunks of *Pinus ponderosa* from Arizona, as well as periods of only two years.

The following table may give some idea of the connection existing between the growth of annual rings and the prevalence of sun-spots.

Growt of wood		Sun-spots	
Years	Length of the period in years	Years	Length of the period in years
1595–1665	11,0 ± 0,5	1615,5–1660,0	11,1 ?
1661–1677	16 ?	1660,0–1675,0	15,0
1677–1770	12,5 and 10,8	1675,0–1769,7	10,5
1770–1793	9,0	1769,7–1788,1	9,2
1793–1817	?	1788,1–1816,4	14,15
1817–1910	11,6; 21,0 and 7,3	1816,4–1905	11,08

The author tries to explain these relations by presupposing the existence of a correlation between sun-spots and rainfall. This theory is, however, far from being proved, and is in any case very complicated; thus for instance, in certain parts of Norway, the maximum development of the annual rings is found to coincide with the minimum occurrence of sun-spots, whereas generally the exact opposite is to be observed.

836 – **Relation of the Weather to the Yield of Spring Wheat in Manitoba.**— Connor, A. J., in *Monthly Weather Review*, Vol. XLVII, No. 12, pp. 848. Washington, D. C., Dec. 1919.

The author presents the results of a series of agricultural meteorological investigations on wheat conducted at various experiment Stations in Manitoba, Canada. In every case, the plots were as near the meteorological instruments as feasible in order to render it possible to make parallel observations, an indispensable feature in this kind of research work.

With a view to obtaining accurate records of the critical periods concerning the various factors or meteorological phenomena, the vegetative period of the plant was divided into periods, taking into account the more important phases in growth.

1) Date of sowing.
2) Appearance above ground.
3) Stooling.
4) Earing.
5) Flowering.
6) Milk stage.
7) Complete maturity.
8) Cutting.
9) Average height of the plants every 7 days.

According to statistical formulae the correlations between the yield in grain and the biological and meteorological conditions, some noteworthy results have already been obtained.

(1) Basing his observations on the " critical period " theory, the author quotes the following as the true explanation of these phenomena: If, in the earlier stages of the growth of the wheat the weather is cool or rainy, earing is delayed and the subsequent yield is heavy; but if, on the contrary, the weather is warm and dry, earing is hastened and the subsequent yield is light.

(2) With regard to the rainfall the pluviometric values are grouped in 3 periods of 30 days beginning 30 days preceding sowing. With the exception of the fourth period, which corresponds to the final stages in growth, namely the ripening stage period, when dry weather is essential, the effect of rainfall is invariably positive, with a maximum coefficient for the period which is correlated with the earing stage.

(3) With regard to the daily range of temperature, it appears that in all the monthly periods succeeding sowing, the coefficient was negative between this and the yield, with a maximum coefficient, in the third period of 5 ½ times the probable error.

(4) With regard to the mean daily minimum temperature: (1) The effect of this factor in the first and fourth periods after sowing is negligible; (2) the coefficient is negative, in the second and third periods, during which the temperature is lowered (compare with preceding values).

It can then be concluded that moisture and temperature are very important factors after sowing, but that in the first 60 days there is in Manitoba sufficient moisture and low enough range of temperature to prevent evaporation to a harmful extent.

With reference to temperature and rainfall, the coefficient became, on the contrary, constant and higher in the third 30 days after the sowing period. This is the critical period in Manitoba. If the cool and moist conditions continue, the yield will prove heavy ; if on the other hand it is warm and dry, the harvest will be light.

Taking the average date of sowing as April 25, the average time of the critical period may be fixed as the last week in June, and the first three weeks in July.

837 - **Climates of the British Empire Suitable for the Cultivation of Cotton.** — Brooks, C. E. P., in *The Meteorological Magazin*, Vol. LV, No. 651, pp. 37-39. London, April 1920.

Cotton is a sub-tropical plant which probably originated in the Eastern Mediterranean, but has become so throughly naturalised in the Southern States of America (" Cotton belt ") that they must be considered as having the most suitable climate for the commercial cultivation of this plant.

The cotton belt includes the States of Tennessee, Alabama, South Carolina, Louisiana, Texas and Oklahoma.

The essential features of a cotton growing climate are :

1) The mean annual temperature not below 60° F.

2) The mean temperature of the warmest month exceeding 80° F, or the mean of the three warmest months exceeding 77° F.

3) The interval without frost at least 200 days or more.

4) The annual rainfall not exceeding 60 in. and not less than 23 in.

5) Plenty of bright sunshine.

A dull and humid atmosphere is very unfavourable to growth of the cotton plant.

In the Cotton belt of the United States the rainfall lies between 23 and 60 in ; the mean annual temperature nowhere falls below 60° F, and the warmest month always just exceeds 80° F.

In the British Empire these conditions are met with in parts of India and in the West Indies, which are already important cotton producing centres.

Other colonies included in the same category are also here dealt with

Uganda. — Represented by Entebbe lies at an elevation of more than 3 000 ft. which effects obviously the equatorial temperature ; the temperature is rather below the specified temperature for the warmest month, but the uniformity both in temperature and rainfall throughout the year should enable cotton crops to be grown with some success.

Nyasaland. — Represented by Zomba at a height of 3 000 ft. The annal rainfall is 55 in. with a well-marked dry season. The summer temperature is nearly 75° F and cotton growing has already been tried with some success. On the lower ground near Lake Tanganyika and the Shire River it should do very well, and only lack of transport is against successful commercial cotton production.

Gambia. — Cotton should do well as an irrigated crop in the dry season. Bathhurst has a very suitable climate for the development of this plant, except for the length of the dry season, and the excessive rain in August.

Soudan. — Represented by Wan, has a very favourable climate for cotton ; in the drier parts, irrigation would, however, be necessary.

Nigeria. — The coastal regions of Nigeria (Lagos) appear to be too moist and rainy ; but, further inland, on the contrary (Zungern), conditions appear to be excellent.

Gold Coast. — The rainfall is very variable, but less than that of the Nigerian coast, and cotton should do well.

Rhodesia. — Similar climate to that of Zomba, and cotton should do well in the low lying parts of the colony.

British east Africa. — Consists of a low coastal region (Zanzibar) and the Kenia plateau (Nairobi). The plateau is too high with too low a temperature and in the coastal belt the rainfall is generally too heavy for cotton cultivation on a large scale.

Union of South Africa. — Hardly warm enough, sparse and irregular rainfall. Cultivation is only possible on the east coast, and in Natal.

Australia. — The Northern Territory is too wet, and the coast of Queensland seems more suitable. Further south, in New South Wales

and Victoria, cotton has been tried but with scarcely any success commercially.

In Western Australia, Egyptian cotton should be a success in the wetter districts but without irrigation the interior is too arid.

NEW GUINEA. — Probably a future source of supply. On the southern coast, the climate is very suitable, where a native cotton of good quality already exists.

The colonies such as Sierra Leone, Borneo, Fiji, Seychelles, British Honduras, Ceylon, Straits Settlements and British Guiana are in general too damp for the production of special quality cotton, whilst in Cyprus and Malta the rainfall is too sparse and irregular.

838 – **Effects of Drought in the Spring of 1919 on the Tea Districts in India.** — *The Tropical Agriculturist*, Vol. LIII, No. 5, pp. 305-308. Peradeniya, Ceylon, Nov. 1919.

In the first week of April 1919, towards the close of the drought from which the tea districts suffered, the following observations were made at the Experiment Station :

1) Unpruned tea showed very distinct signs of suffering and lost leaves in great quantity.

2) Pruned tea, on the other hand, was growing normally although the leaves produced were very small.

3) The water content of the soil at 9 in., deep was about 12 % water, while the subsoil at 3 ft. contained about 15 %. It cannot therefore be said that water was seriously deficient, but what factors influenced the obviously bad condition of the plantations left impruned, and the small size of the leaves of the pruned plants ?

During the period under consideration and especially during the first week of April, the atmosphere was both hot and dry ; conditions very favourable to transpiration. The unpruned tea possessed a leaf area with a rate of transpiration so rapid in relation to the water supply in the soil that the balance was upset, and the plants suffered by dropping leaves because unable to maintain the existing leaf area. On the other hand, with pruned bushes, the leaf area during the drought having been somewhat reduced, the transpiration was limited. In either case, the plants were subject to the same effect, namely the reduction of leaf area.

Certain suggestions are made with regard to effective conservation of moisture in the soil, to assist capilliary rise, and to encourage the growth of deep rooted plants.

SOIL PHYSICS, CHEMISTRY AND MICROBIOLOGY

839 – **Effect of Variation in Moisture Content on the Water Extracts of Soils.** — MARTIN, J. C. and CHRISTIE, A. W. (Division of Agricultural Chemistry, California Agricultural Experiment Station, in *Journal of Agricultural Research*, Vol. XVIII, No. 3, pp. 139-143. Washington, D. C., Nov. 1, 1919.

A knowledge of the effect produced on the water-soluble matter by variations in the moisture content of the soil is an important feature in connection with investigations of the water extracts of soils.

Two typical soils in the air-dry condition were studied : (1) silty clay loam ; and (2) sandy loam. No. 1 was brought to a moisture content of 10 to 25 % and No. 2, 5 to 20 %.

The moisture contents approaching the air-dry condition show a decided tendency to depress the nitrates and potassium in both soils, and the sulphates in the silty clay loam only. These depressions are reflected in the total dissolved material.

The excess water in the sandy loam soil causes a disappearance of nitrates and also decidedly decreases the potassium, calcium and magnesium, these losses also being reflected in the total solids extracted.

Considerable variations in moisture content of soils, provided the saturation point is not reached, do not appreciably modify the results obtained by the water extraction method, and consequently it may be concluded that the study of these extracts need not necessarily be limited to a narrow range moisture content.

840 – **Effect of Calcium Sulphate on the Solubility of Soils.** — Mc Cool, M. M. (Professor of Soils) and Millar, C. E. (Associate Professor of Soils, Michigan Agricultural Experiment Station) in *Journal of Agricultural Research*, Vol. XIX, No. 2, pp. 47-54, tables 8, Washington, D. C., April 15, 1920.

Additional information on the rate of formation of soluble salts in soils as affected by different factors is yet required, including one phase of the subject of special interest, namely, the immediate and residuary effects of fertilising materials.

Because of the experiences of the early agriculturists and the increasing interest in the fertilising value of calcium sulphate, and the widespread use of superphosphate which contains appreciable amounts of sulphate, the authors considered it advisable to investigate the effect of the calcium sulphate both alone, and in conjunction with calcium phosphate, on the formation of soluble salts in soils, as well as the effect on calcium dioxide production. The freezing point method was used to determine the former, and the titration method the latter. Six types of soil were studied : silt loam, sand, sandy loam, very fine sand, heavy silt loam, and silt loam.

The treatment with saturated solution of calcium sulphate caused a considerable increase in the rate of formation of soluble salts ; the same results were obtained a second time, and it is obvious that this treatment results in such changes in the composition of the soil mass, that a soil of different properties is formed. It seems therefore possible to alter the composition of the soil solution ; whether the effect will be favourable or unfavourable with regard to plant growth will depend upon the nature of the soil, and of substances added. Here is a phase of the subject which has not received sufficient attention in connection with field experiments.

Whilst the calcium sulphate increased the solubility of the various soils under investigation, the calcium phosphate decreased the rate of formation, and when used in conjunction with the former, it counteracted the effect of the latter to some extent.

The determination of the calcium dioxide, taken as a measurement of the biological activities does not always coincide with the total quantity of soluble substances formed ; the increase in the rate of formation of these substances brought about by the calcium sulphate treatment, should therefore be attributed mainly to other causes.

MANURES AND MANURING

841 – **Carbonates of Calcium and Magnesium in Relation to the Chemical Composition, Bacterial Contents and Productivity of Two Very Acid Soils.** — CONNER, S. D. (Associate Chemist in Soils and Crops), and NOYES, H. F. (Research Associate in Horticultural Chemistry and Bacteriology, Purdue University Agricultural Experiment Station) in *Journal of Agricultural Research*, Vol. XVIII, No. 3, pp. 119-125, pl. 2, bibliogr. of 8 works. Washington, D. C., Nov. 1, 1919.

Agricultural limestones so frequently contain large quantities of magnesium, that the question of the relative values of calcium and magnesium carbonates as neutralisers of soil acidity is of great practical importance. Many instances where magnesium has had detrimental effects have been reported.

In order to throw light on this question, the authors conducted pot tests on very acid soils of distinctly different types : silty clay ; and sandy peat, using natural carbonates, calcite, dolomite and magnesite, in varying amounts (4000 lb. to 12 000 lb. per million lb. soil), wheat, red clover, and turnip beets were grown in succession. After 10 months cropping under optimum moisture conditions, the soils were analysed for salts, nitrates, carbon, dioxide, acidity, nitrification, and both aerobic and anaerobic bacteria.

Although both soils originally contained twice as much magnesium oxide as calcium oxide, the calcite, dolomite, and magnesite produced good crop increases on both soils, with one exception, namely the 6-ton application of magnesite on the black sandy peat, which killed the crops. The best crop increase were obtained with carbonate applications which produced ratios of calcium oxide to magnesium oxide varying from 2 : 1 to 1 : 5.3 on the clay soil, and from 3.4 : 1 to 1 : 4 on the sandy soil. In the case which caused crop failure the ratio was 1 : 7.9 Wheat, red clover, and beets responded differently toward calcium and magnesium carbonates. With the medium applications, beets, were benefited more by magnesium carbonate, while wheat and clover gave a higher increase in yield with calcium than with magnesium carbonate.

Magnesite in every case, increased the concentrations of soluble salts in the soils more than calcite. Carbon dioxide determinations showed that the carbonates were not entirely decomposed at the end of one year, although the decomposition of the magnesite seems to have proceeded faster than that of the calcite. The magnesite produced more favourable conditions for nitrification than calcite. Magnesite thus encouraged the more rapid multiplication of both aerobic and anaerobic bacteria on the clay soil, more than the calcite, but on the sandy soil the reverse was evident.

The injurious action of the high magnesite application on the sandy soil is difficult to determine, as there appears to be insufficient data

to hand to ascertain if it is due to an unfavourable calcium magnesium ratio, or to a high concentration of soluble magnesium salts ; nevertheless, in view of the fact that the sandy peat still gave an acid reaction after the heaviest magnesite application, it is evident that the crop injury was not due to alkalinity. Moreover, the crop results do not point to any particular ratio between calcium and magnesium which could be called optimum for either crop or soil.

842 – **"Wool Waste" as a Fertiliser.** — SCHRIBAUX in *Comptes rendus de l'Académie d'agriculture de France*, vol. VI, No. 20, pp. 509-510. Paris, May 26, 1920.

The author communicates a statement by Dr. A. DE ROTSCHILD, dealing with the disadvantages entailed by the use of wool waste as a fertiliser. This substance is very cheap, it is true, but through its application, the soil may be contaminated with the seeds of two weeds, Spotted Lucerne (*Medicago maculata*) and Toothed Lucerne (*M. denticulata*) which are present in considerable numbers in the refuse.

M. SCHRIBAUX, Director of the Seed Testing Station, on being consulted by Dr. DE ROTSCHILD, stated that a sample of wool refuse treated with sulphuric acid, proved to contain 3.8 % of the seeds of these two varieties of lucerne. He also said, that 60 % of such seeds germinated, and that there were present, in addition, 20 % of hard seeds, viz., seeds which are inert owing to the impermeability of their integument, and which may germinate after an indeterminate time.

CONCLUSION : every metric ton of fertiliser contains therefore 38 kg. of seeds of which $38 \times 60 : 100 = 22.8$ kg. will germinate immediately These would cover the ground to the same extent as a crop of lucerne intentionally sown. Further, there will also remain in the soil hard seeds which may produce new plants of *Medicago maculata* for several years.

843 – **The Fertilising Value of Sewage Sludge.** — BRENCHLEY, W. E. and RICHARDS, E. H. (Rothamsted Experiment Station), in *Journal of the Society of Chemical Industry*, Vol. 39, No. 13, pp. 177-182. figs. 3. London, July 15, 1920.

The sewage sludges produced by the usual methods of tank treatment have never been highly valued as manure. Recently, two new methods of sewage have been introduced, viz. slate beds and activated sludge. Both these processes have been proved by the authors, to yield sludges which possess a definite manurial value.

An analysis of 3 samples from precipitation tanks gave the following results :

	Activated %	Slate %	Precipitation %
Moisture	7.26	55.65	37.67
Organic matter	76.72	20.76	24.81
Inorganic » (grit)	16.02	23.59	37.52
Nitrogen. — Calculated on sludges dried at 100°C.	7.09	2.63	0.89
Phosphoric acid	3.82	0.34	0.66
Potash	1.12	0.08	0.07

Pot experiments were carried out with poor soil first with barley, second with mustard, and comparisons were made between the results with sodium nitrate and the control. The results relative to the dry matter were as follows.

	% increase over control	
	I Barley	II Mastard
Sodium nitrate	51.12	473.4
Activated sludge	64.77	105.3
Ditto (6 equivalents)	91.74	939.7
Slate bed sludge (1/2 equivalent)	21.75	16.1
Ditto (1 equivalent)	31.80	79.0

It is evident that the activated sludge has a very real manurial value by reason of its relatively high content of available nitrogen as shown by the nitrification experiments compared with dried blood, the manures being added at the rate of 60 parts of nitrogen to 1 000 000 of soil.

	Nitrates: Parts per million of dry soil			
	At start	After 32 days	After 106 days	After 200 days
Soil only	7.3	10.7	17.5	16.8
Soil + slate bed sludge	7.3	18.0	33.1	33.2
Soil + activated sludge	7.3	32.3	56.0	60.9
Soil + dried blood	7.3	34.0	77.6	75.2

While in the second crop it is clear that dressings of slate bed and activated sludges had a certain residual value, it was not so marked as with sodium nitrate. According to the second table, however, the heavy dressing of activated sludge more than doubled the residual manurial value obtained with sodium nitrate.

The practical difficulty of drying the sludge containing 98 % of water as it comes from the settling tanks, has yet to be overcome, but activated sludge promises to become a valuable manure for the farmer and market gardener.

With regard to the slate sludge, this also has a definite manurial value. The process of sewage purification is hardly yet out of the experimental stage, and there are comparatively few sewage works of any size where slate beds are in use.

844 – **New Types of Basic Slag for Sale in the British Isles.** — The Rothamsted Experiment Station in *The Journal of the Board of Agriculture*, Vol. XXVI, No. 8, pp. 829-830. London, 1919.

There are distinct types of basic slag on sale in the British Isles which must on no account be confused.

1. BESSEMER slag, containing phosphoric acid equivalent to 40 % or more of tricalcic phosphate, largely soluble in 2 % citric acid: usually 80 % of the total is guaranteed soluble.

2. Basic "open hearth," containing less phosphoric acid, equivalent to 15 to 31 % of tricalcic phosphate, largely soluble (80%) in a 2 % citric acid, the first pourings being richer than the last.

3. *Idem*, made by the use of lime and fluorspar, containing as much phosphate as the poor grades of the preceding class, but only slightly soluble (20 % or less) in 2 % citric acid.

The first of these 3 types, the Bessemer slag is the fertiliser which for many years was well known to farmers as one of the most effective fertilisers for pasture land. The second and third types have come into prominence in recent years, especially during the war, as a result of changes in the method of making steel. At first sight these two new types do not appear very promising agriculturally, but field experiments have shown that they possess distinct value. Experiments conducted in 4 counties by 4 different experimentors demonstrated that the second type has proved substantially equal in fertiliser value to the old Bessemer slags, when compared on equal phosphate content. The 3rd type proved more effective than was at first assumed from their low solubility in citric acid (2 %). When the growing season has been sufficiently long, these slags have proved approximately as useful as the others, in spite of their low solubility.

With reference to the question as to whether the poor slags are worth as high a price as the rich, although it cannot be denied that the value of slag lies in other constituents apart from phosphates, it is safest however in accordance with present knowledge to adopt the plan of judging the new slags on their phosphatic content, that is to say, according to the unit system, and the degree of fineness. Having allowed for this, there is probably no justification for paying more for the 40% slag than for the others.

845 – **The Retrogradation of Superphosphates.** — Aita, A. in *Giornale di Chimica Industriale ed Applicata*, Year II, No. 5, pp. 227-233, Figs. 2. Milan, May, 1920.

The author gives an account of a series of experiments made at different dates and on several occasions upon certain superphosphates derived from different types of phosphorite. Samples in perfect condition and containing ferrous sulphate or ferric sulphate in different proportions, were kept for a long time at the temperature of the surrounding air, enclosed in bottles with ground-in stoppers. As soon as the mixtures were made, the following substances were estimated : Total phosphoric acid (solution in dilute aqua regia), phosphoric acid soluble in water and ammonium citrate, and that soluble in water according to the official method ; free phosphoric acid extracted by means of anhydrous ether ; compounds of iron and aluminum as oxides (total and water soluble). The progress of the process of retrogadation in the compounds was followed by means of analyses carried out over a whole year at fixed intervals. The following were determined : phosphoric acid soluble in water, in ammonium citrate, and in water alone, according to the official method ; free phosphoric acid, determined by extraction with anhydrous ether (the solvent being afterwards evaporated off), followed by precipitation with magnesia mixture ; iron and aluminium compounds (estimated as oxides) soluble in water. From the difference between the amounts thus

obtained and those found in the mixture directly they were made, the amount of the retrograded phosphoric acid was determined in the citric solution, and the aqueous solution, respectively (relative percentages), as well as the absolute retrogradation percentages, namely, those relating to the amounts found in each product from the time the mixture was made. The latter figures show the progress of the process more plainly.

From the results obtained, it would appear that the retrogradation of the superphosphates must not be attributed to physical causes, but wholly to chemical causes, and that it is the expression of the state of equilibrium which, in the course of time, is established between certain constituents of the product compounds of iron and aluminium, free, phosphoric acid, and monocalcic phosphate — as regards the amount of them present, and the relations existing between them. This way of looking at the matter thoroughly explains what has actually been observed as regards both the normal, and anomalous behaviour of the different superphosphates.

In fact, no retrogradation is observed in superphosphates from phosphorites from North Africa, even after having been stored for many months. In these phosphates, the content of oxides of iron and aluminium never exceeds 2 % and sometimes is below 1% For this reason, the superphospates made from them will contain from about 0.50 to 1 % of the said oxides, as against from 1 to 2 % of free phosphoric acid if they are prepared scientifically, that is to say, the proportion between the free phosphoric acid and the oxides is as 2 is to 1 — the lowest proportion permitting of the establishment of a definitive state of equilibrium. On the other hand, retrogradation is sometimes, but not always, found in superphospates made from the phosphorites of America and the Pacific Islands, which have an oxide content of from 2.5 to 3 %, and even more. It is evident that these superphosphates will, or will not be liable to retrogradation according as to whether, or not, the above-mentioned proportion between free phosphoric acid and the oxides exists.

In the technique of the manufacture of superphosphates, it is therefore of paramount importance to known the exact amount of iron and aluminium compounds in the phosphates to be transformed, in order to treat them in such a manner as to obtain a product with the right proportion between the free phosphoric acid and the oxides, and thus prevent retrogradation. This requires every precaution, and care must be taken not to go beyond certain limits, otherwise the product is lumpy, damp, and doughy; these physico-mechanical characters are due to the proportions of water and of free acid taken as a whole.

AGRICULTURAL BOTANY, CHEMISTRY AND PHYSIOLOGY OF PLANTS

846 – **Physiological Pre-determination: The Effect of Conditions during Germination, and in the Early Seedling Stage Upon Subsequent Growth and Final Yield.** — KIDD F., and WEST. C. in *The Journal of Applied Biology*, Vol. VI, No.1, pp. 1-26, figs: 3, pl. 1, Bibliography of 44 works. Cambridge, September 1919.

Evidence as a whole seems to show that the factors which influence the plant during its earliest stages of development, have a more or less pronounced effect upon the whole of its subsequent life history.

The authors undertook to study the predeterminating influence, and the present paper is a continuation of, preceding work (1) in connection with the effect of the conditions during germination and in the early seedling stage upon subsequent growth and final yield

Seed treatments were classified as follows:

I. *Physical treatments.* — Experimental work was carried out with seeds submitted to high and low temperatures, electrical discharge, and X. rays.

The chief point of importance notified was the fact that the effect of exposure to low temperatures was a very clear and distinct phenomenon. This confirms GASSNER'S investigations which had already showu that it was during the first few hours of germination that the "pre-determination phenomenon" can be most easily and quickly brought about by exposure to cold

II. *Chemical treatments.* (2) Experiments were made with seed soaked in various acid solutions; and other chemical agents such as copper sulphate, other salts; and hydrogen peroxide. Very little experimental work is on record with regard to the subsequent growth and yield of the plants produced from the treated seeds, but all available evidence supports the conclusion that where germination and early seedling growth are stimulated by chemical treatments, the subsequent growth and final yield are favourably influenced in proportion.

Normal plant-growth therefore falls into line with a « compound interest" law of development. Data obtained from growth experiments from plants or seeds deprived of part of their original food reserve, show that broadly speaking, the growth and yield of the resulting plants are proportional to their initial "food capital."

847 – **Experiment made with "Clumine" upon Wheat, Barley and Oats in the Experiment Field of Grotta Rossa (Rome).** — CUSUHANO, E., in *L'Italia agricola*, Year 57, No. 6, pp. 178-180. Piacenza, June 15, 1920.

Prof. LO MONACO, Director of the Institute of Physiological Chemistry of the Royal University of Rome, observed while studying certain asphyxiating gases, that they possessed the property of accelerating the germination of seed. He found, on growing various plants in nutritive solutions, that in the presence of these gases they germinated better, grew more vigorously, and gave a larger yield. He also obtained excellent results with Leguminosae and Gramineae cultivated in the open.

To this new fertiliser Prof. LO MONACO has given the name of "Clumine", and the author has made comparative experiments for the purpose of testing, the effects of "clumine" and other fertilisers. In the above-mentioned article he gives the cultural data, the analyses of the soils before and after the experiments, the crops obtained from manured and unmanured soils, as well as soil analyses and data referring

(1) See *R.* June 1917, No. 533; August 1917, No 717; *R.* Sept. 1917 No. 804.

(2) On the influence of water treatment on cereal seeds, etc. See *R.*, Dec. 1918, No. 1341; *R.* Febr. 1919, No. 177; *R.* Oct.-Dec. 1919, No. 1113. (*Ed.*)

to the crops obtained in different parts of Italy in the course of other experiments with the same fertiliser.

In the experiments carried out by the author at Grotta Rossa (Rome) "clumine" induced more rapid germination, and earlier ripening, (the manured plots being 3 days ahead of the unmanured), and al arger yield of grain (the increase bring 850, 765 and 280 kg. per h ctare in the cases of oats, barley and wheat respectively). Of the three applications of the fertiliser (50, 100, and 150 kg. per hectare), the intermediate amount had the greatest effect. "Clumine" does not exaust the soil, except in so far as it leads to a larger crop. Experiments made in other parts of Italy confirm these results.

The author has the intention of continuing his investigations, but from what he has so far been able to see, he is of opinion that the action of "Clumine" is complex In fact, it acts upon the seed by hastening its germination; it enables cultivated plants to get the better of weeds; it has an effect upon the organic and mineral substances present in the soil, rendering than more easily assimilated by the plants; and it is probable that it has a partial sterilising action upon the soil.

848 – **The Time Required for Chlorophyll to Develop its Maximum Colour Intensity in the Presence of Light.** — COUPIN, H., in *Comptes rendus de l'Académie de Sciences*, Vol. CLXX, No. 12, pp. 753-754. Paris, March 22, 1920.

As the author has stated in a recent paper (1), seedlings grown with insufficient, or intermittent light are of a pale green colour, whereas those exposed for a sufficient length of time to the light are more or less dark green according to the species and the organs taken into account.

In view of the latter fact, the question arises as to the minimum time necessary for the maximum depth of colour to be attained, but data on this subject are very scanty. With the object of solving this problem, the author exposed to the light some young etiolated seedlings (grown in spring water), and noted the time when their green colour ceased to become more intense (the changes in tint were observed by means of a scale of colours or, in a more practical manner, by comparing the seedlings with others that had already been growing for some days in the light). In this way, the author obtained the appended figures giving the minimum time (in days) necessary for the chlorophyll plastids to become saturated with chlorophyll.

Leaves: Winter vetch 1, sugar maize 1, wheat (var *hybride des alliés* 2, nasturtium 2, lentil 2, bean 2, haricot bean 3, American bean 3, Michaux pea 4.

Cotyledons: Lucerne 1, tomato 1, radish 1, scorzia 1, spinach 1, chicory 2, buckwheat 2, carrot 2, pumpkin 2, marvel of Peru 3, dittander (*Lepidium latifolium* L.) 3, sunflower 4, haricot bean 4 (?), red castor plant 4 (?), American bean 4, white lupin 5.

Hypocotyl axes: Radish 3, sunflower 4, dittander 4, scorzia 4, pumpkin 4, white lupin 6, carrot 6, haricot bean 6, buckwheat 7, lucerne 8, marvel of Peru 10, tomato 14, chicory 15, spinach, red castor plant, and American bean did not become green.

Stalks: Nasturtium 4, bean 5, winter vetch 6, Michaux pea 7.

(1) See *R.*, April 1920, No. 400. (*Ed.*)

The above figures were obtained in Paris, during January and February (diffused light and northern exposure) ; during these months, the daylight is weak, and only lasts ten hours.

The figures only apply to plants grown under these conditions, but they give an idea of the extent of the question, and the manner in which different plants behave. No general conclusion can be drawn from the experiments, but the following remarks, which might *a priori* have been expected, have been elucidated, and are worth recording :

(1) The green colour of cotyledons and leaves does not take very long (1-5 days) to reach its maximum intensity.

(2) Hypocotyl axes and stalks take a rather long time (3-15 days) to assume their maximum colour.

(3) The green colour of the different organs of the same plant does not reach its maximum intensity in the some time

(4) In some cases, this maximum colouration is not reached (under the existing conditions during the experiment) before ten hours' exposure to light.

849 – **Carbohydrate Metabolism in Green Sweet Maize During Storage at Different Temperatures.** — APPLEMAN, C. O. and ARTHUR, J. M. in *The Journal of Agricultural Research*, Vol. XVII, No. 4, pp. 137-152, figs. 2, tables 5. Washington, D. C., July 15, 1919.

Report of work carried on at the Maryland Agricultural Experiment Station with a view to studying the character and kinetics of the processes involved in the rapid depletion of sugar in green sweet maize after it is separated from the stalk and more particularly with the relative rates of these processes at different storage temperatures, accurately controlled.

The authors devised a method by which the rate of sugar loss from the green sweet maize could be determined for consecutive 24 hour periods of storage, by comparing analyses of grain from the same ear. The Stowell Evergreen variety was used for these investigations; this was picked in the typical milk stage (water content approximately 80 %), that is to say, the best edible stage.

The depletion of sugar in green sweet maize after it is separated from the stalk does not proceed at a uniform rate, but becomes slower and slower, until finally it ceases, when the initial total sugar has decreased about 62 % and the sucrose about 70 %. Calculated on the basis of original moisture, the maize contained when the depletion of sugar ceased, approximately 1.5 % total sugar as inverted sugar, 0.7 % sucrose, and 0.8 % free reducing substances. The reversibility of the chief processes involved in the sugar depletion, resulting in an equilibrium between the rate of sugar loss, and the rate of sugar formation, would account for the cessation of actual sugar loss.

The raising of the temperature hastens the attainment of the equilibrium positions, which seem to be about the same for all temperatures. At 30° C, 50% or most of the total sugar loss occurs during the first 24 hours of storage. During the same period 25 % is depleted at 20° C, and at 10° C, (a refrigerator temperature,) only about 15 % is depleted.

The rate of the sugar loss, until it reaches 50 % of the initial total sugar and 60 % of the sucrose, is doubled for every increase of 10° C up to 30° C.

Respiration in green maize is comparatively high when the maize is first picked, but falls off rapidly with prolonged storage. This, however, only accounts for a small part off the actual decrease in the percentage of sugar in the maize during the consecutive 24 hour periods of storage, even at 30° C. One ton of husked green sweet maize during the first 24 hours of storage at 30° C would lose approximately 3.2 lb. of sugar on account of respiration. Respiration may become indirectly a more important factor in accelerating the depletion of sugar by raising the temperature on the inside of the large stacks of green maize.

Most of the decrease in the percentage of sugar in green sweet maize is attributed by the authors to condensation of polysaccharides, chiefly starch.

850 – **Researches on the Ripening of Cereals.** — LUERS, H. (Mitteilung aus der deutschen Forschungsanstalt für Lebensmittechemie in München), in *Biochemische zeitschrift*, Vol. CIV, Parts. 1, 2, 3, pp. 30-81, figs. 1. Berlin, 1920.

Our knowledge of the processes taking place during the ripening of cereals is very limited. The experiments hitherto effected have either been made for the purpose of studying the vegetative development or the complete maturity of the plants, or else were carried out by incomplete and defective methods. The sole exceptions were the researches of SCHIERING and of SCHULZE, who studied the nitrogenous substances present during the ripening period.

The author has attempted to follow, by means of analyses, the variations in acidity and amido-nitrogen content observable from the first yellowing of the ears, till their complete maturity as well as during storage. He chose these two methods of determination, as similar analytical methods had been used with success in other fields of investigation.

In determining the amido-nitrogen, the author followed, with some slight modifications, SORENSEN'S formol method. When estimating the acidity he adopted SORENSEN'S colorimetric method, titrating the acid during the same experiment with two different indicators (neutral red and phenolphtalein). The author thsu determined the amido-nitrogen and acid content of different samples of barley, wheat, oats and rye, from the last stage of the yellowing of the ears, until complete maturity, and also after two months' storage. He found that the acidity and the substances that could be titrated with formol greatly decrease during the period between the last stage of the yellowing of the grain and its complete maturity and diminish less after the grain is stored. This diminution was more marked in samples furthest from a condition of equilibrium, that is to say, from germination-maturity. The reason of the decrease in both these classes of substances is to be sought in the fact that the acids combine organically, whilst the amido compounds condense to higher complexes. It may also be deduced from these results that during the ripening and storing of grain, many changes take place in the enzymatic conditions.

Other experiments have shown that desiccation promotes the maturation of cereals, not on account of the loss of water, but owing to the stimulating effect heat, which is connected with the kinesis of intraseminal reactions.

The above mentioned experiments were made on samples of crops from a normal year, 1918; further investigations will be necessary for years that are meteorologically abnormal. From what has already been observed, it is possible to make some deductions, however, even as regards abnormal years, such as, for instance, 1904 and 1911, when the green barleys, by their incomplete ripening caused much trouble in Germany in the manufacture of malt and beer. The data already obtained would seem to show that the premature drying of the grain arrests the processes of transformation, and the building up of more complex molecules. The immature condition of the grain is shown by the presence of considerable numbers of simpler molecular structures belonging to pre-existing substances. These abnormal conditions also influence other factors; thus there is no doubt that the bread-making qualities of a flour depend, to a great extent, upon the ripeness of the wheat.

PLANT BREEDING

851 - **Wheat Varieties from the Rieti "Stazione di Granicoltura" The "Varrone Variety"** — STRAMPELLI, N., in *Italia Agricola*, Year 57, No. 5. pp. 146. pl. 1. Piacenza, May 15, 1920.

This is the type known as No. 92,000 202 4413; it belongs to the numerous types obtained by the cross Rieti × Wilhelmina Tarwe.

Ear: is white, its average density is 23. The number of fertile spikelets varies from a minimum of 21 to a maximum of 25 (average 23 per ear).

Spikelets: from 3 to 4 fertile flowers, and the number of caryopses varies from 52 (minimum) to 85 (maximum). The average per ear is 65.

Glumes: oval, inflated, slightly truncated; very short triangular beak bearing at its base 2 short, light reddish-yellow ribs similar to the median rib.

Paleae: oval, surmounted by short, scarcely perceptible awns (1-2 mm) on the lower portion of the ear, but becoming larger (3 to 15 mm.) on the upper part. They are more marked on one side of the ear than on the other; the most marked ones grow in the direction of the axis of the paleae.

Seed: oval, slightly convex and asymmetrical, with broad, very open ventral suture; lobes triangular in section. They have a characteristic long furrow on the back. Average length 7 mm., width 3-7 mm., dorso-ventral maximum 3 06 mm. Colour yellowish-white. Fracture starchy. weight of 1000 seeds 53.43 gm.

The *culms* are from 1.40 to 1.50 m. in height, but they do not lodge.

Tillering good.

The "Varrone" variety *ripens* rather late — at the same time as "Carlotta Strampelli", but in good years, it is capable of producing a still larger crop than the latter. In 1918, the yield of "Varrone" wheat was as much as 46.2 quintals per hectare.

852 - **Improvement of Native Wheat Varieties by Means of Selection, in Bulgaria.** — Ivanov Iv., in *Zemlediclie*, Year XXIV, Pts 4-5, pp. 66-72, Sofia, April, 1920.

The improvement of cultivated plants by means of selection and hybridisation has contributed greatly to increase the yield, especially in the case of cereals.

The Table given below shows the average data for the period 1907-1912 in Svalöf (Southern Sweden), concerning wheat only.

The new varieties give a yield, at the rate of 20 to 40 % higher than the native varieties.

From a series of comparative cultural experiments with new and old varieties of wheat, rye, barley and oats, conducted under the control of the German Agricultural Society, data have been obtained which prove the part played by selection in the increase of crop yield. Table II shows the average yield in kg. per hectare for the various crops.

	Yield of grain kg. per hectare	Relative % of prodnctivity with deference to *native Swedish*
No. 08o1	4 577	140
Sol	4 334	133
Extra Squarehead II	4 318	129
Grenadier II.	3 958	121
Native Swedish	3 221	100

	Wheat	Rye	Barley	Oats
New varieties	3 130	2 280	2 670	2 770
Old »	2 550	1 910	2 260	2 550
Variation in yield	580	370	410	280

The surplus yield obtained, thanks to the adoption of new varieties and types, is thus raised by a minimum of 280 kg. for oats and 580 kg. for wheat.

With regard to Bulgaria, little has been done up to the present. The introduction of selected exotic types has not so far given good results with the exception of the "Noé" wheat variety, which was inferior to the native varieties during the two somewhat trying seasons of 1917 and 1918. The German wheats of the Squarehead type and, usually, the types coming from the north or from maritime regions do not readily adapt themselves to the special climatic or other conditions prevalent in Bulgaria owing to the length of the vegetative period. The late types which at the end of June and the beginning of July are still at the milk stage, suffer from scorching and produce a low yield of inferior quality.

This points to the conclusion that only new varieties can safely be introduced, which originated in countries with a climate similar to that of Bu garia, if good results are to be expected. Therefore, local selection and breeding is obviously most suitable, especially in Bulgaria, where the local varieties are far from being pure and possess the characteristics of a mixed population consisting of a collection of different individual characteristics. In such cases simple, pure line selection, by means of isolation and propagation of the best varieties, will lead to excellent results. Work of this kind was begun at Rusa, at the Agricultural Experiment Station, in 1911, special attention being paid to the local wheat and the Rasgrad wheat.

The results so far obtained are very satisfactory, as may be seen from the following Table :

	Surplus yield obtained from the original non-selected variety	
	kg. per hectare	%
Local selected wheat var. No. 13.	200	20
» » » » No. 11.	230	21
» » » » No. 83 (white ears)	35	22
» » » » No. 16.	68	48

The surplus yield is thus 200 to 680 kg. per hectare (20 to 48 %).

The cultural tests conducted at the Station in 1919 on a sufficiently large area and under the most uniform cultural agro-geological and topographical conditions, etc., possible, confirm the superiority of the selected types. In the Table, the data take also into account the resistance to rust and lodging, following an empirical scale of value 1-4 (1 = very resistant ; 2 = good ; 3 = fair ; 4 = poor).

	Yield of grain per hectare kg.	Weight per hl. kg.	Weight of 100 grains + gr.	Degree of Resistance	
				to lodging	to rust
1. No. 84 (with white ear *selected*)	3 630	79.9	39.6	1	1–2
2. No. 83 (d.°)	3 400	79.7	34.2	1	3
3. No. 16 (with red ear *selected*)	3 320	79.2	40.3	1–2	2
4. No. 14 (d.°)	3 170	80.5	—	4	3–4
5. No. 1 (d.°)	3 070	79.1	—	4	3
6. No. 7 (d.°)	3 010	80.6	45.5	1	3
7. Red de Rasgrad (non selected)	2 620	79.3	37.8	4	4
8. Local var. (non selected)	2 470	79.4	38.7	4	4

The highest yield obtained was given by No. 84, with 3630 kg. per hectare : followed by Nos. 83, 16, 14, 1 and 7, Rasgrad wheat, and the

last on the list was the native non-selected variety, which gave only 2470. The Table given below brings out the comparison even more clearly.

	Surplus. Kg. of grain per hectare		Relative productivity	
	Rasgrad	Local var.	Rasgrad = 100	Local var. = 100
No. 84	1 010	1 070	138	147
No. 83	770	930	129	138
No. 16	770	850	127	134
No. 14	550	700	121	128
No. 1	450	600	117	126
No. 7	390	540	115	122
Average	640	800	124	132

The superiority of the new varieties obtained by selection is therefore obvious, as much by the yield as by other characteristics such as weight and size, resistance to rust and lodging.

For the various varieties considered individually the following may be taken as the most outstanding characteristics :

No. 84 : white ear awned ; derived from an ear gathered at Kinseleri, in the Dobrié district.

No. 83 : white ear.

No. 16 : red ear, awned ; originated at Azienez, near Rasgrad.

No. 14 : coloured ear, awned.

No. 1 : coloured ear, awned.

No. 7 : coloured ear awned ; characterised by resistance to lodging.

The results obtained encourage future prospects and the possibility of extending and intensifying the work of selection.

The Bulgarian Agricultural Society, in the same way as the Society of German Farmers, should be able to collaborate for the purpose of distributing good quality seed, by establishing more experimental plots in the various districts, with a view to the discovery of the newly introduced varieties that are the best adapted to the local conditions of soils and climate.

853 - **Selection of Rice Varieties at the Rice-growing Station at Cantho, Cochin-China.** — ROBIN, J., in *the Bulletin agricole de l'Institut Scientifique de Saïgon*, Year II, No. 6, pp. 185-189. Saïgon, June 1920.

The method of selection so far adopted at the " Station Rizicole de Cantho " (connected with the Genetics Laboratory of the Scientific Institute of Indo China), resembles very largely that employed by VILMORIN to obtain select lines rather than the Buitenzorg methods.

A choice was first made of the 100 best plants of the variety that was to be selected. These were classified according to the number of ears and then the grains were weighed seperately for each plant.

The 10 at the head of the list, viz., those weighing the heaviest and having the largest number of ears, were sown separately; the plants pricked out one by one at 6.8×6.8 produced the second generation.

Each line was classified according to the number of ears and the 15 or 20 best of each line were weighed.

To avoid the multiplication of an indefinite number of lines which would necessitate unending labour and greatly increase the possibilities of error, owing to the impossibility of following them up closely, the investigations were limited to 10 per variety or lot.

The 10 plants chosen were selected indiscriminately from the 10 lines under consideration; the inferior quality lines were thus eliminated gradually, whilst the superior quality lines were more and more brought to the fore.

In spite of this elimination, there remained (in 1920) 16 varieties each consisting of 10 lots of 15 plants; i. e., $150 \times 10 \times 16 = 24\,000$ plants, whose ears must be counted, sorted, and shelled, whilst 3200 plants must be weighed in order to obtain the 160 parent plants for the year following.

The results thus obtained have been very encouraging

SELECTION OF THE PHUNG-TIEN VARIETY AT THE RICE-GROWING STATION AT CANTHO. — This rice, originating from Bentre, was received at Cantho in 1916 with the following information:

Variety	Phung-Tiên
Weight per hectolitre	57.14 kg.
Weight per 1000 grains	0.275 kg.
Percentage of red grain	3 %
Shape of grain	medium length
Colour	pale yellow
Growth period	157 days

After receipt of the seeds, these were sorted by hand, and blemished or undersized seed eliminated.

The first crop gave 80 l. of seed weighing 48.4 kg. viz., 60.5; kg. per hectolitre.

The seed was sown and the seedlings once more pricked out. One of these plots (No. XII) gave particularly successful results, and 150 fine plants were chosen therefrom and classified according to the number of ears; the 10 best were sown separately to be transplanted later for plant breeding purposes.

The 10 selected plants possessed the following characteristics:

	(1) 1	2	3	4	5	6	7	8	9	10
ears	32	29	29	28	29	25	26	26	25	25
Weight of grain (in gm.)	136	130	127	113	110	110	108	105	95	90

(1) The numbers indicate the number of each generation. (*Ed.*)

Lines obtained (average).

	1	2	3	4	5	6	7	8	9	10
Ears	16.6	16.1	16.1	18.9	19.5	21.1	20.8	22.7	21.7	18.4
Grammes	68.0	63.1	56.1	63.1	57.5	67.6	75.0	87.0	75.1	71.1

The 10 best plants retained were :

Line	(9)	1	20	ears	118 grammes
»	(9)	2	27	»	118 »
»	(8)	3	37	»	109 »
»	(1)	5	30	»	103 »
»	(0)	6	20	»	100 »
»	(8)	7	24	»	99 »
»	(8)	8	20	»	94 »
»	(7)	9	28	»	92 »
»	(8)	0	20	»	92 »

This selection confirms previous results seeing that the highest average, No. 8, gave 4 plants ; next comes No. 9 with 2 plants, and Nos. 1, 6, 7, and 10 with one plant only.

Nos. 2, 3, 4 and 5 pass directly to the lines. The descendants of this generation gave on an average :

	91	92	83	14	65	06	87	88	79	80
Ears	25.2	30	29.6	25.9	28	24.3	29.4	28.8	28.7	27.7
Grammes	105.6	101.9	97.4	91.8	90.8	101.2	120.2	100.3	109.9	103.3

Line 87, the best of the lot, gave 3 plants, and line 91, 2.

The 10 husks chosen were :

	791	922	873	874	875	916	147	068	609	910
Ears	42	52	35	30	29	28	27	27	35	2
Grammes	206	162	162	154	140	138	138	135	134	12

Their descendants gave on an average :

	791	922	873	874	875	916	147	068	659	910
Ears	26.3	25.5	27.2	27.3	27.8	25.4	27.9	28.4	29.9	25
Grammes	104.1	104	107	104.1	112.1	109.6	122.6	107.5	106	104.

The better lots, 147 and 865, each gave 2 female parents ; lots 791 and 922 were the only ones which gave nothing and passed on into the lines.

The ears chosen for 1920-1921 are :

	0681	9102	8753	1474	8735	8756	8747	9168	6599	1470
Ears	45	55	42	36	39	37	38	30	33	32
Grammes	260	258	246	232	220	204	182	180	172	170

The following table shows the improvement obtained.

	Lines average		Average Plants per 10 husks		Husk No. 1 for each generation		Husk No. 10 for each generation	
	Ears	Grammes	Ears	Grammes	Ears	Grammes	Ears	Grammes
1916–1917	—	—	25.4	103	32	136	25	90
1917–1918	19.19	68.36	27.4	112	20	118	20	92
1918–1919	28.76	102.24	32.7	149.8	42	206	22	129
1919–1920	26.66	108.69	38.7	212.4	45	200	32	170

Careful examination of the descendants indicates the same ears sequence of progress :

1st generation . . .	No. 0	25 ears	90 grammes	No. 9	25 ears	95 grammes
2nd » . . .	No. 06	20 »	100 »	No. 91	20 »	118 »
3rd » . . .	No. 069	27 »	135 »	No. 910	22 »	129 »
4th » . . .	No. 0681	45 »	260 »	No. 9102	55 »	258 »

1st generation . . .	No. 8	25 ears	105 grammes	No. 1	32 ears	136 grammes
2nd » . . .	No. 87	24 »	99 »	No. 14	28 »	105 »
3rd » . . .	No. 875	29 »	140 »	No. 147	27 »	138 »
4th » . . .	No. 8753	42 »	246 »	No. 1474	36 »	232 »

These two last tables indicate a decrease after the first generation, and then a regular continuous increase.

Theoretical Yield. — The yields do not include all the crops obtained per hectare.

All the lines give (at the rate of 62 500 plants per hectare) :

Season 1917–1918 : — 0.06836 kg. × 62 500 = 4272.5 kg.
» 1919–1920 : — 0.10865 kg. × 62 500 = 679.625 kg.

and the best plant will give : — 0.260 kg. × 62 500 = 16 250 kg. — the 1917 crop produced only 2967 kg. from the best plot (No. XII).

It is essential that exceedingly favourable conditions prevail if a yield of 400 kg. per hectare be expected at the Rice-Growing Station at Cantho (1).

The theoretical yields tend to demonstrate the actual improvements.

Tillage. — Tillage depends on the improvement of the variety and also to a considerable extent on conditions more or less favourable to growth.

Number of ears per plant	1 to 5	5 to 10	10 to 15	15 to 20	20 to 25	25 to 30	30 to 35	35 to 40	40 to 45	45 to 50	50 to 55
Number of plants:

2nd » . . .	16	270	**480**	397	191	62	11	5	0	1	1(52)
3rd » . . .	12	132	383	**408**	177	22	8	4	3	0	1(55)

On working out the biometric curves corresponding to the figures given in this Table, it will noticed that the position of the summit has moved from left to right.

854 – **Researches on the Genetic Composition of Certain Types of Peas** — KAJANUS, B. and BERGS, S. O., in *Arkiv för Botanick*, Vol. XV, No. 19, pp 1-18, Stockholm, 1919.

An account of the results of a series of crosses made with the object of studying the genetic constitution of *Pisum*. In the crossing experiments, the 4 following types, which represent 4 pure lines, were used:

TYPE I. — Flowers white; stipules colourless; seeds of average size, perfectly smooth, seed-coat without pattern (retrogression of colour); hilum white; cotyledons yellow.

TYPE II. — Flowers light red; stipules red; seeds of average size, smooth; seed-coat light-brown, grey-green, light-green, without pattern; hilum brown; cotyledons yellow.

This type was obtained from a plant with red flowers and light brown seeds which appeared in 1913 at Weibullsholm, in a field of Danish peas (Suedinge).

TYPE III. — Flowers dark-red; stipules dark-red; seeds large and somewhat wrinkled; seed-coat dark-red to brown, without pattern; hilum black; cotyledons yellow.

TYPE IV. — Flowers dark-red; stipules dark-red; seeds of average size, almost smooth; seed-coat grey-green to light-brown with purple clots and dark-brown mottling; hilum black; cotyledons yellow.

(1) Concerning the yields obtained in the Far East compared with those obtained in Europe (especially in Italy). See No. 861 of this *Review*. (*Ed.*)

With these 4 types the following 5 crosses were made :

Type I ♀ × Type II ♂ ; Type I ♀ × Type III ♂ ; Type I ♀ × Type IV ♂ ; Type II ♀ × Type III ♂ ; Type III ♀ × Type IV ♂.

The following characters were taken into account : colour of flowers and stipules, ground colour and pattern of seed-coat, colour of hilum.

These characters seem to depend upon 6 factors indicated by the letters R, G, O, P, M, and S.

R. — This factor, both in the homozygotic RR and in the heterozygotic Rr, determines the light-red colour of the flowers, the more or less light-brown colour of the seed-coat, and the brown colour of the hilum.

Plants of the constitution rr possess white flowers, white seedcoat, and in absence of S, also a white hilum.

G. — This factor when alone, has no perceptible influence, but when combined with R, it gives rise, both in the homozygotic and heterozygotic conditions, to dark-red flowers, a well marked grey-green seed coat sometimes with purple dottings, whereas the colour of the hilum remains unchanged ; rr gg seeds are, as a rule, indistinguish able from rr GG seeds.

O. — This is an inhibiting factor that, in the homozygous and heterozygous conditions alike, suppresses the brownish-red or dark-red of the seed-coat ; in oo seeds the cuticle is if this colour, but only when R, is also present ; in the absence of G, the hilum of oo seeds is blood-red.

P. — Both under homozygotic and heterozygotic conditions, this factor produces very distinct dark purple dottings. Very often this colouration extends to a large part of the cuticle, which sometimes may be entirely purple.

In oo seeds, the presence of P causes the purple part to assume a black hue, and become very clearly marked off. In oo seeds in which the purple colour is diffused, the colour appears uniformly black.

M. — Both in a homozygotic and in a heterozygotic condition, this factor causes dark-brown mottling of the seed-coat. When P and M are present at the same time, they produce brown patches and lines, purple eyes and dottings situated close together, and sometimes superposed.

In oo seeds with M, the mottling is very indistinct.

S. — Determines the black colour of the hilum.

By analysing the offspring of these crosses, the following genetic constitution is obtained for the 4 above mentioned types.

Type 1 — *rr* G G O O *p p m m s s*
» 2 — R R *g g* O O *p p m m s s*
» 3 — R R G G *o o p p m m* S S
» 4 — R R G G O O P P M M S S.

856 – **The Possibility of the Transmission of Certain Characters of *Papaver somniferum*** — KAJANUS BIRGER, in *Arkiv för Botanik*, Vol. XV, No. 18, pp. 1-87, Parts I-III. Stockholm, 1919.

The author given the results of a series of investigations undertaken with a view to determining the genetic constitution of *Papaver somniferum*, especially as regards the following characters: Double and single flowers; petals entire or emarginate; colour of flowers; green striping of petals.

DOUBLE AND SINGLE FLOWERS. — As a rule, the single form is dominant in respect to the double. In only one case out of 27 crosses was the opposite observed in the F_2 of simple × double flowers, which numbered 104 individuals, including 72 double, and 32 simple according to the Mendelian ratio, 3 : 1

The author suggests the following scheme:

P: E E single × *e e* very full
F_1: E *e* from single to fairly full
F_2: 3 single-nearly full: 1 very full.

EMARGINATE PETALS. — Two factors influence the dividing of the petals: S. determined it, while G inhibited it. The possible formulae of homozygous individuals with petals with entire borders would be: GG SS GG ss or gg ss. where the formula of the individuals with emarginate petals would be gg SS.

In the heterozygotic condition G tends to over-rule S, hence the forms are entire, or slightly indented. The scheme is as follow:

P: G G *s s* entire × *g g* S S indented
F_1: G *g* S *s* entire to cut.
F_2:
1 G G S S entire
2 G G S *s* »
1 G G *s s* »
2 G *g* S S cut-entire
4 G *g* S *s* entire-cut
2 G *g s s* entire
1 *g g* S S indented
2 *g g* S *s* indented-cut
1 *g g s s* entire

COLOUR OF THE FLOWERS. — All the shades and variations of colour which occur so frequently in the flowers are due to two fundamental colours, red and purple, which are determined by two genetic factors termed by the author, R and V respectively. As regards the distribution of the colour, two regions are to be distinguished, the border and the central spot. The relative development of these two regions, even when the colour is the same, may give rise to different colour effects.

Each of these factors R and V is always regularly dissociated in F_2 according to the scheme:— 3 purple : 1 not purple and 3 red : 1 not red. The colour produced by these determinant factors is, however, far from being uniform, and varies from light-red to scarlet, and from pale violet to deep purple in the same hybrid generation, and under the

same conditions of soil and exposure. This may be explained by the presence of two intensifying factors that alone would have no effect, but which, added to the fundamental factors R and V have the power of intensifying the colours. The deepest colours are always dominant as regards the palest ones.

GREEN STRIPING OF PETALS. — In 1912, in a group of poppies of the " Bride " variety with single, white, emarginate petals, there appeared one individual with petals striped with green. By self- fertilisation, offspring were obtained consisting entirely of individuals with petals striped with green. By crossing, striped and white hybrids were obtained in the ratio of 3 : 1 in the F_2.

Supposing the existence of a factor U that inhibits green stripes and indicating its absence by u we have the following scheme :

P : U U un-striped × *u u* (emarginate) striped
F_1 : U *u* without stripes, or with very faint stripes
F_2 : 3 un-striped, or slightly striped : 1 (strongly) striped.

The author has been able to discover the existence of special factors for the following characters : White stripes ; polycarpy and concrescence of sepals. The data obtained are, however, not sufficient for it to be possible to determine exactly in what manner these characters are transmitted.

57 - **Colour-Changes in Flowers Connected with Sex in Some *Dianthus* Hybrids.** — BLARINGHEM, L., in *Comptes rendus des Séances de la Société de Biologie*, Vol. LXXXIII, No. 20, pp. 892-893. Paris, June, 1920.

From *Dianthus barbatus* L., there have been obtained, by means of crossing and selection, numerous ornamental varieties with flowers varying in colour from blackish-brown (var. *nigrans*) to white (var. *candida*), as well as others with mottled, spotted, striped, and parti-coloured blossoms. In some individuals, their hybrid origin is betrayed by mosaic dissassociation phenomena.

The author carefully studies the characters of a plant that, in 1919 and 1920, produced floral shoots bearing both red and white flowers. Thus on one branch, there were 10 white flowers in violent contrast to 10 bright red ones, and it was only by very attentive examination that the gradations of colours could be distinguished : 5 yellowish-white, 4 white inclining to pink, 6 bright-red, and 9 flame-coloured. In spite of the contrast between the colours and contrary to what occurs in cases of mosaic inheritance, all the flowers, as they grew old, passed from one colour to the other.

The colour changes are a function of the sexual evolution of each flower. *Dianthus barbatus*, is hermaphrodite and dichogamous, with pronounced protandry. In the climate of Paris, there is about a week between the male phase with open anthers, and the female phase, when the style emerges. These two phases are manifested by the colour of the flowers. The petals, in the floral bud, are greenish-white ; 24 hours later, they open without change of colour, and after having attained $^2/_3$ of

their ultimate dimension, the filament of the first stamen elongates, and the anther opens; next day, two stamens are open, and in 5 to 8 days, according to the temperature, all the anthers are completely mature. At this time, the styles are not yet capable of functioning.

When this phase is concluded, the colour of the petals changes suddenly, and in 2 or 3 days, they become bright red; the anthers wither and fall, whereas after 24 hours have elapsed, the styles rise 5 mm. above the level of the corolla. The red colour lasts till the fall of the petals.

Variations in colour connected with the age of the flowers have also been observed in the case of *Pulmonaria vulgaris*, *Myosotis versicolor*, *Weigelia rosea*, *Ribes sanguineum*, etc.

858 – **Pollen and Pistil Development in Relation to Sterility in Pure Forms and Hybrids of the Plum.** — DORSEY J. M. in *Genetics*, Vol. IV, No. 5, pp. 417-487 pl. IV. Princeton, New Jersey, Sept. 1919.

Apart from outside influences, there are others having a direct bearing upon the germ plasm and therefore on reproduction, and hence upon fruit formation.

The author reports the results of a study of the sterility in the plum in relation to the development of pollen and pistil.

POLLEN DEVELOPMENT. — Pollen development was studied in varieties representing: *Prunus americana*, *P. nigra*, *P. triflora*, *P. domestica*, *P. pennsylvanica*, *P. hortulana Mineri*, and *P. Besseyi*.

With the exception of certain *P. domestica* varieties, self-sterility in the plum is the normal development and to ensure fructification, cross pollination is necessary.

Biological research demonstrates that abortion occurs in most cases between the time of liberation of the microspore from the tetrad and maturity, in other words during the gametophyte generation, the fact that anther development is normal even when pollen abortion is complete or very evident, tends to eliminate conditions in the anther as a constant factor in abortion. In extreme hybrid forms, there is evidence of pollen disintegration as early as the dyad stage. The frequent breaking down of pollen into yellowish gummy globules should be considered as a supplementary enzymatic process entirely distinct from true abortion, since it does not always occur, and sometimes affects mature grains which have every appearance of being normal. The metamorphic process of petalody does not affect the stamen dehiscence and a new type of aborted pollen is not introduced. Aborted pollen varies in quantity up to a considerable amount and appears to be greatest with extreme hybrids.

In the following Table, the individuals of the crosses between *P. triflora* and *P. americana mollis* are classified according to the percentage of aborted pollen found. The two varieties of *P. triflora*, Abundance and Burbank were used as the pistillate parent.

Consequently in every case, the percentage is very high.

The following data concern the various crosses both between distinct species and also interspecific crosses.

	Number of trees	Percentage of aborted pollen																
		5	10	15	20	25	30	35	40	45	50	55	60	65	70	75	80	85
Abundance × Wolf	34	2	3	4	9	4	5	2	1	2	1		1					
Burbank × Wolf	23	4	1	3	1	2	3	3	1			2		1		1		1

« Aitkin » (*Prunus nigra*) 22.0 % — *Amygdalus nana* × *P. persica* 84.4 % — « Blush » (*P. americana*) 12.0 % — « Burbank » (*P. triflora*) 3.2 % — « Cheney » (*P. nigra*) 54.1% — « Compass » (*P. Besseyi* × *P. hortulana Mineri*) 43.5, 100.0 and 57.3% — « De Soto » (*P. americana*) 7.5% — « Etopa » (*P. Besseyi* × *P. triflora*) 24.0 and 12.1 % — « Irondad » (*P. americana*) 14.2 8.6 and 9.9 % — « Loring » (*P. triflora* × *P. americana*) 26.0 % — « Manitoba » (*P. nigra*) 14.5 % — « Ocheeda » (*P. americana*) 6.3 and 28.8 % — « Opata » (*P. Besseyi* × [*P. Munsoniana* × *P. triflora*]) 80% — *P. americana* (*selvatica*) 21.5, 14.5 and 14 0% — *P. angustifolia* 18.1% — *P. Besseyi* 12.3 % — *P. Besseyi* × *P. americana* 63.7 % — *P. Besseyi* × *P. armeniaca* 87.6 and 82.3 % — *P. Besseyi* × *P. Simoni* 35.1 % — *P. nigra* 24.1, 37.9 and 3.6% — *P. pennsylvanica* 26.4% — *P. virginiana* 15.0 and 7.3% — « Rollingstone » (*P. americana*) 9.7% — « Sapa » (*P. Besseyi* × *P. triflora*) 42.0% — « Surprise » (*P. hortulana Mineri*) 34.0 and 7.0 % — « Wolf » (*P. americana mollis*) 23.0 % — « Wyant » (*P. americana*) 16.5 and 18.2 % — « Yellow Egg » (*P. domestica*) 3.1 %.

	Percentage of aborted pollen																			
	5	10	15	20	25	30	35	40	45	50	55	60	65	70	75	80	85	90	95	100
Hybrids	1	1			2		2	1	1		1		1			2	1	1		1
Pure forms	6	5	6	4	3	1					1									

As a general rule, except in the case of the extreme hybrid, *e. g.* Compass (*Amygdalus nana* × *P. persica*) and Opata (see above), where the pollen abortion is practically complete, abortion should not therefore be condemned as the prohibitive factor in the setting of fruit in the case of self-pollination as much as with cross pollination.

Moreover, in view of the extreme hybrid condition of many varieties, abortion of pollen may be considered of great economic importance. The abortion of pollen during the haploid stage appears to point to the conclusion that the cause of abortion is to be found in the condition of the germ plasm of the gametophyte.

Pistil development in relation to sterility. — After having first described the normal development of the pistil, the author speaks of the dropping of the pistil which occurs at three distinct stages :

(1) Immediately after bloom. The flowers which drop at this stage show aborted pistils, and this abortion in some cases takes place

very rapidly, whilst the pistil is still short, not more than 5 mm. long In other flowers the pistils measure a normal length, but both ovules are aborted. The pollen, on the other hand is usually normal.

(2) Two to four weeks after bloom, all the pistils drop off, and for certain reasons, pollination has not taken place. It is interesting in this case to note the appearance of the ovules; for about two weeks the nuclear condition remains normal followed by disintegration in the antipodal nuclei and then in the endosperm nuclei. The embryo sac elongates only slightly, whilst on the contrary, the canal extends as a rule as far as the chalazal. The ovary, before dropping, reaches a size of 2 to 5 mm. in diameter.

(3) June drop. — Two weeks later than the second drop. The small fruits are already formed; pollination has taken place, but the embryo development has been hindered. Therefore in a perfectly normal manner, before or immediately after bloom, one of the two ovules is in each ovary suppressed.

Elimination of Gametes. — Owing to abortion of pollen, pistils, and ovules, a considerable number of gametes are eliminated. To what cause can this be attributed? As a result of the most recent study on this phase of the subject, evidence has been presented that certain factor combinations in heterozygous lines of descent exist which cannot undergo normal development. As regards the heterozygous condition of the genus *Prunus*, the variability is evident in fruit and other characters shown by wild seedlings of *Prunus americana*, *P. Besseyi* and *P. nigra*, as well as studies of a large number of F_1 descendants of controlled interspecific crosses.

Relationship of varieties and species. — Various crosses demonstrate the genetic relationship between the setting of fruit and the dropping off of pistils or small fruits.

Thus, for Compass × Burbank, out of 175 flowers artificially pollinated, 116 fruits set, whilst for Minnesota No. 9 × Minnesota No. 12, out of 537 flowers pollinated, none set. Between these two examples, there is a series of intermediary results. But an aborted setting is not always accompanied by an abundant yield of ripe fruits. For Compass × Burbank, from the 116 fruits set, some 114 mature fruits were obtained, but Compass × Yellow Egg which possessed an equally high setting percentage (out of 1327 flowers pollinated, 652 fruits set), only gave a very low number of mature fruits (8).

This appears to support the hypothesis that certain factor combinations are only able to develop to a certain limited extent, some failing in the zygote, some in the embryo, and some not until the time of formation of the ovule or of the pollen.

Type of sterility in the plum. — Considering only the pollen grains of normal appearance which reach the stigma under ordinary conditions, some do not develop pollen tubes, whilst others are normal in this respect. In a similar way, some produce microspores and others do not. These differences instead of proceeding from a substratum

which in every case is identical in nature, are apparently due to a similarity in the character of the pollen grains, and may be explained by the variation genetically. The fact that there is a marked occurrence of self-sterility in the American varieties does not demonstrate that this condition or character is dominant. However, there are also cross-fertile and cross-sterile groups as in *Nicotiana* and other species. Inheritance studies of sterility bring to the front the importance of the physiology of pollen tube growth which behaves in a way similar to other inherited characters investigated. There seems to be no doubt now concerning the segregation of a character at the time of reduction division, which would produce a difference between pollen tube and stylar tissue, which results in a type of sterility that is merely a physiological impediment. The type of self and cross sterility in the plum, is therefore comparable with that in other forms, and can be ascribed to slow pollen tube growth.

859 – **A Turbine Sorter for Seeds.** — I. RINGELMANN, Selection des blés au trieur, *Comptes rendus de l'Académie d'Agriculture*, Vol. VI, No. 19, pp. 477-478. Paris, May, 1920. — II. ZACHAREWICZ, ED., *Ibid.* pp. 489-491. SEEDS

M. RINGELMANN reports the opinion of the Rural Engineering Section as regards M. ZACHAREWICZ's suggestion of using a turbine sorter for seed-wheat.

The ordinary sorter divides the seeds according to their length and width, but without any regard to their weight, which is a third very important character in wheat used for sowing.

The MAROT turbine sorter allows of bad, light grains being separated from good seeds, which are of the same size.

The so-called air-turbine, or turbine fan, can be affixed to all sorters, and has nothing to do with the small fans or winnowing-machines, that merely remove the dust, husks, and chaff.

The results obtained by M. ZACHAREWICZ with Manitoba wheat are given below:

	Weight per hectolitre	Proportion
	kg.	
Before sorting	78.0	100.00
Sorted with ordinary sorter (without turbine)	79.5	101.92
Sorted with turbine-sorter	80.0	102.56

The ordinary sorter gives an increase of weight, per unit of volume, of 1.92 % with grain that has not yet been passed through the machine; the increase in weight due to the action of the turbine is slight (0.64 %).

In some experiments with the Marot honey-comb sorter, M. ZACHAREWICZ obtained the following results, after adjusting the apparatus in such a way as to obtain the best work:

In these experiments, carried out without a turbine, and with an agricultural type of sorter, the increase in weight per unit of volume of the seed-wheat due to sorting varied from 1.3 to 5.3 % according to the original weight of the grain.

	Weight of hectolitre		Proportion	
	Before sorting	Seed wheat	Before sorting	Seed wheat
	kg.	kg.		
Local wheat (Deux Sèvres): 1st lot . . .	74.6	78.6	100	105.3
Local wheat (Deux Sèvres): 2nd lot.	76.0	77.0	100	101.3
Saumur March wheat (sold for seed). . .	76.0	80.0	100	105.2

860 – **The Canadian Government Seed Purchasing Commission.** — CLARK, G. H. (Seed Commissioner, Seed Branch, Department of Agriculture, Dominion of Canada), in *The Agricultural Gazette of Canada*, Vol. VII, No. 3, pp. 220-221. Ottawa, March, 1920.

The Canadian Government Seed Purchasing Commission which was considered as a war time organisation, under the Branch of the Seed Commissioner, has continued in operation this season in an endeavour to take care of the seed distribution in the Prairie Provinces. In former years, the Commission had also traded with seed coming from the Canadian Government Elevators at Port Arthur, Quebec and Montreal. It is anticipated however, that now, private grain and seed firms, together with the co-operative organisations are capable of rendering efficient service in respect to the seed demand in Eastern Canada. Seed inspection for the established grades of seed grain continues to be available at Canadian Government Elevators to private and co-operative dealers, on the same basis as to the Commission.

Under normal condition of trade, the Canadian people might oppose the idea that the government should interfere with such commercial transactions. It is contended by some, that private companies have not in past years provided a service in respect to seed supply, sufficiently comprehensive to meet the requirements of agriculture. Semi-public organisations of farmers, with a co-operative basis have developed rapidly under the extraordinary conditions of wartime trade. When these organisations become firmly established, they will doubtless under Government control be able to provide seed supplies more efficiently, and with greater satisfaction than can be expected of any governmental organisation. Even now, the distribution of seed grain and other seeds is affected and prices controlled by farmer's co-operative organisations.

The Commission has without doubt rendered valuable service to Canadian agriculture during the trying years of the war, when, notwithstanding extraordinary conditions both in regard to supplies and transport, there was at no time a seed shortage in any part of Canada. Obligations and risks which appeared to be necessary to protect agricultural interests were frequently assumed by the Commission. This course of action could not be expected of private companies, and naturally resulted in losses in connection with several minor transactions. The consolidated balance sheet, however, covering the operations of the Seed Purchasing Commission for the past three years shows a small surplus.

The total sums advanced by the Department of Finance, Canada, for the purchase of seed supplies, on requisition for the Dominion Seed Commissioner amounted to $11 896 540.96, and the total of refunds to the Receiver-General from the proceeds of sales was $11 903 437.76. Net assets, including seed grain in storage were valued at $37 888.85. The salaries and expenses of the experienced Seed Branch officers, comprising the staff of the Commissioner, were not charged against the cost of the seed. The order in council which established the Commission, directed that the seed supplies should be purchased, stored, cleaned, and sacked where necessary, and sold at the net cost as nearly as might be determined.

The Commission started work in October, 1916, ending in September, 1919, not taking into account the above mentioned emergencies. The business included the purchase and sale of seed wheat, oats, barley, rye, maize, peas and beans, subject to inspection based on the established grades for seed grain provided under the Seed Control Act. Inspection was administered by the Seed Inspection Division of the Seed Branch: Every car load purchased or sold was examined by seed inspectors, and samples were submitted for tests as to purity and germination by the Dominion Seed Laboratories at Ottawa, Winnipeg, or Calgary. Delivery consisted of a bill of lading, licensed weighman's certificate, seed certificate and sight draft. This system of meeting emergency situations was adopted on the recommendation of the Seed Commissioner. It is based on the establishment of official seed grades for grain, and on the principle that municipal governing bodies, supported by their provincial government are in the best position to deal with the extension of credits to needy farmers.

CEREALS AND PULSE CROPS

861 – The Yield of European Rice-Fields as Compared with those of the Rice-Fields in the Far East. — CHEVALIER, A., in the *Bulletin agricole de l'Institut Scientifique de Saïgon*, Year II, No. 6, pp. 180-181. Saïgon, June, 1920.

The author's attention has been drawn on several occasions to the very large crops obtained from certain rice-fields in Europe.

At the Rice-Growing Congress held at Valencia (Spain) in 1914, yields of from 7000 to 8000 kg. per hectare were reported from some parts of Spain.

Quite recently. M. P. PAPAGEORGIOU, the Director of the Royal Hellenic Agricultural Station, reported that, in Ancient Greece, and also in Epirus and Macedonia, the average rice crop was from 12 500 to 15 625 kg. per hectare (?). The author struck with these figures (1), which so far exceed the returns recorded in Indo-China, where, under the most favourable conditions, a crop of only 2000 to 2500 kg. per hectare is obtained, applied to Prof. NOVELLI, Director of the Vercelli Rice Growing Station, for information respecting the Italian rice production, and received the following reply:

(1) See *R.*, Feb. 1920, No. 198. (*Ed.*)

" (1) *Minimum, average and maximum yields of Italian rice fields.* — As regard this question, it must be remembered that, in Italy, rice is generally grown in rotation with catch crops, and that in the scheme of rotation, rice is, as a rule, planted for three consecutive years on the same ground. The first year, the most exacting varieties are grown, while the third year the more robust and less productive varieties are planted.

During the first year, the rice-fields produce crops exceeding 70 quintals per hectare; older fields, and those where the soil is less fertile, yield 35 quintals or less; in rice fields of average fertility, from 45 to 50 quintals may be counted upon.

With the planting-out system, when due regard has been paid to the environment, prolific rice-fields of the first year, have yielded above 80 quintals per hectare.

(2) *The present condition of mechanical cultivation in Italian rice-fields.* — On this point M. NOVELLI gave M. CHEVALIER the following information: Of late years, machines have been largely used in the cultivation of rice fields, especially petrol and heavy oil tractors; in some rare cases, electric power has been employed for ploughing. For some years past, mechanical seed drills have been used; rice however does best when transplanted.

Some experiments have also been made with mechanical planters and reapers, but the use of such appliances is still restricted.

On the other hand, mechanical threshers, polishers, and driers are very generally used by rice cultivators, who possess excellent machines of these types. "

862 - **Phung-Tiên Rice, Variety Selected at the Cantho Rice Experiment Station, Cochin-China.** See No. 853 of this *Review*.

863 - **Yield of Different Varieties of Oats in New South Wales.** — PRIDHAM, J. T., in *Agricultural Gazette of New South Wales*, Vol. XXX, No. 11, pp. 777-780. Sydney, Nov. 3, 1919.

Brief report of the results of experiments with different varieties of oats (either grown for grain, hay or fodder), conducted at various Experiment Farms in New South Wales, during a 5 year period, 1914-1918 The Algerian appears to be the most productive variety in districts of assured rainfall; the New Zealand variety Ruakura gave the best results on the coast.

Highest Yield of Chief Varieties of Oats Studied.

Variety	No. of Trials	No. of times showing highest yield	Percentage of number of times showing highest yield
Algerian	71	25	35.21
Ruakura	38	14	36.84
Guyra	37	10	27.02
Sunrise	60	15	25.00
Lachlan	26	3	11.53

864 - **Suburban Forage Crops in Cochin-China and the Philippines** (1). — VIEILLARD, P. (Director of the Genetics Laboratory of the Scientific Institute of Indo-China) and TRAN-VAN-HU (Assistant at that Laboratory), in *Bulletin agricole de l'Institut Scientifique de Saïgon*, Year II, No. 6, pp. 161-167. Saïgon, June, 1920.

In a report on the work done in 1910 by the Agricultural and Commercial Services of Cochin-China of which he is the Director, M. MORANGE wrote (2):

" Excellent results have been obtained at Phumy from the cultivation of forage Gramineae, and it appears likely that it would pay to grow similar crops in the neighbourhood of Saïgon during dry seasons, provided care were taken in the choice of the soil, since the native dry-season fodders, which are sold at the rate of 7 *piastres* per 1000 kg., are of very inferior quality. "

The authors have considered M. MORANGE'S suggestion, and their observations are based upon 3 series of facts :

(1) The present condition of the Saïgon green forage market.

(2) The results obtained from forage crops grown from 1911 to 1916 at the Phu-My Station, situated just outside Saïgon.

(3) The condition of forage cultivation in the Philippines.

I. *The Green Forage Market at Saïgon.* — The present number of horses in the towns of Saïgon, Cholon, and Giadinh, is about 2000. The total number of the horses and mules of the towns of Saïgon, Cholon, and the province of Giadinh would appear to be 2739.

It may be reckoned that scarcely one quarter of the horses of these centres of population are fed on imported hay, or on grass regularly grown for the purpose. The other three quarters live on grass sold in bundles and taken daily to the stables by natives, who make this their occupation.

The grass is found to some extent everywhere ; a great deal of it comes from the banks of the *arroyos,* or of the Saïgon river, as well as from abandoned, or fallow. rice fields, and even from lawns round the villas, as they are carefully cut until they become quite burnt up by the drought The grass is transported on sampans (native boats), and is taken in carts to the various customers.

The price per bundle varies from $0.20 in the rainy season to $0.30 in the dry season, so that the price per metric ton is from 6 to 10 *piastres*.

The average daily ration for a horse is 30 to 40 bundles of 250 to 350 gm., that is, about 10 kg. but it would certainly be increased in the dry season, were it not for the lack of forage. The forage thus collected and distributed, naturally varies greatly in quality; it consists chiefly of *Gramineae ;* there are few *Leguminosae,* but owing to its growing on marshy land, some *Cyperaceae* are found mixed with them.

Taking the total number of the horses belonging to Saïgon, Cholon, and Giadinh which are fed on this cut forage, and reckoning the daily ration of each animal at 10 kg., we find that 15 tons of green fodder are

(1) This study is of a general character, and deals with a question that is of interest to large number of colonies where the climate is hot.

(2) *Bulletin économique de l'Indochine,* 1910, p. 627. (*Ed.*)

required each day, and that its cost varies, according to the season, from 90 to 150 *piastres*. A great deal of this fodder could be obtained, particularly during the dry season, from special crops grown near the town. Of this the experiments carried out at Phu-My are a proof.

II. *The Phu-My Station Forage Crops.* — For 6 years, from 1912 to 1916 inclusively, the green forage crops cut to be fed to the stock animals and those of the collection in the Botanical Gardens were carefully weighed (the results being calculated per hectare) which afforded some interesting comparisons. The figures referring to Para grass and Guinea grass could be taken as they stood, for the plots under these *Gramineae* varied from 10 to 60 *ares*. The figures obtained for the other forage plants were of less value, as only small plots of several *ares* were sown for each experiment.

The average annual crops for the 6 consecutive years were almost the same in the case of Para grass and Guinea grass, viz., from 60 000 to 70 000 kg., per ha. Pastures of Guinea grass appear to deteriorate more quickly than those of Para grass. In addition to the above-mentioned amount of green forage, the pastures formed of these *Gramineae* furnished a considerable number of shoots every year (sometimes many more than 100 000), which were distributed among Associations, or private individuals, in order to stock new pastures.

The results given by the other forage plants from 1912 to 1916 are as follows (the figures in brackets beside the annual yields of green fodder show the number of cuttings) :

Panicum plicatum. . . . 12 400 (1) in 1912; — 14 900 (2) in 1913;
Aleppo sorghum . . . . 8 100 (2) in 1912; — 41 000 (3) in 1913 — 20 000 (1) in 1914;
Miscanthus sp. . . . . 40 600 (1) in 1913; — 27 600 (1) in 1914;
Perennial Senegal rice . 26 100 (2) in 1914;
« Fayotier » . . . . . 142 000 (7) in 1913; — 33 400 (4) in 1914 — 9 500 (1) in 1915 — 6250 (1) in 1916;
Leucaena glauca . . . . 115 300 (5) in 1913; — 76 500 (6) in 1914 — 31 500 (4) in 1915 — 46 900 (6) in 1916;
Aeschynomene sp. . . . 7 500 (1) in 1913; — 42 800 (4) in 1914;
Albizzia occidentalis. . . 13 000 (1) in 1913; — 34 300 (2) in 1914.

The experiments have proved that forage crops can be grown in the immediate vicinity of Saïgon with every chance of success. Agriculturists cultivating them will be certain to find a ready market for the produce of 50 hectares of rice-field turned to this account, and will obtain good prices either by the direct, daily sale of the green fodder, or by contracting to supply it, and also hay to the Military Authorities or the Public Services.

III. *Suburban forage crops and hay production in the Philippines.* — By way of example, in order to show what may be done along these lines, the authors give a summary of an article published on the same subject in the Philippines, in the *Philippine Agricultural Review*, No. 2, February, 1918 by Mr. C. M. Conner, Head of the Agronomic Division of the Department of Agriculture in the Philippines. The native horses

of these islands are fed on green fodder (*zacate*) of different kinds : — " barit " (*Leersia hexandra*), " luyaluya " (*Panicum repens*), and " manimanian " (*Alsicarpus*). The forage crops dealt with in this study is *Leersia hexandra*, there being an area of 500 hectares of meadow-land near Maniba under this *Gramineae*.

These crops are grown on plots treated in the same manner as rice-fields. The soil is ploughed 2 or 3 times and harrowed, then the water is let in, and kept standing for several days at a depth of 10 cm., until the soil is transformed into mud. " Barit " (*Leersia hexandra*) is gathered in a field set apart for the purpose, and carried in bundles to the field to be planted ; the bundles are opened, and spread out one next the other, their bases being buried in the mud. At the end of the operation, the field looks as if it were covered with straw. The water is again let in and kept at the same height, until the plants have revived, when the field is left to itself.

The forage can be cut for the first time from 8 to 10 weeks after transplanting. The other cuttings are made every 6 or 7 weeks. The grass is tied up in bundles of about 6 cm. in diameter, which are bound together in large bales that can be carried to the town by two men.

The average annual yield is from 50 to 60 tons per hectare. Manila, however, does not entirely depend upon locally grown forage : as in Saïgon, boats arrive every day bringing to the city fresh grass cut in the lake district, or in the neighbourhood of Santa Cruz.

865 - **Fodder Trees and Shrubs for South Africa.** — LEPPAN, H. D. (Transvaal University College, Pretoria) in *The South African Journal of Industries*, Vol. III, No. 4, pp. 334-343, bibliogr. of 15 works. Pretoria, April 1920.

The author deals with the following points : the chief limiting factor of agronomic production (which in South Africa is represented by the rafnfall) ; dry land farming ; indigenous fodder crops ; methods of grazing ; exotic species : useful stock fodder crops ; a proposed experimental station at Kalahari.

In the parts of South Africa having more than 15 in. of rainfall per annum, the ordinary fodder crops grow quickly and well, and consequently it are more profitable than trees and shrubs. Where, however, the annual rainfall is decidedly less, it is necessary to have recourse to such plants. It is true that even there, it is possible to cultivate the two most drought resistant plants in South Africa, namely sorghums and millets, but only with the utmost care ; this necessitates an expensive outlay and even then normal yields are produced only once or twice in 5 years.

South of latitude 22°, fully half of South Africa is arid : Going from east to west of longitude 24°, with the exception of the south-western corner of the Cape, the rainfall decreases from 15 in., to less than 1 in. along the coast of the South-West Protectorate ; in the same direction it changes from a summer to a winter precipitation. The extremely high temperatures prevailing in the east together with the high summer evaporation and torrential character of the rainfall, render growth of

fodder crops too precarious an undertaking. Towards the Western portion in Namaqualand West, the rainfall is only about 8 in. per annum. Since, however, this occurs almost entirely in winter, and is of a misty character, cereals and vetches can be grown under sparse sowing conditions, sufficient to mature on a small amount of available moisture. Wheat sown at the rate of 7 to 10 lb. per acre should give a only about 250 lb. per acre. The cost of production under these extensive methods of cultivation is very low ; and the total production is also limited.

The fodder plants of South Africa include numerous trees and shrubs, which even in the less arid regions furnish food for the livestock during periods of drought : for example :— Ganna Bos (*Salsola zeyheri*) in Karroo ; various species of *Mesembryanthemum* in Namaqualand ; *Acacia horrida* and *Cussonia spicata* in the Eastern Province.

The principal fodder plants which have been tried with success in some of the driest parts of South Africa are as follows :— Old Man Saltbush (*Atriplex nummularia*) and Creeping Saltbush (*A. semibaccata*), introduced from Australia, both very tolerant of soil alkalinity *Opuntia* spp. introduced chiefly from Mexico, Spekboom (*Portulacaria afra*), an indigenous perennial found in the eastern parts of Cape Province — *Mesembryanthemum floribundum* and other indigenous species; — Goed Karroo (*Pentzia virgata*) found in Karroo ; — Mesquite (*Prosopis juliflora*) and Screw Bean (*P. Pubescens*), species introduced the first self propagated in the South-West Protectorate; — Carob tree (*Ceratonia siliqua*).

The following plants, indigenous to South Africa have been used for grazing purposes, but do not offer equally satisfactory results as those in the preceding list : — Kiepersol (*Cussonia spicata*), Zoetdoorn (*Acacia horrida*), — Wild Olive (*Olea verrucosa*), — Rozyntjebos (*Grevia cana*), — Narranarra (*Acanthosicyos horrida*), — Vaal Karroo (*Phymaspermum parvifolium*) Vaalbos (*Tarchonanthus camphoratus*), — Karreboom (*Rhus viminalis*), — Draai-bossie (*Aster filifolius*) : — Cape Saltbush (*Atriplex capensis*)

The four undermentioned species have been introduced and tested in South Africa : — Tagasaste (*Cytisus proliferus*) which seems to require a cooler and more humid climate than that found in South Africa ; — *Atriplex halimoides, A. leptocarpa, A. vesicarium* which have succeeded well in the Orange Free State, but these are annuals and grazing must be watched carefully (especially as stock eat these with avidity), otherwise self propagation will cease ; farmers therefore prefer the perennial species.

Acacia aneura, Jacksonia cupulifera and Kurrajong (*Sterculia diversifolia*), have proved most useful in Australia during droughts, and the author considers them worthy of trial in South Africa.

866 – **Losses of Organic Matter in the Preparation of Brown and Black Alfalfa.** — Swanson C. O., Call L. E., and Salmon, S. C., in *Journal of Agricultural Research*, Vol. XVIII, No. 6, pp. 299-304. Washington, D. C., Dec. 15, 1919.

The product resulting from the stacking of alfalfa in a partially wilted condition is known as brown and black alfalfa. The stacking

excludes the air, and fermentations occur similar to those which occur in a silo. The degree of colour thus obtained depends upon the conditions which control the nature and extent of the fermentations such as ; moisture content of the alfalfa when stacked, size and shape of the stack, and temperature and rainfall during the time of curing, etc. Both brown and black hay are relished by cattle.

Each time, however, that fermentation occurs, there is evidently a loss in nutritive value. Since the nature and amount of these losses were unknown, the authors decided to investigate them, and also to compare the feeding value of these hays with that cured in the ordinary way. These investigations were carried out at the Kansas Agricultural Experiment Station.

The alfalfa was cut and left to wilt for some hours and stacked in the open. Towards the latter part of December, a sample was put to the test ; one quarter was analysed, and the three other quarters fed to steers. The remainder was left intact and a sample was taken towards the end of March to be analysed.

The average dry matter content of the partially wilted alfalfa put into the stack was 46.72 %. The loss increases with the length of time in the stack and with the changes during fermentation.

Alfalfa which has become black as a result of fermentation is very inferior as a feed for steers in comparison with ordinary alfalfa hay of good quality and with the brown hay.

The feeding tests were carried out with 3 lots of 14 steers each covering a period of 180 days. The following concentrated rations were used :— shelled maize and oil meal ; roughage ; alfalfa hay. The average daily gain, per head per lot, fed with black, brown and ordinary hay was 262.1, 350.1, and 353.8 lb. respectively.

867 – **Hemp-Growing in Tran-Ninh, Indo-China.** — Miéville, R. in the *Bulletin agricole de l'Institut Scientifique de Saïgon.* Year II, No. 5, pp. 157-159. Saïgon, May, 1920. FIBRE CROPS

At the present time, hemp is exclusively cultivated in Indo-China by the Meos, and only for their own requirements. The hemp grown by them is *Cannabis sativa* L., the so-called " Chinese Giant hemp ". The male and the female inflorescence grow on separate shoots. Its average height is from 3 to 4 metres ; when left to bear seed, it may grow to 6 metres, the diameter of the stem being from 4 to 5 cm. at the collar. If grown sufficiently far apart, *Cannabis sativa* assumes a pyramidal form, its base covering an area of from 2 to 3 metres. In the hemp crops at Tran-Ninh, about $^2/_3$ of the shoots are male and $^1/_3$ female.

Cannabis sativa is cultivated in the mountains, at altitudes between 1200 and 2000 metres, and especially in forest clearings situated at the bottom of ravines, on account of the large humus content of the soil in such places.

The Meos gather the stems 70 days after sowing, which is too early. They always leave some plants on the edges of the fields, to provide seed for future crops. The natives know nothing of retting, but extract the fibres by hand.

At Tran-Ninh, no pond is required for setting the stems, all that is necessary being to leave them lying on the fields, where they are macerated naturally by the action of the rain on dew. The stems have only to be turned every 2 or 3 days, and retting is complete in from 8 to 12 days.

The author has made experiments in growing hemp. This plant does not appear to depend on altitude as much as has been supposed, for fine specimens have been obtained at an altitude of only 450 metres.

After setting and scutching, the author obtained 6 kg. of tow per 100 kg., of dry stems (in France, according to a paper published in the *Bulletin économique de l'Indochine*, No. 51, New Series, 1906, dealing with the textiles of Tran-Ninh, 35 kg., of tow was furnished per 100 kg., of dry stems on ordinary soil, and 50 kg., on rich soil).

868 – **Note on Cambodian Cotton** (1). — PRUDHOMME, E. (Director of the Jardin Colonial de Nogent-sur-Marne, France), in the *Bulletin agricole de l'Institut Scientifique de Saïgon*, Year II, No. 6, pp. 182-184. Saïgon, June, 1920.

M. DE FLACOURT (Inspecteur, Chef des Services Agricoles et Commerciaux du Cambodge) sent, in July, 1919, to the Colonial Garden for examination by experts, three types of Cambodian cotton (*Gossypium hirsutum*) obtained through selection carried out by the Department of Agriculture of the Protectorate.

As in a previous case (2), the Colonial Garden requested M. Ch. MARANDE, Vice President of the Colonial Cotton Association, to examine the samples, and the author gives an account of this examination.

The three types of cotton showed a quality at least equal to that of the samples examined in 1918. They are classed "fully good middling" to "middling fair." The fibres are fairly long, and in due recognition of the length, M. MARANDE emphasises the importance of producing cotton with a good staple running from 28-28/29 and 28/30 mm., which forms the basis of the French consumption as well as of other countries.

PLANTS YIELDING OILS, DYES, TANNINS ETC.

869 – **The Exploitation of the Oil Palm *(Elaeis guineensis)* on the Ivory Coasts** — TEISSONNIER, (Chef du Service de l'Agriculture, Bingerville), in the *Annales de l'Institut Colonial de Bordeaux*, pp. 69-78, Figs. 4. Bordeaux, 1919 (1).

Of the Colonies under the jurisdiction of the General Government of French West Africa, the Ivory Coast occupied the first place as regards climate, soil fertility, and the methodical utilisation of the numerous natural products found there. The products of the oil palm (oil and palm-oil) give rise to exports valued at 200 000 000 francs. The enormous stands of these trees on the Ivory Coast have scarcely been touched; they, however, represent a large source of wealth and, further, a very sure one, as there is no limit to the demands of commerce. The appended table gives the exports of the Colonies of French West Africa, and show

(1) As regards Cambodian cotton, see "The Possibility of Developing Cotton Growing in Cambodia" by M. de FLACOURT, *R.*, Dec., 1918, No. 1355. See also *R.*, Jan., 1919, No. 46 and *R.*, May, 1919, No. 595.

(2) See *R.*, April, 1920, No. 423. (*Ed.*)

(1) See *R.*, April, 1920, No. 423. (*Ed.*)

that Dahomey exports much more of its palm products than the Ivory Coast, although the zone suitable for the cultivation of the oil palm is smaller, but in Dahomey the population is larger and the palm-groves are better tended.

Year	Guinea	Ivory coast	Dahomey	Total
	Tons	Tons	Tons	Tons
		Palm oil.		
1910	15	5 055	14 630	20 640
1911	10	6 625	15 250	21 885
1912	140	6 775	11 950	18 835
1913	165	6 015	7 970	15 150

1917	7 070	6 130	17 017	30 216

Elaeis guineeensis is unusually dependent on the care it receives, and in the colonies of French West Africa, it has never been cultivated scientifically. Although these colonies derive great advantages from the fact that the oil palm grows wild, they will soon be outdistanced by the Dutch Colonies, where a remarkable system of cultivation has been evolved, unless they make efforts to increase the output.

Without there being any immediate danger of such a contingency, it would, however, be wise to study the situation, and not to rely exclusively upon the wild stands of oil palms, though at the same time, the natural benefits accruing from their existence should be turned to the best account.

In short; the systematic exploitation of the oil palm should include: (1) The care of natural palm-groves; (2) the selection and propagation of varieties with large yields; (3) regular cultivation; (4) the installation of oil-factories. With the exception of selection, the rest of the programme could easily be carried out; all that is required is good will. The management of the palm-groves, which has already been begun in the lagoon zone, will give appreciable results from the end of next year, and the natives will lose no time in observing and valuing them.

870 – **Improved Methods of Cultivating the Groundnut in Senegal.** — I. Report of the Mission, CHEVALIER, A. (Head of the Permanent Colonial Agricultural Mission), in the *Bulletin des Matières grasses de l'Institut Coloniale de Marseille*, 1920, No. 2, pp. 61-74 Marseilles, 1920. — II. La lutte contre les insects attaquant l'arachide, ROUBAUD E., (Chief of Service of the Pasteur Institute), *Ibid.*, pp. 74-83. — III. Note sur la selection des arachides, VUILLET (Director of the Agricultural Services in Upper Senegal-Niger), *Ibid.*, p. 84.

Some years before the war. consternation was aroused in Africa and France among persons engaged in the groundnut trade and industry by the deterioration of the groundnuts of West Africa, and the decrease in their oil content (1).

The Colonial Institute of Marseilles urged the Governor-General of F. W. A. to have the question investigated by thoroughly competent experts ; M. A. CHEVALIER accordingly made it to the subject of special enquiry, and M. ROUBARD was entrusted with the task of deciding upon the control measures to be adopted against the insect enemies of *Arachis hypogaea*. The reports of these two investigators are published in the *Bulletin des Matières Grasses* of the Colonial Institute of Marseilles together with M. VUILLET's remarks on the selection of groundnut seed.

I. — REPORT OF M. A. CHEVALIER. — Rubber (2) and groundnuts are the two chief sources of wealth in West Africa, unshelled nuts of *Arachis* being exported annually to the value of 50 million francs, while its straw, which forms excellent fodder, is a very important article of trade in the country itself.

Nearly the whole colony of Senegal finds its means of livelihood in the groundnut trade, from 151 000 metric tons (1907) to 164 900 t. (1911) of unshelled groundnuts being exported annually. The plant is being more extensively cultivated every year, especially along the railway from Thiès to Kayes. Exportation, however, does not keep pace with production. This is due to the deterioration of the quality of the groundnuts, and their smaller oil content, which depend upon the attacks of its animal foes (insects, etc.) and also upon other causes.

According to M. ADAM, Director of the Senegal Agricultural Service, the yield of groundnut grown in the different regions of Cayor has been greatly decreasing for a very long time not only on account of the injuries inflicted by insects, but also because of the following factors :

(1) Soil exhaustion ; (2) diminished rainfall resulting from deforestation ; (3) the invasion of the northern districts by drifting sands. The crops of the Louga region are now of very inferior quality, the nuts being small and not filling up the shells.

The North-East wind also carries moving sands, which ultimately cover the soil, so that the plants cannot grow or are buried

M. ADAM is of opinion that the method of groundnut cultivation practised by the natives will entail the progressive sterility of Senegal for

(1) See, in this connection, the paper by M. ANGOULVANT, *R.*, July-Sept., 1919, No. 888, (*Ed.*)

(2) For African Rubbers and their crêping, see No. 872 of this *Review*. (*Ed.*)

for the following reasons: (1) The natives destroy the trees; (2) they impoverish the soil without restoring (by means of manuring, and fertilising) the nutritive substances abstracted by the crops.

The groundnut, however, is more suitable than any other plant for cultivation in Senegal, where the dry and excessively hot weather prevailing for more than 7 months in the year is only adapted to annual crops of very rapid growth. The rainy season lasts about 4 months and, during this time, from 25 cm. to 75 cm. of rain falls; this is the total annual amount in the districts where the groundnut grows, but it is all that is required for the crop. Further, the soil, which is sandy or a sandy-clay, is very fertile and admirably suited to the plant. As this leguminous plant is especially cultivated in Senegal in districts very far removed from any rivers, or streams, and which could never be irrigated, it would be difficult, if not impossible, to find any other important crop that could replace it.

The groundnut is thus a treasure to the country, but a treasure that requires supervision, and also increasing this is a matter of no great difficulty, seeing that, in the groundnut districts of the colony there are millions of hectares of uncultivated land through part of which the railway from Thiès to Kayes already runs, or will shortly do so.

It is therefore of paramount importance that this plant should be studied, and that the experiments should be resumed which were formerly begun, but had to be suspended.

Serious attempts to plough the land were made in 1898 and 1899, but the outbreak of yellow fever in 1900 led to their being abandoned. In 1905 and 1906, experiments were made in sowing foreign groundnuts from Egypt, Mozambique, and Java, but as the conditions were unsatisfactory, only very meagre results were obtained that admit of no conclusions being drawn.

Since 1907, these experiments have been suspended, and it may be said that no one has troubled any further about the matter.

In order to develop groundnut cultivation, it is necessary to follow the example of the colonists of Malaya, who devote all the resources of special Experiment Stations to the study of the different plants that are the foundation of their wealth (sugar-cane, tobacco, tea, hevea, etc.). The groundnut is of sufficient importance in French West Africa to have a similar Station devoted to its interests.

The Governor-General has approved of the suggestion that such an Experiment Station should be founded, and the local Government Authorities have voted the credit necessary for its establishment and maintenance; it now only remains to organise the work. The author gives some details as to the constitution of this Station and the problems it would have to solve. The programme of the Groundnut Experiment Station should include the following 3 principal branches of research:

(1) *The scientific study of the plant from a general point of view.* — A careful study must be made of every way in which it can be improved. The introduction of seed of foreign varieties; the selection of

these and of local varieties ; the influence of the different soils of the Colony ; the action of various fertilisers ; the question of the spacing of the seed when it is planted ; the different methods of cultivation (especially dry-farming) ; the agricultural implements to be used.

(2) *The special study of the groundnut from the point of view of its cultivation by the natives.* — The production of groundnuts in Africa is entirely the work of the native, therefore it is very necessary to improve his methods of cultivation. Attention must be devoted to the best manner of obtaining seed and implements of a superior quality ; more enlightened cultural methods must be adopted, as well as useful measures of an administrative character, such as the creation of small inalienable holdings, sinking wells and making paths to the railway stations. The natives should be encouraged to emigrate from over-populated regions, like Massa and Fouta-Djalon, markets must be opened for the sale of produce, the number of Cooperative Seed Association and of native Cooperative Credit and Purchasing Societies increased, and prizes and rewards offered to the natives whose crops are in the best condition, etc.

(3) *The special study of the groundnut with a view to its cultivation by Europeans.* — Experiments have been made by Europeans in cultivating groundnuts on a large scale. Investigations lasting several years should be carried out at the Experiment Station for the purpose of studying the type of labour-saving machinery and implements most fitted for the country, and also the cost of the different cultural methods, in order to provide the colonist with all the necessary information. To show the practical importance of such researches, it may be stated that whereas the native cultivator in the most favoured regions of Senegal only obtains in good years from 1000 to 1500 kg. of groundnuts per hectare in the United States, a crop of 3500 to 4500 kg. per hectare may be got by means of intensive cultivation.

The author next deals with the question of the *diseases and pests of Arachis hypogaea.* At Fouta-Djalon, he found the fields infested with *Alectra arachidis* A. Chev. (a *Scrophulariaceae* which is probably only a variety of *A. Senegalensis*). In Senegal, the leaves of *Arachis* are often attacked by a fungus which produces black patches on the leaflets causing them ultimately to fall. This parasite seems to flourish chiefly in wet seasons, and it is only then that the plant suffers to any extent. This disease has hitherto not been studied. In F. W. A., the chief foes of the groundnut are insects. The author studied successively the insects attacking the harvested nuts, and those infesting the growing plants. He is of opinion that a commission of experts should be appointed to study the diseases and pests of the groundnut and the best means of controlling them.

II. — THE CONTROL OF INSECT PESTS OF THE GROUNDNUT (1). — (1) *The effect of insects and drought upon the growing plant.* — The chief inju-

(1) Extract from the *Annales de Géographie*, Vol. XXVII 1818 (Note from the *Bulletin des Matières Grasses*).

ries are caused by the small termite *Eutermes parvulus* ; the attacks of these insects coincide with the drought and increase the bad effects of the latter. Dry-farming is the best method of combating drought and controlling the termite, as it renders the surface of the soil less compact. It is, however, also necessary to remove from the surface of the soil all plant remains (particularly the stalks of dried millet), in order to hinder the multiplication of the pests ; finally, early kinds of groundnut (especially the " Volete " variety) should be cultivated as much as possible in the arid parts of Senegal.

(2) *Damage done by insects to harvested groundnuts* — After the harvest, groundnuts (still in their shells) are often left piled up in enclosures where they remain in the open air for some months. They are never attacked by insects, except by a bug, *Aphanus sordidus*, which, however, does little harm. Most of the injury is done in the huge closed store-houses at the exportation centres by numerous destructive insects that attack nuts with damaged shells and, further, impart to them a disagreeable odour which depreciates the value of the oil made from the nuts and causes it to become rancid. The greatest precautions have to be taken, especially when shelled nuts are to be exported. This affords matter for much research.

(3) The author considers the *intensification of groundnut cultivation in Senegal*, and expresses the hope, that an Experiment Station will be founded for the sole purpose of studying all the biological questions connected with this plant, and that the researches will be carried on methodically and uninterruptedly under scientific, and at the same time practical, direction.

III. — Observation on the Selection of *A. hypogæa*. — Even if the Upper Senegal-Niger district alone were taken into account, it would not be wise to have only one centre of seed-production. A variety of groundnut should be well adapted to the soil and climate of the region where it is grown, and the different Sudanese varieties are very dissimilar in their botanical, agricultural, and industrial characters. An early variety suiting a district with a short rainy season would, if grown in a wet zone, give a crop inferior to that of a later kind, and would have a larger proportion of damaged seeds. A spreading variety produces a better crop on sandy soil, but does badly on heavy or stony soil, where it is difficult to extract the roots. Finally, some varieties grow vigourously on wet soil, where others wither and perish.

The author has, however, found, that, as is the case with other cultivated plants, productivity is not a varietal characteristic but is a line character. Thus the preliminary work to be done is of two kinds :

(1) The determination of the cultural types most adapted to the following conditions :

A) rainfall below 60 cm.	well-drained soil	light soil
B) rainfall between 60 and 90 cm.		heavy soil
C) rainfall above 90 cm.	damp soil	stony soil

(2) The selection of pure lines with heavy yield (answering well to the requirements of the industry) in the case of each type that is especially suited to determined natural conditions of cultivation. This work might practically be done separately. Thus, the first object might be the improvement of the product in zones where the normal rainfall varies from 60 to 90 cm. (as, for instance, in the Kaynes and Ségon region of Upper Senegal-Niger) and where the soil is well drained. To try to grow in the Niger valley between Kouroussa and Sigueré those types which had been selected for the Kayes district, would, however, be to court certain failure.

When a highly productive line suited to the cultural conditions of a given large natural region has been obtained it will be possible to induce the growers of a special centre to cultivate this type exclusively. The quality of the line will be maintained by selecting the shells for thickness, and the kernels for size, and by the growers at the chosen centre only using seed sorted by this double process, and reserving the rest of their crop for distribution at cost price at the sowing season to the groundnut cultivators of the neighbouring districts.

871 – **Four Tannin-Yielding Trees of Indo-China (especially of the Camau Region): "Cây-Duoc" "Cây-Duoc-quanh" "Vo-Duoc" and Vo-Già *(Fam. Rhizophoraceae).*** — I. POILANE. — II. VERNET G. and NGUYEN-DUC-LONG in the *Bulletin de l'Institut Scientifique de Saïgon*, Year II, No. 4, pp. 116-123. Saïgon, April, 1920.

I. — The promontory of Camau forms part of the Province of Bacliêu. It has a fine future before it, being a very fertile region, admirably situated (near Singapore, a free port), and watered by several large *rachs* (1) that allow of a network being formed throughout the district. The plain is, in fact, well furnished with water-ways, which are at present the sole means of communication.

The clay soil consists of recent alluvium that is still travelling seaward, so that the transported mud, which is a first very soft, is gradually arrested by the mangroves.

Hitherto, the natives have contented themselves with exploiting the forests nearest the bays, rivers and *rachs*.

The chief trees of the region (most of which are exploited) are the following :

Cay	Tram	fuel, posts, stakes.
»	Duoc	charcoal, posts, tannin.
»	Dà	Dye
»	Dà Quanh	Dye
»	Dec Tach	Little used?
»	Dec Du	Dye, posts
»	Su	Wood of first quality for all purposes.
»	Mâm	Not used.

The author only deals with Cây-Duoc and Cây-Dà, the bark of which is chiefly used for its tannin.

(1) The name given to water-courses and canals in Indo-China. (*Ed.*)

" Cây-Duoc " (*Rhizophora* sp.). — This tree reaches a height of from 25 to 30 m., its circumference varying from 2 to 3 m. It puts forth numerous adventitious roots, which start from the trunk at two or three metres from the ground, and bury themselves in the soil at distances varying in proportion to the height at which they originated. These roots, after coming in contact with the soil, have the power of giving rise to other adventitious roots, which penetrate the soil at a still greater distance. Sometimes there are also aerial roots descending from the principal branches, that is to say, from a great height. The trunk is usually straight and cylindrical, forming a shaft 15 to 20 m. high without any branches. The wood is very close-grained, the bark thick, and the leaves are oval, smooth and thick.

This tree alone furnishes about one third of the trade of the region; its wood is used for making charcoal of excellent quality as well as for posts for houses and the blades of rice hullers. It is also a good wood for fuel. The bark supplies tannin, and a dye for fishing-nets. The charcoal and bark are transported on the Cholon.

Cây-Duoc is used to such an extent by the natives, that they may be said to be systematically destroying it. It is certain, that unless some measures are quickly taken for its preservation, this very valuable tree will shortly give place to others of less importance. This destructive exploitation of " Cây-Duoc " naturally began on the banks of the streams and rivers, but even now it is necessary to go far into the interior of the country before meeting with fine specimens.

" Cây-Dâ-Quanh " (*Bruguiera* sp.). — This tree is from 8 to 10 m. high, with an average circumference of 0.30 m. The trunk is clothed with small branches, that wither as the tree grows. It grows very rapidly, attaining its industrial development in about 10 years.

The bark is used for dyeing purposes by the natives, and is therefore transported by the Sadec, Vinhlong and Cantho. At the present time, this wood is the dearest and the most-prized for local consumption. Its content is high. It is used for fishing-stakes, being considered very resistant to the action of water ; and also for fuel. The tree is exploited very wastefully by the natives who strip it of its bark while it is still standing ; they do not even trouble to take all the bark, the rest remains on the trunk, where it dries and is wasted. Further, in the majority of cases, the wood itself is spoilt, and many dead trees, in all degrees of decay are met with, which proves that this method is by no means recent. This explains why trees of little value which are never interfered with, are gradually taking the place of those that have been so barbarously destroyed. It may be reasoned that more than one third of the Cây-Dà-Quanh trees have already been killed in this manner.

II. " Vo-Duoc " (*Rhizophora* ?) and " Vo-Già " (*Bruguiera* sp.). — The information respecting these trees is of two kinds :

1) The Chinese tanners consider that drying decreases the value of Vo-Duoc bark, whereas it has no effect upon the bark of " Vo-Già " ;

hence they insist upon the former being consigned to them in a fresh conditions, though they have no objection to the latter being dried.

2) These two tannin-yielding trees are used very wastefully by the natives of the Camau district, who leave a large portion of the bark upon the tree (note what has already been said on this subject in the case of the Cây-Dà-Quanh).

The authors have investigated the statement of the Chinese tanners, and have tried to ascertain whether the natives have any industrial reasons for only exploiting the trees of such a restricted zone. They have also, begun to study the value of the wood of these two *Rhizophoraceae*.

The authors have also analysed bark samples before and after drying, in order to ascertain the effects of desiccation. In the case of Vo-Duoc bark, the loss in tannin due to resin formation was 21.24 % whereas in that of Vo-Già bark, it was only 4.09 %. The results of the analyses, therefore, proved the truth of the Chinese tanners' statement.

Messrs VERNET and NGUYEN-DUC-LONG subsequently investigated the tannin content of bark taken from different parts of Vo Duoc, and found by analyses, that it decreases from the base to the top, but that the bark of the branches is nevertheless very useful, as it contains a large amount of tannin. On the other hand, there is but little tannin in the trunk bark, though that of the twigs is tanniniferous enough to pay for extraction. The wood and bark of every part of the Vo-Già, however, is of industrial value, but the tannin content of the bark varies greatly, according to the age of the tree and the part of the tree from which the bark is taken.

RUBBER GUM AND RESIN PLANTS

872 - **The Improvement of West African Varieties of Rubber.** — VAN PELT (Head of the Rubber Service of the Institut Colonial de Marseille), in the *Bulletin des Caoutchoucs de l'Institut Colonial de Marseille*, 1920, No. 1, pp. 58. Marseilles, 1920.

The defective preparation and wilful adulteration of African rubbers has caused them to have depreciated to such an extent that some kinds can find no purchasers when offered for sale.

M. G. VAN PELT, Chief of the Rubber Service of the Marseilles Institut Colonial, who was sent on a Mission to West Africa with the co-operation of the principal commercial houses of F. W. A., has returned after spending 9 months in Guinea, Upper Senegal-Niger, and the Ivory Coast. In the course of his travels, M. VAN PELT investigated the conditions of the African rubber industry, and tried to discover how it would be possible to remedy the depreciation of the product. The conclusions arrived at by this specialist are given in his report.

It became apparent that if it were in reality a question of technique, it would be necessary to study, from a general point of view, the organisation of the country and the methods of work adopted both by the Europeans and the natives. Only in this manner would it be possible to obtain the data necessary for deciding upon the best measures to advise, and to feel assured of their feasibility.

The report is divided into the following 3 parts :

A) FRENCH GUINEA : I. *The Guinea Office* ; II *Crêping*.

B) Ivory Coast : I. *The improvement of the native products :* II. *Creping.*

C) Organisation of Production.

A) French Guinea. — (1) *The Guinea Rubber Office* : Guinea rubber is a liane rubber obtained from *Landolphia*, therefore it has naturally much tensile strength and is relatively little liable to great alteration, such as stickage. This places it in a higher class than the *Funtumia* rubber which comes chiefly from the Ivory Coast.

If, like all African rubbers, Conakry " Red Nigger " has been sold at prices considerably below that fetched by plantation rubber, it must be admitted that, far from going from bad to worse, it has been able, since the serious crisis of 1914-1915, to regain a most satisfactory position on the market, and the credit of this is due to the Guinea Office.

This Office was fortunately established in time (September 18, 1918) to permit of the application of the only means by which wild rubber could continue to compete satisfactorily with plantation rubber. It aimed at giving a guarantee that all the tested rubber exported had been thoroughly sorted, and that all the badly prepared, or adulterated portions had been removed. This practically corresponded to the use of a trade-mark ensuring the quality of the rubber sold under its auspices. Before the Office was established, the rubber was tested in a very unsatisfactory manner by the Custom House Officers.

At the Guinea Office, which works under the auspices of the Conakry Chamber of Commerce, the sorting of the rubbers is based upon individual examination of all the blocks or strips, composing the more or less compact masses sent from the purchasing factories to the port for shipment. This sorting, which necessitates the complete disaggregation of these masses, is carried out by a specially-trained native staff under the direction of a European. Any consignment that is still damp is re-dried, and only sorted when all the moisture has been removed. All blocks or strips containing impurities, or showing traces of alteration, are rejected.

The rubber passed by the Office is exported in sealed sacks. The rejected rubber may be exported by the owner, but only on condition, that he pays a fine of 5 fr. per kg., and that the bags are marked " adulterated rubber. "

It may well by supposed that the effects of such severe regulations were soon shown. In the course of the first season (1916-1917) the Office rejected as much as 25 and 30 % of some consignments ; after the second year (1917-1918), the percentage of rejected rubber rarely exceeded 15 % in the worst cases, whereas in the majority of the consignments, only from 3 to 4 % were refused. In 1918-1919, the average number of rejections exceeded 3 %.

By means of very careful collection, theoretically it would be possible to obtain a much higher standard than that required by the Office, but given the difficulties of getting workers, and the apathy and sloth of the natives, the degree of purity exacted by the Office is the highest that it is possible to obtain in practice.

The Office has clearly demonstrated the superiority of the block over the strip (1), the former being more easily tested.

(1) As is well-known, the blocks and strips are obtained by the native tapper placing upon the incision small cords of coagulated rubber. (*Ed.*)

The author thinks that the working of the Guinea Rubber Office could still be improved. For this, it would be necessary to have at Conakry a working expert technical staff in close connection with a scientific staff, such as that of the Marseilles Institut Colonial. All that then would be needed would be to collect the data obtained from the examination of the rubbers in question, which could be used in classifying the products, and form a basis for improvements in the methods of preparation.

II. — *Crêping.* — So far, only the possibilities of improving rubber by different methods of sorting, or collecting it have been considered. It now remains to be considered how to put the Guinea rubbers on the market, after freeing then by mechanical means from their impurities, that is to say after crêping (1).

In a previous paper on the subject of the crêping of African rubbers, the author principally aimed at bringing forward all the conditions required in order to ensure the maximum chance of success to this operation, should it be carried out by the importers. He then points out that crêping should not merely be a means of cleaning the rubber, but a method of creating standards for wild rubber, each type being characterised by constant properties.

With a view to determining the conditions under which it would be possible thoroughly to carry out the operations necessary for the complete crêping of Guinea rubbers, the author sets forth the results to be attained:

(1) To obtain after washing, a perfectly clean rubber retaining, after the process, the maximum of its original properties.

(2) To carry out the washing, crêping, and drying, under such conditions that a pure homogeneous standard product is obtained.

If valuable results are to be obtained from the experiment, it is necessary (the details of the operations being fixed and maintained constant) never to introduce more than one variable factor at a time (for instance : duration of washing, temperature of the water used for soaking, etc.).

(1) *Soaking.* — It is necessary to determine : (*a*) The length of time necessary to soften the masses of rubber sufficiently ; (*b*) the temperature of the water in the process : (*c*) it is also well to test the acidity of the rubber when put to soak, and to find whether the alkaline soaking water has a good effect upon the rubber by causing it to vulcanise more readily (the presence of very small amounts of acid are known to retard this process).

(2) *Washing.* — The work of the " Universal Washer " must be distinguished from that of crêpe washers. In the case of each kind of rubber, the following data are to be determined : (*a*) The content of mechanical impurities and the loss on washing: (*b*) the minimum time of washing required to remove these foreign bodies ; (*c*) the best means of counteracting any bad effects produced upon the rubber by the mechanical treatment during washing, and the conditions necessary to reduce them to a minimum.

As a regards the last point, the author states that the bad effect of crêping and washing on the tensile strength of the rubber has been greatly exaggerated. This is especially the case with mixed African rubbers, that are washed some time after coagulation, whereas the plantation crêpe coagulum from the Far East is treated while yet fresh.

The mechanical process can be controlled by carrying out vulcanising tests on samples of rubber that have been washed for a shorter or longer time. Further, by referring to

(1) See *R.*, Jan., 1920, No. 119. (*Ed.*)

previous experiments on the effect of the temperature of the soaking water, it will be seen whether it is necessary to alter this factor.

(3) *Drying.* — Three factors come into play : (1) The thickness of the crêpes ; (2) The temperature of the drying chamber (this is of special importance in the case of rubbers that are inclined to stick) ; (3) ventilation (natural or artificial).

The author describes in detail all the operations to which the rubber should be subjected in the crêping-factory, viz. (1) soaking ; (2) washing ; (3) drying.

The treatment that has been proved by experiment to be the best for a given rubber, should always be applied in exactly the same manner. It is only in this way that it will be possible to create standards for rubber.

The extent of the scientific investigations required would entail the establishment of a laboratory at Conakry, which is hardly possible ; further, even the mechanical washing cannot *at present* be carried out there, as crêping is intimately connected with preliminary laboratory work.

The author states that if Conakry were selected for the site of the crêping-factory, many of the difficulties he had anticipated prior to his voyage to Guinea with regard to its installation would be overcome, as the supply of physically pure water, motive force, and labour would then constitute no difficulty.

The climatic conditions, however, constitute a very serious difficulty, especially the fact that the year is divided into a clearly marked rainy season, and a dry season. The extreme humidity of the atmosphere during the former renders it impossible to dry the washed crêpe by natural means. Unless recourse were had to special drying-apparatus, a crêping-factory could only work under favourable conditions during the 6 months of the dry season, that is to say, from November to April. The consignments of rubber arriving during this time would have to be stored until work was resumed or else shipped to Europe without the treatment the other rubbers receive.

The author has studied the question of the machinery and staff necessary for installing a crêping-factory in Africa.

Taking into account the fact that work can only be done during 6 months of the year, and at the rate of 25 working days per month, i. e., a total of 150 days, a factory with 1000 tons of rubber to crêpe (a quantity which the writer states is the average annual production of the Colony) would need plant capable of treating 6 ½ tons a day : 7 sets of machines, each consisting of 1 universal washer and 2 crêping-washers.

Another arrangement, which would obviate the use of so much plant, would be to work the factory continuously throughout the dry season, by employing 3 gangs of workers on 8 hour shifts. Under these circumstances, a factory with 3 sets of apparatus would suffice. As, however, the native staff requires constant supervision, this would entail doubling the European staff.

Seeing that the natives have to be taught their work and cannot be depended upon, the author considers that it is not advisable to carry on

the work only during the dry season and that it would be better to consider the question of installing an artificial drying-plant that would allow of operations being continued during the whole year.

All things considered it would be best, then, if the importers themselves carry out the crêping. During the time that must elapse before the operation, the scientific laboratory and the factory should be installed in Europe. Later on, when all the woking details are established and the special Staff formed, the whole plant could, if it appeared ecomically advisable, be transported to Conakry, where the rubber would be concentrated

After examining the circumstances in which it would be possible for the importers to undertake the crêping, the author considers that they would have every chance of success in starting this autonomous industry.

They would in fact find themselves in such a situation that, as regards the mechanical cleaning of rubber, they would obtain results far superior to those obtained by manufacturers in their factories.

B) Ivory Coast. — Most of the rubber in the Ivory Coast is obtained from *Funtumia*, and though there are also large quantities of the liane, *Landolphia*, similar to that yielding the Guinea rubbers, tree rubber has always taken the first place.

Funtumia rubber is inferior to that from *Landolphia*, and has less tensile strength ; a block of the former offers more resistance to stretching than a similar piece of the latter) ; its resin content is high (it may amount to from 7 to 15 %), thus needing more sulphur in vulcanising ; and it has a great tendency to stick.

Plantation rubbers caused a considerable fall in the prices of *Funtumia* rubber which reached the market in a bad condition, owing to the presence of impurities, to stickiness and intentional adulteration. So much had it depreciated that at times no purchaser can be found for the consignments.

Rubber is no longer allowed to be made up in " lump " as formerly, but has to be formed into thin blocks, or " biscuits " ; this tends to hinder fraud, but it cannot affect the sticky alteration that takes place in the rubber itself.

It was formerly supposed that the stickiness was due to microbiological action, but more recent investigations would seem to show that the alteration is caused by depolymerisation followed by the oxidation of the rubber. Before starting on his mission, however, the author had examined, at the Marseilles docks, many samples of *Funtumia* rubber from the Ivory Coast, and had found that the sticky zones seemed to be formed around imperfectly dried pockets from which the uncoagulated serum and latex had not been able to exude. This observation suggested a line of work for the experiments that he intended to make during his voyage.

In the case of he Ivory Coast, just as in that of Guinea, it was a question of directly improving the quality of the rubber by changing the methods of preparation, and of subsequently seeing whether it would be

possible and desirable to undertake the mechanical purification of the rubbers of the Colony.

I. — *The improvement of the native methods of preparation.* — It has been seen that it was the direct intervention of the trade, by means of the Rubber Office, that saved the situation, as far as the rubbers of Guinea were concerned. No such Office exists on the Ivory Coast, though it is greatly needed on account of the very bad quality of the rubber. The only measures that have been taken are: (1) The enforcement of a decree prohibiting the preparation or sale of rubber in any other form than that of "biscuits"; (2) the enforced inspection by the Custom Officers, assisted by a dealer, of all consignments of rubber on their arrival at the port of exportation. These measures proved wholly insufficient, the inspection being a mere formality, and carried out in a perfunctory manner.

The author is, however, at pains to prove that certain measures might be taken which would ensure an improvement in the Ivory Coast rubbers. Some of these have to do directly with the preparation, while the others are of a general nature.

The Ivory Coast natives coagulate the latex with boiling water, and as M. VAN PELT had come to the conclusion that no better method could be devised, he devoted his attention to improving it to the utmost, in order to obtain rubber of the best possible quality. Experiments made at the Bingerville laboratory led to the following conclusions:

(1) The volume of boiling water should be at least 4 times as large as that of the latex to be coagulated.

(2) A large number of portions of latex ought not to be successively coagulated in the same boiling water, as the accumulation of serum due to each of the previous operations greatly decreases the coagulating power of the water. The coagulum obtained from water containing a large amount of serum, is dark and is less easily stretched.

(3) The bad effects of an excessive amount of serum and water, both as regards the colour and keeping qualities of the rubber, showed that it was necessary to make the coagulum into biscuits containing as little serum and moisture as possible. This can be done by the help of a small hand cutting and stretching machine.

II. *Crêping.* — Theoretically, the need for crêping this rubber is disputable for, as *Funtumia* is a tree, its latex can be extracted in a sufficiently clean, pure condition. In practice, however, crêping is indispensable, as when the natives work alone and without any competent control, the results of their labours leave much to be desired.

The author thinks that as the climate of the Ivory Coast is even more damp than that of Conakry, any factory set up there would have to be provided with artificial drying-plant, for a factory only working during the dry season is quite out of the question.

It is necessary to begin by setting up such a factory in Europe; if, after the crêping is working properly and the results of the operation have been tested industrially, it is found that the return is sufficient to warrant the expense entailed in transporting the plant to the Colony, this could

then be done, and the whole factory might be removed to the place where the rubber is collected for shipment.

C) *Organisation of production.* — The mistakes that have been made with regard to African rubbers should serve as a warning that ought not to be disregarded in the case of the other products of West Africa. When rubber was selling at a very high price (15 to 20 fr. per kg.), no trouble was taken in its production, as no matter how inferior its quality might be, it was sure to find a purchaser.

The natives and dealers, who were often unscrupulous, cared only for the present gain, and gave no thought to the future. Is was only when large supplies of rubber reached the market, that any trouble was taken to improve the quality of the product, and it was hoped that this would be effected by the help of administrative measures. Unfortunately, everywhere, and in West Africa in particular, there is a great difference between making a decree and having it carried out. This is a commercial matter, and those interested must follow in the steps of the Guinea Office.

The author draws attention to the neglect from which other French West African products are suffering (palm-oil for instance) and states that no time should be lost in trying to improve them as much as possible. The organisation and development of production are the only means by which so-called savage countries can be made more civilised. What is required is an understanding between the traders. The commercial companies must see that their produce, rubber, etc., is properly prepared; they need competent experts and of common accord and at their joint expense, they should provide a complete technical research organisation.

It must, however, be well understood that the suggested improvement and increasing of the rubber production by means of changes in the native methods are only temporary expedients, and the real object is the introduction of systematically worked, regular plantations.

The plantation system has proved so satifactory in the East that it might be advisable, even now, to make plantations of latex-yielding trees in West Africa. This does not apply to other trees the systematic cultivation of which is still on trial in other countries.

The idea of making plantations at once raises the question of labour in Africa. By the use of machines, however, this could be supplemented to a certain extent, and on the other hand, the natives could easily be attracted to the plantations by providing them with confortable dwellings good food crops, and hospitals, etc. For these very reasons, the sanitary condition of both the European and native staffs is, as a rule, better in the Eastern Colonies than it is in Africa.

The author is convinced that the moment has come for the large African companies to take these steps. It was for the very purpose of finding a solution to the difficulties set forth above, that two of the most important of these companies the Compagnie Française de l'Afrique Occidentale, and the Compagnie commerciale de l'Ouest Africain, entrusted to the author the mission which he carried out under the auspices of the Colonial Institute of Marseilles and of which he now renders account

873 – **Coconut Milk, it is Characters, Composition and Uses.** — LAHILLE, A., in the *Bulletin économique de l'Indochine*, Year XXIII, New Series, No. 140, pp.125, figs. 1, diagrams 4. Hanoï-Haïphong, Jan. Feb. 1920.

Much has been written about the coco palm (*Cocos nucifera* Linn.); certain parts if its fruit, such as copra, have been the subject of careful study, and used in many different ways. The milk found in the cavity of the nut is certainly one of the products that has been least analysed, and therefore very little is known of the details of its composition. Wherever the coco-nut palm grows, however, the inhabitants make great use of the milk.

The author principally deals with the coconuts of Cochin-China, where there are 4 chief varieties of *Cocos nucifera*: those known as "Bi" and "Ta" yield much copra, but little is obtained from the "Luà" variety, and still less from the "Xiêm".

The nuts of the first two kinds are almost exclusively used for their milk, which is taken fresh. The "Bi" variety of coco palm bears large fruits, and is already intensively cultivated in a good number of plantations. The third variety is most grown in the provinces of Gia-dinh, Mytho and Bentré. The Xiêm variety is rather common in the provinces of Gia-dinh, Mytho, Bentré and Thudaumot. The author mentions a certain number of analyses made previously by different investigators, but the results were very incomplete and inaccurate. The new experiments required were carried out at the chemical laboratory of the Pasteur Institute at Saïgon, and the author, gives a detailed account of chemical investigation of coconut milk, which varies greatly according to the variety, the age, and the region where the tree grows, as well as according to the season, the degree of ripeness attained by the fruit, etc.

The author only devoted his attention from a practical and utilitarian standpoint to the milk of the fully-developed and unripe nuts of the Xiêm and Lira varieties, and to that of nuts with ripe copra.

1) *The coconut milk from fully-developed and unripe fruits of the Xiêm and Luà varieties.* — The average amount of directly reducing sugars (levulose, glucose) present per litre of the milk of these nuts, may be reckoned at from 50 to 55 gm. There are usually about 3.5 to 5.5 gm. of salts, consisting, for the most part, of potassium salts, sodium chloride, lime, and phosphates.

When the milk is required for drinking, it is best to select green nuts which are quite developed and have their cavity as full as possible. As the nut ripens, the milk becomes poorer in sugars, and the salts content increases, so that it is no longer a pleasant drink, and does not quench thirst. Further, if the salt taste is too pronounced, it may have other disadvantages. If good nuts are selected, and this only requires a little practice, the milk when taken in moderation is a wholesome, pleasant drink for tropical countries, costing little or nothing, and saves the use of other food. The coconut provides travellers in the bush with excellent food, and its milk affords a refreshing beverage to town-dwellers.

2) *The milk of ripe plantation coconuts.* — Copra-yielding nuts, while still green, give, like the other varieties mentioned, milk of the first quality, but as they are grown for their copra, they cannot be gathered till they are ripe. At this time, as is shown by the author's analyses, the amount of sugar falls to 20 gm. per litre, the numeral content rises to from 5 to 6 gm., and the proportion of nitrogen compounds also slightly increases. The author advises feeding this milk to stock; if used for this purpose, it must be collected in a cleanly manner and given to the animals a few hours after the nuts are opened. The coconut milk can be added to the animals drinking-water; experiments in this connection are being carried out by M. GIRARD.

The author urges the planter not to waste coconut milk, even if only on account of the potassium salts it contains. It it is not intended for the use of stock, it can be collected in vessels, and before, or after fermentation, a little slaked lime, or phosphate of lime, can be added, so as to form a mixture to be used as a manure for heveas or coconut palms.

The adulteration of cows' milk with coconut milk. — This is done more frequently than is supposed, but the fraud is easily detected by means of chemical and microscopic analysis, in the way described by the author in his article.

Coconut milk used in medicine. — From its composition, coconut milk has therapeutic properties, and is a true vegetable serum, as well as an ordinary beverage. Very interesting experiments have been made, at the Saïgon hospital, upon patients suffering from beri-beri, neurasthenia, malarial anaemia, pneumonic influenza, etc. The experiments will be resumed, but so far it can be stated that:

(1) Coconut milk taken in moderation, that is to say, to a maximum of 500 gm. daily, is not poisonous; green, fully-developed, but unripe nuts must be chosen.

(2) Coconut milk has undoubtedly diuretic properties, and seems to have a beneficial effect upon many acute, or chronic, cases if the kidneys are not obstructed.

In short, in the colonies, at great distances from well-supplied and equipped hospitals, coconut milk is most useful, as it is a medicinal solution which is easy to procure, sterile, cheap, and efficient. When removed from the nut, filtered, and sterilised in an autoclave, it will keep a long time.

Coagulation of rubber latex. — In some newspaper articles, coconut milk has been recommended as a coagulant for latex. The author has made some experiments on this subject, using 4 cc. and 6 cc. of coconut milk to 100 cc. of latex; at the end of 48 hours, however, coagulation was still incomplete and the latex was of a brown colour. With age, and in contact with air, coconut milk becomes acid, thus if the acid content at the time the fruit is opened, is 0.37 gm. per litre, it will have increased, after 11 days, to 8.88 gm. If it were used at this time, it might after

being clarified, act as a good coagulant for latex. But if the process depends upon the action of the acids, pure acetic acid, which can easily be added in the amount required, is preferable.

874 – **A Contribution to the Study of the Citronellas.** — SCHAEFFER, in *L'Agronomie Colonial, Bulletin mensuel du Jardin Colonial*, New Series, Year, IV, No. 27, pp. 65-73; No. 28, pp. 114-118, No. 29, p. 168-169; No. 30, pp. 192-208, figs, photographs. Paris, 1919-1920.

The citronellas belong to the genus *Cymbopogon* of the family Gramineae, and are plants that yield essential oils. According to Dr. P. STAPF (1), the genus includes:

(1) "Palmarosa": *C. Martini* Stapf. var. *Motia* = *Andropogon Martini* Roxb.

(2) "Ginger Grass": *C. Martini* Stapf var. *Sofia* = *A. Martini* Roxb,

(3) "Lemon Grass": *C. citratus* Stapf. = *A. citratus* D. C.
C. flexuosus Stapf
C. pendulus Spapf.
C. coloratus Stapf.

(4) "Citronella": *C. Nardus* Rendle var. *Linnaei* (*typicus*) Stapf.
C. Nardus Rendle var. *confertiflorus* Stapf.
C. Nardus Rendle var. "Lena-batu"
C. Winterianus Jowitt, "Maha-pengiri".

The author studies these different varieties successively. The cultivated citronellas are *C. Winterianus* Jowitt, or, "Maha-pengiri" and *C. Nardus* Rendle, or "Lena-batu".

He also studied the citronella in Ceylon and in Java from the standpoint of cultivation, uses, and trade. By distillation, oil of citronella is obtained, this consists of geraniol and citronnellal, which are employed in perfumery and soap-making, chiefly on account of the strong rose scent of the geraniol. After distillation, the citronella stalks are used as fuel in steam-generators, and can also be made into paper.

The cultivation of citronella is much to be recommended on account of the growing demand for geraniol, and the many ways in which citronella oil is employed. The best variety to grow is "Maha-pengiri", as the oil it yields is of superior quality. This plant requires a very hot, damp climate, and a rich soil. The cultivator must have plenty of labour at his disposal if a paying cropisto be obtained.

The French colonies, thanks to protective duties (which amount to an actual bonus of 1 fr. per kg.), could cultivate citronella to great advantage for the purpose of supplying the Paris market with essential oil.

---

875 - **The Colas of Indo-China.** — VERNET, G., NGUYEN-VAN-LIENG and NGUYEN-DUC-LONG, in the *Bulletin agricole de l'Institut scientifique de Saïgon*, Year II, No. 5, pp. 151-156. Saïgon, May 1920.

The variety grown in Indo-China is *Cola nitida mixta*, for it has only 2 cotyledons, and its seeds are red, white or of various intermediate shades (1).

Different Indo-Chinese Agricultural Stations have possessed some of these trees for a long time, but as they are few in number, they have hitherto only been used as a source of seed, or cuttings when required. Planters have naturally hesitated to cultivate the plant on a large scale, as it has no certain future before it.

There are, so far, no regular Cola plantations in the country, though on many concessions there are sufficient trees for the fruit to serve as a basis of a certain amount of trade.

All soils do not appear to be equally well-suited to *C. nitida ;* thus, at the Honghiem Experiment Station, the average yield in 1916 was only 6.45 kg. fresh nuts per tree, although their caffeine content was very good.

Some of these trees exist at Suõi-Giao, in the plantations belonging to the Pasteur Institute, but their yield has always proved extremely irregular, and whereas certain of them have borne large crops, others are completely sterile. Some trees that fruited regularly hitherto, now produce much less, owing to their having been gradually buried in the midst of a hevea plantation, where the thick shade prevents the fruit ripening.

If, however, the crops at these two Stations are unsatisfactory, this is not the case everywhere in Indo-China, especially on certain red soils of Cochin-China. In fact, M. GIRARD planted 11 cola trees on his concession at Suzannah in 1913 ; they are now 7 years old, and although all the crop has not yet been gathered, they produced between November, 1919, and March, 1920, 418 kg. of fresh nuts, i. e., 38 kg. per tree.

The authors deal solely with nuts from the Suzannah Station (2) supplied by M. GIRARD.

The size of the fruit and the nuts is very variable. It can be said that, as a rule, the fruits that ripen first, and those gathered at the height of the season, are finer and contain larger kernels than the late ones. Generally speaking, the finest fruits have the largest kernels. Sometimes, owing to the abortion of some of the ovaries, each fruit has very few kern-

(1) In his article " Etude sur les kolatiers du jardin économique de Singapore " M. E. MATHIEU writes in *The Gardens Bulletin of the Straits Settlement*, Nov. 11, 1918 : " *Cola nitida* includes those trees having only 2 cotyledons and *Cola acuminata* those with more than 2 cotyledons. The kernels or " nuts " of the cotyledons trees are considered the best ; the natives of West Africa (who are great consumers of cola nuts), prefer them to those borne by trees with more than 2 cotyledons ."

3 varieties of *Cola nitida* are known, viz., (1) *C. nitida alba* with white kernels ; (2) *C. nitida rubra* with red kernels ; (3) *C. nitida mixta* which both white and red kernels. (*Ed*).

(2) Mention has already been made in the *Review* of the fine hevea plantation at Suzannah. See *R.*, Feb., 1919, No. 205 and Jan., 1920, No. 50. (*Ed.*)

els, but these grow to a great size, and are larger than the finest usually produced.

The greatest variations observed by the authors in the weight of the seeds was between 8.2 and 43.3 gm. in the case of fresh specimens, whereas the weight of the fruits varied between 256 and 631 gm.

The white pulp surrounding the seeds contains nearly 9 % of sugar, from which by fermentation, about 4 % of absolute alcohol can be obtained.

Hitherto, the cola nuts are the only part of the fruits regularly used, e. g., in medicine in the preparation of different extracts and wine. In the country where they grow, they are much eaten by the natives, and they enter into the preparation of different European food products, after being mixed with sugar, chocolate, various kinds of flour, etc.

In the manufacture of alcoholic extracts, the dry powdered seeds are extracted with 60 % alcohol, and the extract thus obtained is concentrated until one litre of the solution contains an amount of extracted matter corresponding to 1 kg. of dried seeds, or in other words, until this alcohol contains 12.5 % of dry extract (Codex 1918, and Dr. BRISSEMORETS' formula).

When fresh fruit is used containing 40 to 50 % of moisture, more highly concentrated alcohol may be added ; in such a case, the authors used 75 % alcohol.

The following two analyses will give an idea of the high content of cola nuts from Cochin-China :

Analysis No. 2303.

1) Matter extracted in a Soxhlet in 75° alcohol	15.34	% of dry nuts
Ash of extract	0.32	»
2) Matter extracted in a Soxhlet in 75° alcohol	13.11	»
Ash of extract	0.27	»

Analysis No. 2306.

Colouring matters and not estimated		4.120
		100.000

In the same fruit, sometimes the dark seeds, and sometimes the lighter ones, are the richer in alkaloid, so that, there is no correlation between the colour of the seed and its caffeine content.

Cochin-China cola nuts have a very good average caffeine content, and the authors found that it varied from 1.19 to 2.39 % of the dry nut, whereas the powdered nut of commerce contains from 1.25 to 2.2 %.

With a view to the utilisation of the nuts grown in Indo-China, the authors suggest that the concentrated alcoholic extract should be made on the spot, instead of sending the dried fruit (which may become mouldy on the voyage) to Europe. In this way, products with a finer flavour would be obtained.

According to the researches of GORIS and ARNAULD, a portion of the caffeine is combined with the red colouring matter of the cola nut, and this organic salt splits up progressively in the organism. To this peculiarity is due the prolonged action of caffeine when used in this form.

Messrs GORIS and ARNAULD have also shown that this organic salt disintegrates gradually during the drying of the cola nut under the influence of a special diastase that is present. It was for the purpose of preventing the disintegration that the idea was entertained of destroying this diastase before the nuts were dried, so as to preserve all the original value of the product. They advised that the nuts should be exposed in an autoclave for some minutes to the action of a temperature of 105°C, or else immersed for a few minutes in boiling 90 % alcohol. These investigators also prepared their "intraits" (1) of cola by treating the freshly-ground nut with 90 % boiling alcohol.

876 – **"Tam Thât" (*Panax repens* (?)) a Medicinal Plant Serving as a Substitute for Ginseng.** — CREVOST, Ch. in the *Bulletin économique de l'Indochine* Year XXIII, New Series, No. 140, pp. 107-110. Hanoï-Haïphong, Jan.-Feb., 1920.

Tam-Thât should be very carefully examined in order to settle its botanical identity, many different opinions having been held on the subject. It appears that the plant has been correctly determined as *Panax repens* Max., an *Araliaceae* of the same order as ginseng.

Its rhizomes yield a medicinal substance said to be the nearest substitute for true ginseng (*Panax Ginseng* Ness.), which has a wide-spread reputation as a tonic stimulant and aphrodisiac, which builds up the strength of convalescents, and especially of women after childbirth.

The author deals with the cultivation of "Tam-Thât", and the trade in its rhizomes. He has reached the following conclusions :—

Being a long-lived plant, it cannot be grown in high latitudes as easily as an annual like the opium poppy ; for this reason, it can only be cultivated by well-to-do persons, and would not suit most of the mountain peasants. Nevertheless, it would be worth while cultivating it more intensively in those high districts where it has already established itself to some extent, and substituting it in a considerable measure for the

(1) "Intraits" are solutions containing vegetable principles in the same chemical condition as those found in the living plant. (*Author's note*)

poppy. This has been done to a certain degree in Yunnan, so that there is nothing to prevent the same course being adopted in Tonking. The product, like ginseng, is a panacea and not a drug for the cure of any specified disease, but no doubt, it would be used in Europe. Even if it found no market there, howevever, its intensive cultivation in Tonking would still be advisable, the only disadvantage to be foreseen being a possible fall in the price of the rhizomes, but this is a fate that awaits many other crops.

877 – **The "Primativo di Gioia" (Early Gioia) Vine.** — Musci, G. and Sannino, J. A., in the *Rivista di Ampelografia* Year I, No. 2, pp. 1-5, figs 1. Alba-Livorno, January 15, 1920; No. 3, pp. 36-37, February 1, 1920; No. 4, pp. 49-51, February, 1920. VINE GROWING

Prof. Sannino gives an exhaustive summary of the monograph written by Prof. G. Musci (Royal Technical Delegate, Director of the Bari Consortium for the Protection of Vine-Growing); and appends some short observations.

"Primativo di Gioia" is a vat grape which appears on the Italian market during the last 10 days of August. This vine, which is also known simply as "Primativo". or "Primaticcio", belongs to the hilly zone of the districts of Gioia del Colle and Santeramo, which is composed of the spurs of the Murge, the lower slopes losing themselves in the rich alluvial plain of the Matine. On these hills, which rise from 400 to 500 metres above sea-level, it finds the most favourable conditions of growth, for the number of calories necessary for ripening its fruit is considerably less than that required by the other varieties cultivated in Apulia.

"Primativo" grapes are largely imported into France, where the must is mixed with that obtained from local grapes, because it imparts to the wine a bouquet much resembling the flavour of certain French wines.

Nothing is known of the origin of this vine, but some persons have regarded it as a degenerate Burgundy Pinot, and others have identified it with the Cesanese vine, but Sannino has pointed out that there is a great difference between the leaves of these 3 vines. As Pulliat observes, in "*Mille variétés de Vignes*", the Gioia "Primativo" much resembles a black Piedmontese "Dolcetto". The researches of Musci have revealed that towards the end of the XVIII century, a vine was selected at Gioia del Colle which was more adapted than the others to red soils ("terre rosse") (1) and should produce early abundant, and

(1) This earth is rich in hydrated sesquioxide of iron mixed with varying proportions of clay and at times silica, but rarely lime. It is formed beneath the upper layer of soil and is derived from the disintegration of the compact limestone on the subsoil. Although this red earth is sometimes more then 80 cm. thick, it is often much less, and occasionally thins out altogether, in which case, the compact calcareous rock of the subsoil in exposed. The limestone is traversed by conchoidal fractures in some places; the strata are usually 1 m. thick, and are either horizontal, or slightly inclined. Occasionally, intercalary beds of a few centimetres thick occur, but as a rule, the rock is uniform, showing no signs of stratification. This red earth belongs to the cretaceous, and as has been shown by De Giorgio it corresponds to the "terra rossa" of Frioul, the Carso, and Albania. From the lithological and stra-

excellent grapes. It is owing to its early ripening that this vine was named " Primativo ". From Gioia de Colle, it spread throughout Apulia, and was grown a little in Basilicata. If its identify with Dolcetto can be proved, the " Primativo " variety is the vine most cultivated in Italy.

The Gioia " Primativo " has the following chief ampelographical characters :—

Stock rather vigorous ; habit upright.

Shoots of average length and diameter; internodes short, striated, and wine-coloured, the tint becoming darker near the nodes. The latter are regular, and bear average-sized, prominent, spherical buds ; tendrils few and bifid.

Buds downy, green, and bordered with red.

Adult leaf of average size " five-lobed, upper surface rather bright green, not glossy, smooth, flat, supple and glabrous ; the lower surface is pale green, rugose, and covered with thick down ; petiolar sinus deep, rounded, forming a V. Dentation consisting of one series of irregular, slightly-bent, unequal, sharp teeth. Veins raised, inclining to red in the centre, tomentose on the lower surface.

Petiole $^3/_4$ length of median vein, thin, thickening at base, grooved throughout its length, tinged with red, forms a right angle with the lamina. In autumn, there are red patches on the leaves ; the latter fall early.

Bunch of average size, cylindrical with long wings. Stalk green, penduncle short, slender, herbaceous, woody at base, pedicels short, average, green ; brush of average size, white. Grapes usually small, round and dark-blue, with thin, glossy, delicate skins, rot easily. For this reason, grape-sellers knowing that " Primativo " does not carry well, send the pressed grapes in tanks or barrels.

Pulp. Soft, fleshy, very ripe, with very sugary juice, a pleasant vinous flavour and characteristic aroma.

Pips nearly always 2 in number of medium size, long, brown.

" Primativo " is a vine that shoots late, and is therefore little exposed to spring frosts. It buds during the first ten days of April in the Province of Lecce, from April 10 to 20 at Conversano, etc., and not until the end of April or the beginning of May in the hills of Gioia, Santeramo, etc. It is fairly resistant to chlorosis, fairly immune from fungous diseases, but very susceptible to prolonged drought.

In Piedmont, " Dolcetto " buds equally late and also suffers from long drought.

---

tigraphical standpoint, it is analogous to the " bolo rosso " of Basilicata, and to the " bolo " covering the mountains of Gargano, the hills of Fasano, Ostuni, Cisternino, Locorotondo Martina Franca, Ceglie Messapica, and those of Conversano, Castellana, Putignano, Noci, Alberobello, and the Murge of Canosa, Minervino, Spinazzola, Gravina, Altamura, Santerano, Gioia, Cassano and the Serre of Galatone and Alesano. (*Author*)

Regarding *terre rosse* and other soils of Apulia, see *R.*, May, 1919, No. 560 ; July-Sept., 1919, No. 822 ; February, 1920, Nos. 293 and 304. (*Ed.*)

In Apulia, " Primativo " flowers late ; it is much affected by bad weather conditions, so that its crop there is uncertain. Cold wet springs do much harm to vines planted in deep soil which also suffer considerably in rainy damp autumns and winters. MUSCI advises bleeding, annular incision, and the application of sulphur during the flowering season, to prevent the flowers falling, and to promote the setting of the fruit. When the flowers do not fall, " Primativo " fruits abundantly. In Piedmont, " Dolcetto " is not subject to its flowers falling.

The " Primativo " grapes ripen very early : — During the last ten days of August and the first days of September along the Adriatic coast and on the Salentine peninsula ; from September 10 to 20 at Conversano, etc., and from September 20 to October 1 on the hills of Gioia, Alberobello, etc., according to the date of budding.

As the skin of this grape is delicate, it gets scorched by the sun in very hot seasons. On shallow soils (Mola, Polignano, and Monopoli) the grapes wither before they become completely ripe.

This can, however, be prevented by two extra hoeings carried out ten days before the ripening of the grapes.

The early maturity of " Primativo " is of great importance, especially in high districts where other varieties do not ripen till about the middle of October, when heavy continuous rain falls which rots the grapes, or the green berries are destroyed by the autumn frosts. " Primativo " ripens at the same time as Dolcetto and Pinot noir, which is the first period according to PULLIAT.

" Primativo " is characterised by the productivity of its side-shoots, which bear the small bunches called " racemi " by M. MUSCI. These contain more grapes than ordinary bunches when the vines are thinned, or topping before the flowering season causes the development of shoots bearing many of these bunches. In Apulia, these grapes ripen and yield a light red wine, rich in acids. M. MUSCI advises the removal of these shoot-bunches, if ordinary blending wines are required, and for this reason it is better not to top the vines.

The wine made from " Primativo " grapes is of a violet-red colour and has a vinous smell. It is difficult to make it in the hot zone of the Apulia coast, on account of the high temperature of alcoholic fermentation which produces sweet wines that do not keep well. In the cooler hill districts, " Primativo " furnishes a table wine especially if its grapes are mixed with white grapes. In Apulia , wine from the " Primativo " vines can be aged, and when very old it assumes a yellow amber colour like that of Marsala.

According to the data collected by the " R. Cantina sperimentale " at Barletta, the average sugar content of " Primativo " must is 20.65 % ; average acidity is 5.80 ‰ ; the average must yield is 74.23 kg. or 63.37 litres per 100 kg. of grapes ; the alcohol content varies from 11 to 12.6 % for grapes growing in the cooler districts, to 13-15 % and, in exceptional cases, to over 17 % for those cultivated in warm districts ; the former are

used in the manufacture of table wines, and the latter for blending-wines.

« Primativo " can be successfully grafted on the chief phylloxera-resistant varieties, as has been proved by the Directors of the Apulia Antiphylloxera Consortiums during trials lasting 15 years.

In the " Primativo " zone, the most commonly cultivated stock is Rupestris 3309, which is resistant to drought ; number of successful grafts 96 % ; growth vigorous, yield high. When Primativo is grafted on Riparia gloire and Riparia grand glabre 90 % of the operations performed in the vineyard are successful and 60-50 % of those carried out in the nursery, whereas in temperate or cold districts, the contrary is the result, especially if any forcing is used.

In Apulia, the wood of the scion on the Riparia stock grows very thick, which is a disadvantage in the case of vines without props, as they easily break off at the point of union. For this reason, Musci advises that the point of the graft should be placed some centimetres beneath the soil, and that the roots growing on the scion should be removed during digging operations.

" Primativo ", when grafted on Riparia, needs deep moist soil (" lame ") ; if the ground is too dry the graft grows little and the difference between the diameter of the stock and of the scion becomes still more accentuated.

Berlandieri Riparia 420 A is undoubtedly an excellent stock for " Primativo ". It grow vigorously in sandy clay or marl, even with a rocky subsoil, provided there are numerous crevices in the latter. Under such conditions, it proves very resistant to drought and excessive heat, its yield is regular and constant, and the grapes ripen early. During the first few years, the scion grows but little, but after the 4th or 5th year, it becomes luxuriant ; 70-80 % of the grafts made in the nursery are successful, and 90 % of those executed in the vineyard. On Berliandieri × Riparia 157-11, " Primativo " does very badly in shallow rocky soils, but succeeds marvellously on sandy clays or clay loams even if they are heavy, and also in very calcareous soils. The percentage of successful grafts rarely reaches 70 %.

When grafted on Berlandieri × Riparia 34, it the soil is deep and damp, " Primativo " is more vigorous and productive than when grafted on 420 A and 157-11, even on soil containing 60 % of carbonate of lime.

On Aramon × Rupestris Ganzin No. 1, " Primativo " does splendidly on account of its affinity to the former vine, which is also proved by its complete union on deep, moist clay loam soils with a calcareous marl subsoil very rich in carbonate of lime. The only defect of Aramon × Rupestris is that it has little affinity to " Primativo " and the Apulian vines, with the exception of " Turchiesca ", especially when the grafting is done in the vineyard. Musci is of opinion that this difficulty could be overcome by flute grafting, which has proved successful in 92 % of the cases. Aramon × Rupestris does not flourish in deep moist, rich soils, in which the " Primativo " grafts are inclined to set badly.

Mourvèdre × Rupestris 1202 which has been given up by the Sicilians on account of its lack of affinity to the local vines, is however an excellent stock for " Primativo ".

Grafted on Rupestris du Lot, " Primativo " grows extremely vigorously but rich damp soils must be avoided, as these always cause the flowers to fall. In Apulia, Rupestris du Lot prefers rocky ground with many crevices which allow the roots to penetrate deep. The scion grows fairly strongly there, and produces early grapes. On the other hand, on shallow soils, the growth decreases after the first few years, and on sandy soils, the vine suffers from drought.

Musci mentions the facility with which this stock is attacked by bramble-leaf (*roncet*), while grafts 8 or 10 years old become rachitic and weak, even if planted in suitable soil.

Rupestris metallica grafted with " Primativo " behaves in the same way as Aramon × Rupestris No. 1. The graft rarely succeeds, as is the case with the other black Apulian varieties.

" Primativo " grafted on the hybrids Rupestris × Berlandieri 301 and 219 A, and on Berlandieri × Rupestris 17-37, grows rather slowly at first, but becomes very vigorous after 3-4 years, it is always very fruitful, the grapes ripen early, and the vine is very resistant to drought. 301 A is a more productive and stronger stock than A 219, but the latter is, on the other hand, more resistant to drought and excessive heat. 17-37 is superior to both the others, especially on the shallow, rocky soils of the Murge chain.

Riparia Cordifolia × Rupestris 106-8 was abandoned without reason, for Musci's experiments in growing it on shallow sandy clay or clay loam soils proved it to be an excellent stock, the grafted vines being very strong and productive.

878 – **Hybrid Vines for Table Grapes.** — Pée Laby, in *La vie agricole et rurale*, Year 9, No. 19, pp. 325-327, Paris, May 5, 1920.

The following is a list of the vines which the author thinks produce the best table grapes.

First of all comes *Seibel* 5279, surnamed *Aurore*, because its fruit ripens very early about 15 days before Chasselas. The bunches, of an average weight of 150 gm., are composed of grapes about 16 mm. in size ; their skins are of a fine golden colour, they are very juicy, sweet, and have a pleasant aroma When ripe, however, their pulp is not firm and this, together with the thinness of their skins, renders them unsuitable for exports. They have many good qualities to compensate for this one defect. No. 5279 is immune to mildew and oidium. In 1915 and 1917, without any copper treatment, they resisted all fungoid diseases.

This vine is also very vigorous, it grows on its own roots in good soils, and adapts itself well to the various stocks in general use. It is said to be a little susceptible to time but this, however, the author has had no opportunity to test.

It is very productive, bearing 3 or 4 bunches on each side-shoot. It buds in the second period.

The wine remains sweet for a long time, it lacks the acidity necessary for normal fermentation, and could therefore be used in making dessert wines.

Seibel 5279 thus produces excellent table-grapes, but they have to be consumed where they are grown.

Seibel No. 2653 bears such attractive golden grapes that they are known under the name of *Flot d'or*. Unlike those of *Seibel* 5279, they are firm, though equally sweet, a little larger and slightly ovoid in shape. They ripen late in the first period.

The chief defect of this hybrid is that it is apt to *millerander* in too damp places. In a well drained soil, and with age, this trouble can be overcome.

It is very easily protected from disease, since 2 sulphatings are ample; it is almost immune to oidium. All it needs is one good application of sulphur at the right time. This hybrid can well be used in place of Chasselas.

Seibel No. 3013 is as susceptible to mildew as Chasselas, and must be treated as frequently. Its grapes are, however, finer.

Girerd 157. The author only recommends this hybrid for the production of table.grapes if no better can be found, for it is very susceptible to fungoid disease. Its grapes have, however, been used for the table on many occasions, especially, in 1919, when the Chasselas were destroyed by mildew. When grown on rather dry soils, the grapes of this vine can be kept fully 3 months. If required for keeping, the grapes should be gathered before they are quite ripe.

Seibel No. 5409, on the other hand is one of the cases of true hybrids needing no treatment in normal years. It has already proved its worth though not very extensively, as a producer of excellent table grapes. The bunches are of average size and round, with spherical crisp, very sweet grapes, above the average size ; their flavour is excellent. These grapes bear transport well. They ripen late in the first period.

Seibel No. 5901 resembles the former in its characters, and the quality of its grapes, which are above the average size, round and crisp, i. e., firm., and carry well. They ripen at the same time as those of *S.* 5409. Its foliage seems very resistant to mildew ; it also withstood oidium well in 1920.

Two other later white hybrids can also be recommended for supplying the table : *Seibel* Nos. 4762 and 867. They are very resistant, needing no treatment and they also have the advantage of producing grapes that ripen late in the 2nd period and can hang a long time on the vine without rotting. Hence, when the early varieties are over, these grapes provide fresh fruit without it being necessary to touch the reserve store. They also keep very well. The bunches are composed of average size berries which are very sweet and delicate.

Persons liking grapes with a musk flavour can gratify their taste by growing a recent *Seibel* No. 6102, without having recourse to the numerous

treatments required by the Muscatels of Hamburg, Alexandria, Frontignan, etc. This vine is very resistant and productive.

The author does not advise the cultivation of the following hybrids, unless they are to be looked after like Vineferas: Malègue 51-20, which has grapes of a true muscatel flavour, and No. 1897-12 of the same hybrid. The latter is a little less susceptible to disease than the former, but nevertheless needs a good deal of treatment.

The author is also very reserved on the subject of the Couderc hybrid surnamed *Muscat du moulin*; he never found it in good condition, although it had been treated several times.

As excellent and very decorative table grapes, two *rose-coloured Seibel* hybrids should be mentioned: —

(1) No. 5670, of the 1st period, with average bunches composed of firm, crisp, very sweet grapes with a delicate flavour. The bunches can hang on the vine without injury. The foliage is very resistant.

(2) No. 6090 ripening at the 2nd period; it bears splendid grapes that keep for a long time. The foliage resistance is good.

The author concludes his description by mentioning 2 black hybrids producing grapes that would grace any table. One, *Seibel* No. 4643, whose fruit ripens at the beginning of the 1st period, has average sized bunches, with medium, round, fairly firm, very sweet, high-flavoured grapes with a delicate taste.

The other *Seibel* No. 5813, is of more recent cultivation, and may be used as a substitute for Morterille, or Cinsault from South-West France, The bunches are only of medium size, but the berries are large, ovoid, and crisp, ripening during the 2nd period. They stand travelling well, and will be as useful as the grapes of Morterille for sending to countries where black table grapes are in demand. The foliage will probably require treatment with sulphate in seasons when disease is rife, but this hybrid is at all events immune to oidium, which renders it clearly superior to Morterille.

As we have just seen, Franco-American hybrids are in no wise inferior to French vines as regards the character and variety of their fruit. After those furnishing colouring grapes for blending, and the grapes used in making the ordinary red and white wines, the magnificent golden and succulent dessert grapes should be mentioned. It may also be added that grapes with a muscatel flavour suitable for making liqueurs are also to be found among the products of these crosses.

The chief reason for ranking them above the *Viniferas* is that they can easily be cultivated without many applications of Bordeaux and other mixtures, and of copper and sulphur powders, which give a bad appearance to the grapes and greatly increase the cost of production.

879 – **Vines Affected by the Frosts of April 6 and 7, 1920** (1). — Biron, M. in *Le Progrès agricole et viticole*, Year 37, No. 21 pp. 495-496. Montpellier, May 23, 1920.

The author studied the effect of the white frost of April 6-7, 1920, upon the vineyards which had suffered most. These were situated on rich

(1) For the behaviour of frost-bitten vines in North Italy see *R.*, June, 1920, No. 664. (*Ed*).

soil (ancient alluvium) on the banks of the Hérault. He summarises his observations under the following headings:

(1) *Influence of the configuration of the ground.* — The vines growing on the sloping ground bordering the river (at the height of about 1 metre above it), had not suffered at all, in most instances.

(2) *Effect of ploughing.* — The author first investigated the *gobelets bas* or vase-shaped vines, this type of pruning being the commonest in the district.

Vineyard ploughed the day before the frost.	Great damage
Surface of soil turned over	
Many clods and weeds dug in	
Vineyard ploughed (weeds high)	Great damage, but less than in previous case
Vineyard ploughed without ridges (without weeds) . .	some damage.

Vases of new shape (very short branches on high stem).

Stock uncovered	No injury observed (except on a few very low vines)
Vines earthed up 1 ridge	More or less injured, but not seriously
» » » 2 ridges	
» » » completely	
» » » with grass	
» » » without grass«	

(3) *Influence of the Vine.* — The observations refer to vines situated under the same conditions.

Bourrets	No injury
Clairettes	No injury
Carignans	No serious injury
Aramons	Serious injury
Alicantes	Serious injury
Jacquez	Buds totally destroyed

(4) *Effect of method of pruning.* — Vase-pruning: The young low vines suffered more than the others.

Vase-pruning (very short branches on tall stem): — (*a*) little injury in the case of uncovered vines; (*b*) some injury to earthed up, or grassed up vines; (*c*) vines grown on wires hd not been touched by the frost.

(5) *Effect of date of pruning* — Vines that had undergone "espoudrassage" (1) and then repruned a fortnight before the frost, were found to have suffered least.

Conclusions. — From the preceding observations, the author was able to draw the following conclusions: —

A vine suffers less from the effects of frost in proportion to its height above the ground, and to the compactness of the soil.

(1) « Espoudassage » is the system of autumn pruning, which consists in cutting out the surplus shoots and those which will be repruned in spring to a height of 50–40 cm. (See *Dictionnaire d'Agriculture et de Viticulture.* Seltensperger (*Ed*).

Other factors of equal importance are the frost resistance of the vine and its power of breaking from a second eye found at the base of the young shoot in certain varieties (Aramons).

880 – **The Figs of Smyrna.** — *The Cyprus Agricultural Journal*, Vol. XV, Pt. 2, pp. 189-190. Nicosia, April, 1920. FRUIT GROWING

Some thirty years ago only about 10 000 acres of land in the Vilayet of Aidin were planted with fig trees which gave an average crop of about 9000 tons ; to-day the orchards cover some 25 000 acres, and 23.000 tons is the medium yield. However, the cost continues to advance, but, notwithstanding this fact, the demand keeps steadily ahead of the supply. The majority of fig plantations are owned by Turkish peasants, being mostly found in the Meander Valley. The districts where the best figs are produced are Inovassi and Ortaxe. The transport is dependant enterely on the single railway line belonging to the Ottoman (Aidin) Railway Company. The quality of the Smyrna fig is superior to all other. The fruits are dried by the peasants and transported to the markets in Smyrna where they are sold to the highest bidders. Packing methods are then adopted to suit the requirements of the different countries to which they will be exported.

LIVESTOCK AND BREEDING

881 – ***Syngamus laryngeus* Parasite in Cattle and Buffaloes in India.** — SHEATHER, A.L. and SHILSTON, A. W. in *Agricultural Research Institute Pusa, Bulletin* No. 92, figs, 28. Calcutta, 1920. HYGIENE

Nearly 200 buffaloes, 100 plains cattle and 500 hill bulls have been examined by the authors. Worms (*Syngamus laryngeus*) were found in about 13 % of the buffaloes and hill bulls and about 15 % of the plains cattle, and were as a rule attached to the larynx. The maximum number of worms found on any one animal was 17 in the case of hill bulls, 24 in the case of buffaloes, and 16 in the case of plains cattle. Generally, however, only. one or two were found.

The only published account of a *Syngamus* parasite occurring in cattle appears to be that by M. RAILLIET in the *Comptes Rendus de la Société de Biologie* for 1899, p. 174.

The parasite, the morphology of which is described in detail by the authors, does not cause material damage to the animal which serves as host, as a general rule. Occasionally, however, the pharynx becomes affected, followed by congestion.

882 – **New Methods of Treating Epizootic Aphthic Fever** (1). — DE BENEDICTIS, A., in *La Propaganda agricola*, Second Series, Year XII, No. 7, pp. 93-99. Bari, April 15, 1920.

During the outbreak of epizootic aphthic fever in Italy in 1919, several methods of treating it were suggested : those proposed by Prof. TERNI and Prof. MORI (2), respectively, gave satisfactory practical results.

(1) See *R.*, March, 1920, No. 335.
(2) Abstract in *R.*, July-Sept., 1919 No. 923. (*Ed*).

Prof. TERNI advises the use of the following remedes : 100 gm. ether + 100 gm. 95° alcohol + 100 gm. physiological salt solution (0.8 gm. of sodium chloride in 100 gm. distilled water) + 15 gm. crystallised carbolic acid. This mixture is injected subcutaneously daily during the acute stage of the disease (4-5 days), and then every 2 days for 5-6 days ; from 20-30 cc. being used for large animals, half the amount for those of average size, and a quarter for small ones.

Simple sub-cutaneous injections of carbolic solutions have also given good results : 5 gm. crystallised carbolic acid + 100 gm. of physiological salt solution ; the doses being 20 cc. for large animals, 10 to 5 cc. for average sized and from 5 to 10 cc. for small ones.

The best place for the inoculations to be made is in the region behind the shoulder and in front of the stifle, and the hair should be shaved off an area 30 cm. square in order to be able to disinfect the skin with alcohol.

In very serious cases, in addition to giving these injections it is necessary to give cardiac stimulants. Prof. TERNI advises the injection of 25 cm. caffein + 34 gm. sodium benzoate + 100 gm. of distilled water, the amount used being 10 to 20 cc. for large and average-sized animals, and from 5 to 10 cc. for small ones.

The infected animal should be kept on reduced fare during the fever period, and should gradually return to its normal rations. The intestine should be kept quite free, in order to prevent the development of gaseous fermentation in the rumen and intestine due to the presence of excreta, which hinders the circulation of the blood, and fatigues the heart. In order to prevent such fermentation, especially in the rumen, it is well to give every second day a dose of sodium hyposulpite dissolved in tepid water (150 to 200 gm. for large animals, 100 gm. for average-sized and small ones).

883 – **Stomach Worms in Sheep. Prevention and Control.** — *United States Department of Agriculture, Department Circular* No. 47, pp. 1-10. Washington, D. C., Aug. 1919,

Amongst the stomach worms in sheep which give rise to serious difficulties owing to economic losses thereby entailed, must be included *Haemonchus contortus* which is common on farms in North America, particularly during wet summers. This parasite has been studied in detail by the Zoological Division of the Department of Agriculture, and although still under investigation, sufficient information has been gathered to show how affected sheep can be successfully treated, and also how to combat the parasite by means of adequate prophylactic measures.

MEANS OF RECOGNISING SHEEP AFFECTED BY " HAEMONCHUS CONTORTUS " IN THE STOMACH. — In most cases, the disease is only discovered by the death of one or more lambs, followed by a post-mortem examination. If however, the flock is under careful observation, signs of disease will be noticed on the living animals. Towards the middle of summer, or even before, dullness and general indisposition are among the first indications, accompanied with a bloodless appearance of the skin, and of the mucous membanes. The whiteness of the skin has caused the trou-

ble to be termed in some sections " paper skin ". In many cases there is a watery swelling under the jaws.

Doubt as to the cause of the trouble can be removed by an examination of the 4th stomach as anyone unfamiliar with the ailment can well afford to kill the animal in question. If the *Haemonchus contortus* is present, they can be seen, often in large numbers, wriggling around in the stomach fluids. The worm measures from ½ to 1 ¼ in. in length; it is as thick as an ordinary pin, and spirally striped with red and white. When the stomach is empty, some of the worms can often be seen adhering to the mucous lining of the stomach.

How can the Worms injure the Sheep? — The injurious action of these stomach worms may be attributed to two causes:— first, the loss of blood abstracted by the parasites, and second, the destruction of red corpuscles by a poisonous substance which is secreted by the parasites, and which passes into the blood circulation. Evidently the older sheep are more resistant to attack than the lambs. Furthermore, in the blood of adult sheep, there appear to be substances tending to neutralise the poisonous matter secreted in the parasites that are absent from the blood of lambs, or that, if present, occur in smaller quantities. Besides the direct injury caused by stomach worms, it should not be forgotten that damage may also be done by bacterial infection through the wounds made by the worms in the mucous lining of the stomach.

Treatment of Infested Sheep. — (a) *Medicinal.* Dissolve ¼ lb. of powdered copper sulphate in ¼ pint of boiling water. Add sufficient cold water to make the solution up to 3 gallons. This will make approximately 1 % solution and enough to dose 100 adult sheep In the preparation thereof, only clear blue crystals of copper sulphate should be used, and these crushed into powder each time. The following doses to be administered per head are here quoted. namely: — lambs under 1 year 1 ¾ oz., sheep over 1 year old 3 ½ oz.

For purposes of administration, is employed: (1) a strong rubber tube measuring about 3 ft. long and ⅜ in., in diameter; (2) a hard rubber, porcelain or enamel funnel at one end of the tube; (3) a brass mouth piece 1 in., long and ⅜ in., diameter, fastened to the other end. It is preferable that the end of this tube should be closed at its lower end, and holes made in the sides about the last two inches of its length.

It is wiser to apply this treatment when the animals are fasting. For the best results, sheep should not be watered for 2 hours afterwards.

While being treated, care should be taken that the liquid is kept free from the windpipe and consequently from the lungs. The animal must therefore be held horizontally and the brass mouthpiece placed in the mouth not to reach farther than the base of the tongue. The liquid should not be administered rapidly, but sufficient time allowed for the sheep to swallow comfortably.

(b) *Change of Pasture.* — Although losses from stomach worms, may in many cases be minimised by the above mentioned treatment,

it is always advisable to change the pasture and place the flock on ground free from infection.

It is wise to institute preventive measures before the infection becomes evident, in order to forestall economic loss. It is important therefore that the shepherd should know how and when infection occurs

Method by which Sheep become infested by *Haemonchus contortus* :—

a) *Infested pastures.* — Stomach worms are able to live and carry out their reproductive function only in the alimentary canal of sheep and other ruminants, and usually only in the 4th stomach.

Each female produces thousands of eggs, which pass out of the intestine in the feces and which in a few hours, days or weeks, according to the temperature, if they are not killed by drought or frost, start to hatch. The larvae are able to withstand inclemency of weather and periods of drought better than the eggs. During the larval stage, the stomach worm is active in the presence of moisture. A decrease in relative humidity causes momentary suspension in activity. In the stomach of the sheep in the course of 2 or 3 weeks the worm reaches maturity.

The length of life of a worm in the stomach has not yet been determined. Experiments have nevertheless demonstrated that 19 months after the first sign of infection, stomach worms were still found, although in limited numbers. These experiments do not prove anything definite, as there is always a possibility of reinfection developing through the feces of the sheep in question. If these experiments prove nothing as to the length of life of the adult worm, they demonstrate however the futility of attempting to rid sheep entirely of stomach worms by simply keeping them away from infested pasture.

b) *Length of time pasture may be infested.* — The maximum period during which the larval stomach worms are able to survive on pastures, or pastures on which infested sheep are grazed is not yet definitely known. It has however been found that larvae were still apparently active after nearly 8 months (October 25 till June 16). Laboratory tests have proved that larvae are still alive after 9 months (September 14 to June 5). Cultures in which the larvae were allowed to develop still showed signs of vitality after 2 or 3 months, although submitted to a temperature of 0° and even lower, while in other cultures, eggs and newly hatched worms were killed within a few hours when exposed to a similar temperature.

These observations show that the pastures may remain infected by larvae several months after sheep have been removed. They show in every case that cold hinders a spread of infection on pastures occupied by infested sheep.

There are two ways by which a pasture may be freed of infection:— 1) by excluding sheep and other ruminants for at least 1 year from previously infected fields ; 2) by turning the pasture into a cultivated field.

Methods to be employed to Prevent Loss from Stomach worms. — In seeking to find a method which will eliminate the evil effects of

stomach worms, it is necessary at present to be content with reducing the amount of infection to a minimum, and maintaining this standard.

a) *Early development of lambs.* — It has been proved that if the lambs are born early in the year and fed as much as possible before they are sent to pasture, the danger of infection will be practically negligible, as the lambs will develop into a marketable weight before the summer.

If, however, lambs must remain for several months on pasture, frequent changing of pasture will be necessary.

b) *A practicable method of pasture rotation.* — It has already been stated that a pasture occupied by infested sheep ought to be kept from use for a year at least in order to become freed from stomach worm larvae.

From 10 to 20 days, according to temperature and moisture, must intervene between the feces containing eggs, and the development of the larvae. If the sheep are moved into pasture before the eggs develop into larvae, there is no danger of infection. The practical difficulty lies in always having fresh pasture available. If the same pasture is always used it would be necessary to separate into lots, allowing the flock to be moved at least every 2 weeks, and without occupying the same ground twice within 12 months.

Ploughing the land infested, following by sowing forage crops, greatly reduces the danger of infection. This fact allows the same land to be use 2 or 3 times each year for sheep grazing. Even the lambs can stay there, and this is a distinct advantage as they may safely remain there from weaning time until the winter.

If this pasture rotation system is employed in conjunction with the treatment described, excellent results will be obtained.

884 – **Rabbit Coccidiosis.** — Vilcoq (Director of the School of Agriculture at Chesnoy, Loiret, in *Comptes rendus des Séances de l'Académie d'Agriculture de France,* Vol. VI, No. 24 pp. 609-613. Paris, June 23 and 30, 1920.

In many country places, rabbit rearing is attended with serious difficulties on account of the diseases with which the rabbit-breeder is obliged to contend. One of the commonest of these maladies is hepatic coccidiosis, popularly known as « maladie du gros vente » (swollen belly).

The infected animals gradually lose their appetite, grow thin and weak, becoming anaemic and having all the symptoms of cachexia. The abdomen swells, diarrhoea sets in, and death supervenes in from 2 to 3 months. The liver is hypertrophied, and covered with whitish or yellowish-white patches, usually of the size of a millet-seed, which occur isolated or in streaks, and contain a sort of cream-like mixture.

The disease is due to *Coccidium oviforme.* The author gives its symptoms, and speaks of the wide-spread nature of the malady and the measures adopted for its prevention. He describes the curative treatment he employed and states that the ether extract of the roots of the male-fern containing 24 to 25 % of the active principle, filicine, has undoubtedly a therapeutic effect upon hepatic coccidiosis. Although the experiments

made were not sufficient to allow of being able to give an exact prescription, the author thinks that 0.75 gm. of extract mixed with 4 gm. of sweet oil would be sufficient, in the majority of cases, to effect a cure. In his experiments, the infected rabbits were at once isolated and some oats were added to their food to make it more nourishing. After a short time, they regained strength and were on the road to recovery. The cure was complete, and the rabbits, on being killed for the table some time later, were found to be suffering from but slight hepatic troubles.

FEEDS AND FEEDING

885 – **Nitrogen Metabolism of Two Year Old Steers.** — Bull S., Grindley, H. S., in *Journal of Agricultural Research*, Vol. XVIII, No. 5, pp. 241-254. Washington D. C. Dec. 1 1919.

The authors conducted an experiment on metabolism at the Illinois, Agricultural Experiment Station, upon eight 2 year old steers, covering a period of 37 weeks. Determinations were made of the quantities of nitrogen ingested and excreted and the results are expressed in the appended Tables, and in the discussion.

The steers maintained a positive nitrogen metabolism for long periods, when receiving considerably smaller amounts of digestible protein than are usually considered necessary for maintenance.

Curves showing the nitrogen consumption, the total nitrogen excretion, the urinary nitrogen, and the nitrogen balance are more or less parallel.

Steers which received larger amounts of nitrogen stored larger amounts.

The authors state that 14.7 % of the total increase in live weight was protein. Each steer stores from 18.9 to 25.1 % or an average of 22.37 % of the protein digested. Although the various lots (2 animals per lot) were given different feeds, varying from the ordinary maintenance ration to the maximum amount readily eaten by steers and although the proportion of maize in the ration had been increased as the experiment proceeded, and that towards the end of the latter, linseed oil meal had been introduced (during the preceding part of the experiment the chief feed was clover hay) ; the differences in treatment had no effect upon the percentage of protein in the increase of live weight, nor on the percentage of nitrogen absorbed and retained. As a general rule in every case, there was a decrease in the percentages of protein stored, towards the end of the experiment, but this fact may be attributed to the advancing age of the animals.

Out of 284 nitrogen metabolism records, 5 only gave negative results, two concerning maintenance fed steers and 2 on full feed.

886 – **The Use of Weeds as Forage.** — Pouget I., in *Revue agricole de l'Afrique du Nord* Year 18, No. 51, pp. 61-63. Algiers, July 23, 1920.

Many wild plants are refused by animals when they are offered to them dry, though they are readily eaten in the form of silage. This is the case with the weeds that grow very rapidly in spring time on waste ground or on the roadsides ; they could often be used for feeding stock but at present are only rarely turned to account.

In Tunisia, Col. REBILLET has obtained excellent results with a mixture containing nettles, wallflower, sow-thistle, euphorbia, mallow, fumitory, thistles, arums, and the leaves of asphodel, fennel, etc.

In Algeria, M. BARROT, of Philippeville, collected all the wild plants which grow more or less everywhere and ensilaged them.

M. LÉVY, of Sétif, did the same, and thus obtained a large amount of additional food for his large dairy farm. The plants chiefly found in his silage are rat barley, a wild lucerne, some kinds of ray-grass, mustard, brome-grass, and species of *Leucanthema*.

When ensilaged, the food value of these plants compared well with that of ordinary forage, crops as is shown by the following analysis :—

	Unsilaged green forage	Silaged forage
	Per cent.	Per cent.
Water	75.0	76.0
Ash	2.0	3.3
Total nitrogenous matter	3.1	2.1
Fats	0.6	0.6
Cellulose	6.1	6.1
Sugars	1.0	—
Extracts (not sugars)	4.6	1.8
Starch	7.6	6.1
Butyric acid	—	4.0
	100.0 %	100.0 %

It is well known that forage always loses weight by being silaged, and this loss may here be estimated, from the increases and the ash content, at about 30 %. This loss of weight is chiefly due to the disappearance of the sugars, and the decrease in the extracted matter, nitrogenous substances, and especially the digestible nitrogenous substances (the latter

Character of forage ensilaged	100 parts of the forage contain:—								
	Crude principles					Digestible principles			
	Dry matter	Protein (total nitrogenous matter)	Fats	Nitrogen-free extract	Cellulose	Protein	Fats	Nitrogen-free extract	Cellulose
Lucerne	16.9	3.7	1.4	4.8	5.0	2.5	0.7	3.3	2.1
Red Clover (*Trifolium pratense*)	21.7	4.4	1.2	6.9	6.5	2.9	0.6	5.1	3.5
Forage of Gramineae and Leguminosae	20.0	3.4	1.0	7.2	6.0	2.2	0.5	5.1	3.3
Maize	18.5	1.6	0.8	9.0	5.7	0.8	0.4	6.2	3.2
Forage consisting of weeds	20.0	3.3	0.6	7.9	6.1	1.6	0.3	4.9	3.0

formed 2.6 % of the green forage, and only 1.6 % of the silaged forage).

In the present case, these losses are only of secondary importance, for the process transformed worthless raw material into a valuable food. Further, it is possible to reduce these losses to a minimum.

In the present case, acid silage was made, as is shown by the large proportion of butyric acid present. In making sweet silage the losses are much less. It would be of advantage, therefore, to obtain sweet silage, which can be done with certainty by adding to the mass, at the moment of ensilage, lactic ferments (such as the lacto-pulps of MM. BOUILLANT and CROLBOIS (1).

The above table giving, on the one hand, the average composition (according to KELLENER) of some silage forages and, on the other, the composition of the silaged weeds, shows that the latter is of quite the same value as the former, which consisted of cultivated plants.

887 – **The Use of Poppy Seed Cake as a Cattle Food and Its Effect on Yield of Milk and Composition of Butter.** — ANNET H. E., and SEN J. N. in *The Journal of Agricultural Science*, Vol. IX. Pt. 4, pp. 316-429, charts 7. Cambridge, Oct., 1919.

India produces a considerable quantity of poppy seeds, the greater part of which is exported, especially to France. This seeds is used chiefly for oil extraction, and the residue forms the so-called poppy oilcake. SMETHAM gives the following analyses of this oilcake :—

Water	10.15 %
Albuminoids	35.38
Oil	11.43
Carbohydrates	20.04
Woody fibre	7.90
Ash	15.10

It is generally believed that this oilcake encourages the animals to become sleepy. KELLNER considers that poppy oilcake is injurious to milk or young cattle or pregnant animals, but is suitable for fattening stock.

The experiments undertaken by the authors were designed essentially to detect any noxious properties in poppy oilcake and to determine its nutritive value ; but there were not sufficient animals for this latter purpose. One cow (Phulia) and two buffaloes (Rukminia and Lachminia) were the only available animals for the experiment.

The buffaloes received a daily ration of 20 lb. straw, 6 lb., bran, 3 lb., of pulse husks, and 3 lb., mustard cake. The cow's feed consisted of 13 lb., straw, 6 lb., bran, 2 lb. husks, and 2 lb. mustard cake. At a certain date the mustard cake was substituted by an equal amount of poppy cake and this was continued for 6 weeks.

The weight of the animals from beginning to end of the experiment did not signify any marked change : the cow showed a diminution of 28 lb., one buffalo 14 lb. and the other conserved its initial weight. The

(1) See *R.*, January, 1916, No. 109; *R.* Feb., 1916, No. 232; *R.* Feb., 1918, No. 221; *R.*, Feb. 1919, No. 257 ; *R.*, July-Sept., 1919, No. 1010; *R.*, July-Aug.. 1920, No. 802. (*Ed.*)

condition of animals was not found to be affected by the action of poppy cake ; there was no indication of the reputed action of the same in bringing about drowsiness.

The quality of the milk and butter remained the same during the whole course of the experiment. With regard to the milk yield, the cow Phulia yielded on an average 10.2 lb. milk per day during the first period (fed on mustard cake), 9.6 lb. during the second period (poppy cake) and 10.2 lb. in the third period (mustard cake). The buffalo Rukminia yielded 10.5 lb. milk per day during the first period and 7.5 lb. during the second, during the course of which she dried off. The yields of milk by the buffalo Lachminia were 13.5, 15.3 and 14.9 lb. respectively during the 3 periods of experiment. Judging these data as a whole, the feeding of poppy cake in place of mustard cake does not seem to injuriously affect the milk yield.

The average fat contents in the milk were :— 3.6,04.3,05.3 % for the cow ; 5.5 %, 6.1 % and 6.4 % for the buffalo Lachiminia during the 3 periods respectively. The buffalo Rukminia's milk contained 6.8 % during Period I, and 7.5 % in Period II. Poppy cake did not appear to have any deleterious effect on the fat content of milk.

The authors also conducted investigations as to the composition of butter fat and made determinations of refractometer values, the Reichert-Meissl number, the Polenske number and the saponification value.

The average refractometer figures at 40° C for butter fat from cow's milk was 42.3 during Period I (mustard cake ration) 40.7, during Period II (poppy cake ration), and 40.2 during Period III (mustard cake ration) The average figures for the buffalo Rukminia were the same for the Periods I and II and the variation was 0 to 0.7. The refractive index for Lachiminia for the 3 periods was 41.4, 40.4 and 40.8 respectively.

Reichert-Meissl numbers. — Butter fro mmilk yielded by the cow gave an average of 27.4, 28.7, and 30.6 at the 3 periods respectively ; 26.6 and 25.7 for the buffalo Rukminia, in Periods I and II ; 36.1, 37.4 and 36.1 for the buffalo Lachminia at the 3 periods respectively.

It may be concluded as a result of the comparison of the refractometer values and of the Reichert-Meissl numbers that, generally speaking, a fall in the refraction value is accompanied by a rise in the Reichert-Meissl number.

Polenske numbers :— Butter fat of milk from the cow had the average values of 1.8, 2.0, and 2.4 for the 3 periods ; the corresponding figures for Lachminia being 2.0, 1.1 and 1.7 respectively, and for Rukminia, 1.3 and 1.4 for Periods I and II.

Saponification values : — Butter fat of milk from the cow for the periods were respectively : 219.3, 228.3, and 228.6 ; for Lachminia, 223.6, 233.6 and 230.0, and for Rukminia, 214.6 and 222.2 during Periods I and II respectively.

The author has drawn the following conclusion : the substitution of poppy seed cake for mustard cake does not produce any ill effects. The animals readily ate the first mentioned cakes ; but the amount fed, however, was not great.

BEEDING

888 – **Reorganisation of the Normandy Herdbook.** — BERGE, R., in the *Comptes Rendus de l'Académie d'Agriculture de France*, Vol. VI, No. 18, pp. 479-484. Paris, May 19th 1920

The author laid before the Academy the new regulations, as well as the new score to be adopted in the Herdbook of Normandy Cattle which has just been entirely changed.

Since the end of 1919, the Regional Agricultural Office of the North has been engaged in re-casting this Herdbook, having been encouraged to undertake this task by the progress already made in other countries, particularly Holland, and the special conditions of breeding and using Normandy cattle.

A Commission held several meetings for the purpose of drawing up the new regulations which were finally adopted on May 8, at Caen, first at a full meeting of the Herdbook Commission, and afterwards, at an important meeting, to which had been invited a large number of the breeders from the 5 departments of Normandy.

The former Herdbook Commission had been composed of 15 members, 3 being appointed for each department by the Prefects of la Manche, Orne, Calvados, Eure, and Lower Seine. It was presided over by the Prefect of Calvados.

It was constituted a legally-recognised Association, capable of including all persons or associations interested in breeding the Normandy breed of cattle, and willing to conform to its statutes and regulations. The Association is of unlimited duration.

Its principal work is to keep a Herdbook, in which it has been decided to enter, in the case of each animal, its purity of breed, points, performance, and a well-authenticated pedigree (Art. 4 of regulations).

Article 5 states that the special objects of the Association are :— to preserve, by means of selection, the purity of the Normandy breed of cattle ; to contribute to improving their performance as beef and dairy animals ; to encourage the rearing of stud cattle for breeding purposes, first in Normandy, then in other suitable parts of France, and finally abroad. Severe penalties are to be imposed upon any member, who by wrongful action, shall do anything to hinder the progress of the work of the Herdbook Association.

The Association is administered by a Council consisting of :—

1) Fifteen members (3 for each of the Departments of Normandy) elected for 3 years by the General Meeting ; one additional member shall also be nominated annually for each of these Departments by the General Meeting.

2) The President of the Regional Agricultural Office of the North, or his deputy.

3) The President of the Regional Chamber of Agriculture of the Departments of Normandy, when appointed, or his deputy ;

4) The 5 Directors of the Agricultural Services of the Departments of Normandy, or their deputies, Professors of Agriculture.

One third of the 15 members nominated are eligible for re-election every year. The subsequent article of the regulations fix the composition of the Committee, which is nominated by the Council, and define the powers of its members, the nature of the resources of the Association, and provide that if it should be dissolved, its funds shall be devoted to the improvement of the Normandy Breed of Cattle.

The Score gives the scale of marks awarded for purity of breed, points, performance, and pedigree.

It fixes the standard of the breed.

Two classes of animals are at present registered :— (1) Those admitted on their own merits (breed characters and points) ; (2) the offspring of parents already entered in the Herdbook.

From a date to be fixed by the Council of Administration, only the progeny of cattle already registered will be entered.

The chief innovation that has been introduced into the Normandy Herd-Book is an Advanced Register (*Livre d'Élite*), in which may be entered by order of the committee: —

(1) Bulls and cows having at least 2 generations of ancestors registered in the Herdbook, and which themselves have all the pure-bred characters, and have been prize-winners at general shows or special shows for Normandy cattle.

(2) Breeding animals which are considered by the Registration Committees as of exceptional merit, especially pure-bred cows, with very good points, having produced (according to the figures of the Syndicates of Milk Control, achnowledged by the Committee) larger amounts of milk and butter than those fixed annually by the Council.

Great care is taken in the registration of the offspring. Each owner of a registered bull is given a book of forms with counterfoils, in which to enter the services of the animal.

When a registered cow is served by a registered bull, the owner of the former sends, within 6 months of the date of the last service, a certificate of the service made out on one of the forms of the book.

During the week following the birth of the calf, the owner, on his own responsibility, sends to the Herdbook Committee the birth-certificate of the animal, together with a fairly detailed description, mentioning especially the markings and patches of colour on its face and cheeks.

As soon as this certificate reaches the Herdbook Committee, the latter appoints an Inspector to investigate the correctness of the information furnished.

These Inspectors are chosen preferably from the Inspectors of the Dairy Syndicates, the Members of the Breed Syndicates Committee, of Mutual Cattle Insurance Societies, or of other Associations. They can also receive a salary which is fixed by the Council. In addition, the Council has also the power of assigning the work to one or more Inspectors appointed by the Herdbook Association.

Animals thus recognised are entered on the merits of their lineage.

In the case of each registered animal, there is provided a separate

numbered sheet stamped by the Herdbook Committee, on which the owner writes the pedigree of the animal, notes regarding its points, prizes obtained at Shows, and in the case of cows, the results of the tests of its milk and other dairy produce, and the destination to which they are sent.

Then come some regulations of a general character, of which the following are worthy of mention :—

Markings. — The animals shall be marked in a certain special manner by tatooing in the inside of the left ear.

The breeder is required to send a photograph to be put in the Advanced Register.

Certificates. — Registration certificates for animals to be exported shall be granted under the auspices and control of the Ministry of Agriculture, and of the National Society for the Encouragement of Agriculture. A clear distinction shall be drawn between Herdbook certificates, and Advanced Register certificates.

Publications. — The Council shall publish a periodical Bulletin, as well as notices and monographs respecting the best animals, and the best herds of the Normandy breed. The former Herdbook Committee has bequeathed all its property to the Association which has superseded it, and which will enter on its registers all the animals already entered on the Normandy Herdbook.

889 – **Herdbooks.** — DECHAMBRE, P., in *Comptes Rendus de l'Academie d'Agriculture de France*, Vol. LI, No. 20, pp. 498-505. Paris, May 26, 1920.

A report made in the name of the Section of Animal Husbandry (*Section d'Économie des Animaux*) upon a paper by M. De LAPPARENT entitled "*Les livres généalogiques*". The Association supports M. De LAPPARENTS' suggestion, and recognises that for the progress of stock-breeding, it is not only of advantage to have Herdbooks for all kinds of animals, but that it is necessary to institute them in France with as little delay as possible.

Breeding must be intensified, in order to make good the deficit due to the loss and slaughter of stock, but attention should also be paid to increasing the individual yield, in order that greater productivity may be obtained with fewer animals. In fact, the increase in individual yield is perhaps a more important and efficacious factor than the actual multiplication of the number of head.

This leads to an expression of opinion regarding the general organisation of stock-breeding methods in France.

The creation of a strong organisation to supervise and direct stock-raising in France is the only means of thoroughly and systematically improving it. The Section is of opinion that a Stock-breeding Department (*Direction d'Élevage*), or if preferred, a Department of Animal Industries, should be established at the Ministry of Agriculture, having under its jurisdiction all matters relating to foreign trade in domestic animals, their breeding, exploitation, feeding, improvement, and hygiene. Further, that this Department should work on the lines adopted by the

Bureaux of Animal Husbandry in the United States, and that it should be called upon to give a strong impetus to all branches of stock-raising.

While awaiting the creation of this organization, and in order to prepare the way, it would be well to appoint a Chief Stock-breeding Council (*conseil supérieur de l'Élevage*) to study all questions, which like that of the institution of Herdbcoks, are certain to have a decisive influence on the raising and yield of the various races of animals.

The Section of Animal Husbandry (*Section d'Économie des Animaux*) thus proposes that the Academy shall adopt the following resolutions :—

(1) That herdbooks shall be instituted and extended as rapidly as possible.

(2) That the period during which so-called original entries are permitted shall be brief, that is to say, 5 years.

(3) That these herdbooks shall only be used for well-defined breeds and those of real economic importance.

(4) That the statutes shall provide for the severe control of the births and the careful marking of the animals.

(5) That the juries of the itinerant shows, who are already qualified for judging bulls, shall always conclude several members of the Herdbook Committee that are especially entrusted with the task of pronouncing upon the admissibility of the animals shown. No animal may be entered on the herdbook that has not the minimum marks required by the said Committee.

(6) That, to insure the systematic improvement of the stock, stock-breeding must be thoroughly organised in France by means of the creation of a Bureau of Animal Husbandry.

M. R. BERGE states that all the opinions expressed by the Section of Animal Husbandry and formulated in M. DECHAMBRE'S report, are already realised in the new Statutes and Regulations of the Committee of the Normandy Herdbook (1).

890 – **Native Horses and Cattle in China.** — LEVINE, C. O. (Canton Christian College), in *The Journal of Heredity*, Vol. XI, No. 4, pp. 147-155, figs. 4, bibliogr. of 13 works, Washington, D. C., April, 1920.

HORSES. — Horses, donkeys and mules have been little used in China, except in the northern and western provinces, where they are used almost exclusively as pack animals and for riding.

The southwest and western border of China and Tibet is the native home of the Chinese pony, which is known under the name of Tibetan or Chinese pony.

Up to the present time no horses have been raised in Kwangtung. Horses have been imported chiefly from Yunnan. The Tibetan pony is excellent for this region where it thrives well in this climate ; its somewhat small size (it usually weighs about 500 lb.) is well suited to the narrow roads and the steep gradient bridges. It appears to keep quite free

(1) See No. 888. of this *Review* (*Ed.*)

from diseases and unsound constitution; the better horses are intelligent and easily trained, provided they have not been improperly handled. They have colours common among other horses: black, white, sorrel, bay, tacheté, grey, white, iron grey, with bay predominating.

The Mongolian horse is quite common in the north of China. It is considerably larger than the Tibetan pony, weighing about 700 to 800 lb., or more. It is supposed to be the ancestor of most of the modern breeds of horses. It is raised in Mongolia in a semi-wild manner. It is strong and swift, fairly free from diseases, but does not succeed well in Southern China. It is the horse used in the annual races of Shanghai and Hongkong; in Canton there are only about 50 as compared with about 250 Tibetan ponies.

In Canton the demand for horses is rapidly increasing. The usual concentrated feed for horses consists of maize, cooked rice (this is used also for other classes of livestock), wheat bran and roughage such as green grass and straw, which are usually cut up before feeding.

CATTLE. — Shantung, Chihli and Honan provinces in the north, and Szechwan, Yunnan and Kwangsi in the southwest, produce cattle in the largest numbers. Estimates would place the number of native cattle at 50 million at least, and the average value of these at $30.00 (Mex.) a head. The export of cattle from China is small, but is ever increasing; from 1915 to 1919, exportation has increased from 1000 to 100 000 cattle per year.

Shantung is one of the biggest cattle producing provinces in China.

Generally speaking, the Shantung cattle are large in build. The ox usually weighs from 600 to 1000 *catties* (1 catty = 1.33 lb.), and has well developed loins and limbs which lends the form an almost rectangular shape. According to a native, a German missionary imported cows of a foreign breed with which he undertook the improvement of cattle in this locality; this was the origin of the present day cattle. The fact which demonstrates that the Shantung cattle are an improved type is the comparatively thin hide, and what is more, the tendency to early growth and fattening. A large number of cattle now in Shantung were introduced from Honan. Although they are called Shantung cattle, there is no doubt that they originated in Central China; they have gradually migrated eastward from Honan, Shonsi, Shansi, and Kansu, which are situated in the centre of continental China. The Yellow River which passes through these territories, makes the vicinity of its watercourse unfit for cultivation owing to the tremendous overflow of the river which takes place annually; the district forms as a result, one vast pasture land of thick weeds, and the thriving industry of cattle raising is noticeable.

Usually, a farmer keeps from 5 to 6 cattle which when not at work are turned loose on the fields. These are fed twice a day, morning and evening, and the feed consists of about 21.28 lb., + 5.32 lb., of mixed feed (" Kaoliang ", i. e. sorghum, beans and other similar feeds, mixed with cut straw or hay). In the working season they are fed twice more per day, at noon and in the evening. The straw fed is generally millet;

but wheat straw is also employed. In some places, dry peanut stems and sweet potato vines are used. As cattle for beef, Shantung breeds are far better than Korean or Mongolian cattle. At the time of the German administration in Tsingtau, distinct efforts were made to improve the cattle.

The methods of raising and feeding in Shantung are the same as those generally employed in the whole of China. The feed, however, differs according to the locality. In the Canton region the grain fed is usually cooked rice and wheat bran. The cattle in this region are not as large as those in Shantung; the average cow weighs 665 lb., the bull 1064 lb., and in exceptional cases have been noted to weigh as much as 1330 lb. when fat.

In southern China, the cattle consist of the so-called Zebus, but the hump and the fetlock are less developed compared with the Indian species; the females only have a comparatively insignificant hump.

The colour of the Chinese cattle varies from yellow red to a brown red and almost pure black; white and spotted cattle are rare because the meat in these two cases is considered inferior. The amount of milk obtained is so small, that the cows are seldom used for this purpose; the fat content is very high, varying from 5 to 8 %.

On the Hongkong market are found:— zebus from the region of Swatow (Kwangtung) much appreciated as beef stock. The second place is occupied by those from Wuchow and the third by those from Canton. Cattle are sold by the head, and not by weigt, at the rate of $28 to $50 (Mex.) for one zebu weighing from 600 to 800 lb.

The hills and mountain regions of China now being utilised only for wood fuel purposes will furnish sufficient pasture for at least wtice as many cattle as are being produced to-day in China. With the present prices paid for milk in this country (12 to 18 cents local currency per lb.) and for butter ($1.20 per lb.), there are few industries that offer better opportunities than the breeding of dairy cows.

The buffalo in China has been chiefly employed as a draft animal and later to be used for beef. In recent years in the south of China, the buffaloes have begun to be used for milk, and there have actually been cases of animals that give more than 12 lb., of milk per day, containing from 10 to 15 % fat. Six buffalo cows raised at the Canton Christian College have produced an average of more than 250 lb., of butter fat, during a complete lactation period.

Out of the 3 methods of cattle improvement namely: selection within the breed; mating with outside improved breeds; introduction of pure bred animals and continuing to breed them pure; the first method is safest, but a somewhat slow process. The crossing of the zebu with European breeds attempted in the Philippines and in India has not proved popular; the cross produces better beef cattle, but lacks the hump, which is so well adapted for the yoke, and has less value for work purposes.

The introduction of pure bred European stock encounters numerous difficulties, especially with regard to sanitary conditions; if practised,

care must be taken not to introduce tuberculosis into China. The native cattle are highly resistant and some of the buffaloes are apparently immune to this disease.

CATTLE

891 – **Inheritance of Colour in Jersey Cattle.** (1) — HOOPER, J. J. in *The Journal of Dairy Science*, Vol. II, No. 4, pp. 290-292. Baltimore, July, 1919.

The author consulted the Registry books of the American Jersey Cattle Club, and tabulated the colour markings of 1145 calves male and female, and of their sires and dams. These indicated that the following were the dominant characteristics ; 1) solid colour over mottling ; 2) black tongue over white ; 3) black switch over white. There was a marked tendency towards the combination of the charcteristics solid colour, black tongue and black switch. The roan colour which was hitherto fairly common amongst Jerseys was apparently dominant to the ordinary colour.

892 – **Calf Feeding Experiments with Crushed Oats and Whole Oats.** — *Department of Agriculture and Technical Instruction for Ireland*, Vol. XX, No. 2, pp. 201-204, Dublin, 1920.

These experiments were carried out with a view to determining the comparative value of crushed oats compared with whole oats fed to calves in conjunction with separated milk. Previous experiments showed good results from a mixture composed of 1 part ground flax seed, 2 parts maize meal, and 2 parts oat meal. Variations were introduced later, in order to obtain a more economical mixture, In more recent trials, it was found that calves can be reared successfully by feeding the separated milk alone and supplying crushed oats and whole oats.

With the idea of controlling this method of feeding during 1918 and 1919, experiments were conducted at 21 centres. At each centre two lots of calves were selected of uniform size, and 1 lot was fed on separated milk supplemented with crushed oats, and the other on separated milk + whole oats. The total number of calves included in the test was 140 and the experiment extended over 122 days ; the average age of the calves at the commencement of the test was 6 ½ weeks.

Details regarding the live weight increase of both lots of calves on similar rations are given as follows :

Lot	No. of Calves	Average weight at beginning	Average weight at close	Average increase in 122 days	Average daily gain
		cwt. qrs. lb.	cwt. qrs. lb.	cwt. qrs. lb.	cwt. qrs. lb.
Lot I - Crushed Oats.	70	1 0 16	2 2 11	1 1 23	1.34
Lot II - Whole Oats	70	1 0 18	2 2 10	1 1 20	1.32

The difference in the results obtained from the 2 groups of calves is almost negligible, although there appears to be a slight tendency in favour

(1) See *R.* Jan., 1920, No. 81. (*Ed.*)

of the group which received crushed oats. At one centre only, the use of whole oats caused digestive troubles, and at another great difficulty was experienced in getting the calves to eat this food. When whole oats are fed to young calves, the quantity given at the commencement should not exceed 2 oz. per day, and should be increased gradually.

The following useful conclusions may be drawn : the cooking of meal is not necessary, and calves can be reared economically and successfully solely on foods produced on the farm ; where facilities are lacking for the crushing or bruising of oats, whole oats may be given instead.

893 - **Yield and Composition of the Milk of the Moroccan Cow.** — LEROY, A. (Préparateur de Physiologie, at the National Agronomic Institute), in *L'Agronomie Coloniale, Bulletin mensuel du Jardin Colonial*, New Series, Year IV, No. 30, pp. 177-186 + figs. 2. Paris, May-June, 1920.

In Morocco there are 1 200 000 head of cattle, among which we may reckon nearly 250 000 cows producing milk every year.

These animals, which are of small size (1.20 metres high at the withers), seem to belong to two distinct types, one with fawn coat passing into black towards the head and legs, with black muzzle, curved horns directed slightly upwards, and one with a straw-coloured coat, muzzle without pigment, white hoofs, lyre-shaped horns with white tips. In some districts (especially Meknès and Fez), there are piebald black and piebald fawn cattle with white patches limited to the abdomen and root of the tail. Most of the Moroccan cattle seem to be the result of the indiscriminate crossing of the first two types.

The author gives some details of the cattle breeding methods practised by the natives, and especially of the milking (the calf being allowed to take some of its mothers milk at the beginning and end of the operation).

The town herds are better tended and selected than the country ones.

The lactation period of Moroccan cows lasts about 9 months but in the case of exceptionally good cows, may last for 1 year). The milk yield of town-bred cows is on an average, 1400 kg per lactation, that of unselected animals bought at country markets may be as much as some 850 kg. Taking into account the amount of milk consumed by the calves, the milk yield of the town cows may be estimated at 1650 kg., and that of cows of rural origin at 1100. On an average 20.5 kg. of milk is required to obtain 1 kg. of butter fat.

Compared with the milk of French cows, that of the Moroccan cows has the same casein and lactose content, but usually is richer in fat-free extract and butter fat.

The milk of the Moroccan cow is more acid when first milked, than that of the French cow. For this reason, special care must be taken, if it is kept more than 12 hours, otherwise it coagulates on boiling.

The author concludes from his study that, under existing circumstances, it is best to use Moroccan cows, rather than imported French ones for supplying milk to the European customers in the towns, for

the imported animals are subject to tuberculosis and piroplasmosis, to both of which diseases the native cows are immune. By means of systematic selection, which is beginning to be practised by the natives, the author hopes that it will be possible before long to create herds of milch cows each producing, per lactation period, about 2000 litres of milk containing 4 % of fat. To effect this, it would only be necessary to supply the animals with food corresponding to thir live-weight and milk-yield, and to endeavour to prevent the calves sucking their dams during milking.

SHEEP

894 – **East Friesian Sheep at the Latium Stock-Breeding Station** (1). — Moreschi, B. in *Giornale d'Italia agricolo*, Year III, No. 25 p. 1., Rome, July 4, 1920.

With the twofold object of trying whether it was possible to acclimatise Friesian sheep to the Campagna Romana, and to cross them with Italian breeds, the Latium Stock-Breeding Institute bought, in 1916, 8 ewes and one ram of this German breed, celebrated for milk and wool production. In Friesia, the average milk yield of a ewe during a lactation period of 8 or 9 months is from 300 to 400 litres (some sheep give even as much as 6 or 7 litres of milk daily), while the annual yield of wool in the yolk is from 4 to 5 kg. Friesian sheep mature early and are very prolific; the ewes bear many twins (as many as 8 % of the flock), and sometimes three, four, or even five lambs are produced at a birth.

The results obtained from 1916 to 1919 are as follows:—

In 1916, the Friesian sheep gave birth to 6 ewes which produced 5 ewe-lambs and 3 ram-lambs; 1 male lamb and 2 ewes died.

In 1917 » » » gave birth to 5 ewes which produced 3 ewe lambs and 4 ram lambs: 3 male lambs and 1 ram died.

in 1918 » » » gave birth to 6 ewes, which produced 1 ewe-lamb and 7 ram-lambs; 2 ewes, 4 rams, and 1 male lamb died.

in 1919 » » » gave birth to 3 ewes, which produced 1 ewe-lamb and 4 ram lambs: 13 animals died.

Thus, at the end of 1919, there only remained 4 ewes, one of which afterwards died in lambing. This high mortality was due to the attacks of parasites. As the Friesian ram could no longer be used, a ram of the *gentile* breed of Apulia was mated with the Friesian ewes.

The high proportion of twin births, 3 out of 6 in 1916, 2 out of 5 in 1917, 2 out of 6 in 1918, 2 out of 3 in 1919, proved that the breed preserved its prolific qualities.

Prof. Giuliani, Director of the Latium Stock-Breeding Institute, stated that a Friesian sheep gave at the beginning of the lactation period 3 kg., of milk a day; this is much less than the usual yield in its own country. The milk of Friesian ewes reared on the Campagna Romana contains from 4.5 to 6.5 % of fat.

The amount of wool washed on the sheep by dipping in summer is, on an average, 2 kg., in the case of ewes, and 2.412 kg., in that of rams The average of the Latium flocks is 1.7 kg., per head. The wool of the

(1) See also *R.*, July-Sept., 1919, No. 953. (*Ed.*)

Friesian breed is of long staple, strong, rather elastic, but somewhat coarse, slightly and irregularly curled.

The Friesian breed maintained ther precocity in Latium ; at birth, the lambs weighed from 3 to 5 kg., and attained the weight of between 40 and 60 kg., in 6 months. At the age of eighteen months, the ewes weighed from 70 to 80 kg., and the rams 1 quintal, or even more. Cross bred lambs born as a result of the mating of Friesian ewes with the *gentile* Apulian ram, weighed at birth 3 to 5 kg., and after 8 weeks, 17.1, 20.4 and 21.9 kg., respectively ; their daily increase of weight being a little less than ⅓ kg.

From these results it may be concluded that the Friesian breed, which requires a damp and temperate climate, cannot be acclimatised in Latium, and under the unfavourable conditions prevailing there, it soon loses its characteristics.

If, however, breeders giving up the idea of rearing pure bred stock, would cross Friesians with the native races, they would doubtless achieve good results as regards milk-yield and size, and perhaps increase the productivity of the Italian sheep.

895 – **Beet Pulp for Fattening Lambs.** — Leadley, T. A.; in *The Nebraska Farmer*, Vol. 62 No. 14, p. 994. Lincoln, Nebr., April 3, 1920.

A ration of alfalfa, hay, dried hay, beet pulp, cottonseed cake and silage, produced the largest gain and returned the most profit on a lot of 31 lambs in a 100 day feeding experiment with 12 different rations, recently completed at the Scottsbluff Experiment Station.

Lot Number and Ration.

* CSC = Cottonseed Cake.

The following points are outstanding from the detailed results given in the above table: Dried beet pulp when properly supplemented with alfalfa hay and cottonseed cake is an excellent feed for fattening lambs. Cottonseed cake added to the ration at the rate of one-third pound per lamb daily in every case increased the daily gain and the net profits.

Silage added to the ration of hay, dried pulp and cottonseed cake increased the daily gains, lowered the cost of gains and increased the net profit per lamb. Beet tops added to hay and maize ration produced gains at a lower cost, and increased net profits. Beet tops added to hay, dried pulp and cottonseed cake ration increased the daily gain slightly, increased the cost of gain and decreased the net profit. Lot 7 shows an increase in the amount of cottonseed cake from ⅓ to ½ lb. per lamb daily.; slight increase in gain, but increase in cost of gains and lowering of net profit.

GOATS

896 – **Goats and Levroux Cheese.** — Bonafé, A. (Directeur des services agricoles de l'Indre), in *La Vie agricole et rurale*, Year 3, No. 42, pp. 276-277, figs. 2. Paris, October 18, 1919.

The goat plays a very important part in the rural economy of the Department of Indre. It is found more or less everywhere, but most frequently on the limestone plains of Champagne, where it takes its place beside the sheep, large flocks of which belong to the large estates. Goats to the number of 5, 10, 15 or rarely 20 heads, are, however, kept by the owners of small holdings, and by agricultural labourers. The goat is *par excellence* the animal of the poor as it can be managed by the family without any outside help, and is a source of considerable profit.

It is of average size; its coat is usually brown with white at the extremities; on the forehead is a brown stripe, that finishes at the muzzle, and has wide white borders; horns are as a rule absent; beards may be present or absent (very variable).

Mated with the ram on November 1, the females give birth, at the beginning of April, to two kids, which they suckle for a fortnight; the kids are then sold, and the milk is used for cheese making. Kids kept for breeding are reared with the bottle and cows milk.

During the winter, the animals remain at the sheep-fold; their rations are composed of bran, dry forage, and a mash consisting of bran, beetroots, and boiled potatoes.

In summer, after a small ration of forage and bran, which they eat at the farm, the little herd is driven to the fields by the old men or the quite young children of the family, who are helped by a well-trained dog. The goat browses on the sainfoin aftermath, or that of temporary pastures; it requires succulent appetising food, and is not content with the meagre pasturage that suffices for sheep.

Milking is done twice a day, morning and evening; on exceptional occasions, the goats are milked a third time, at midday.

The milk yield is rather small after the first time of kidding (this takes place when the goat is about 14 months old), but it attains its nor-

mal amount after the goat is 3 years of age. From this time, the animal gives at least 1.5 litres daily for 7 months (May to December); this would mean a minimum of 210 cheeses per annum (allowing 1.5 litre of milk for each cheese). When its milk-producing power decreases, towards the age of 9 to 10 years, the goat is no longer kept, but is sent to the butcher.

After each milking, the milk is put into earthenware vessels, taken to the cellar, and as soon as it is cold, the rennet is added. For 1 litre of milk, is used a piece of solid rennet the size of a pea, which is specially prepared by the pharmacists and grocers of the district. The curd forms in 24 hours in summer and in 48 in winter. It is placed to drain in a form or cheese-basket that gives it the shape of a truncated pyramid, with a square base. The curd is put into the form by degrees, a little at a time, and no small amount of dexterity is required to ensure a homogeneous paste. The cheese takes one day to drain ; next day, the exposed surface is salted, and the following day, it is taken out of the form and salted all over. When covered with salt, the cheeses are put on a layer of straw in a large wickerwork basket, and hung up in a well-ventilated room, where they can dry and acquire the proper consistency, or else they are put on a wire-stand with compartments and placed in the garden. The farmers wife turns the cheese every day, placing the bottom surface uppermost.

After a week, the blue mould begins to make its appearance on the surface of the cheese, and develops more or less rapidly according to the surroundings. Sometimes it is necessary to remove the cheeses to a damper place, and to wrap them for some hours in damp cloths.

The making of these cheeses is not regulated scientifically; after some experiments, the most favourable conditions are found out.

A week after the appearance of the first blue specks, the fungus mycelium is fully developed, and the cheese is ready for sale. It is not, however, fully ripe, but this is the best time for transporting it; the rest is left to the consumer or cheese-monger. The cheeses are ripened by being placed in earthenware receptacles that are first covered with a cloth and later closed. In this new enviroment with limited air and a high degree of humidity, the mucidineae grow more slowly, whereas the bacteria show great activity, the paste gradually becomes oily, and the flavour develops. The process is permitted to continue for a longer or shorter time according to the wishes of the customer.

When well-made, Levroux cheese is one of the most highly prized goat cheeses. Its fame exceeds that of the Berry variety, it figures largely at the Paris restaurants, and the demand for it cannot be adequately satisfied.

It is estimated that there are 40 000 goats in the Department of Indre, and that an average of 9 million cheeses are produced annually. In reality, however, more cheeses are made, for not infrequently, cows milk is used to dilute the goats milk to a small extent.

The best cheeses come from Vineuil, Levroux, Brion, Brittany, and Champenoise, where there are great plains covered with sainfoin which forms the staple food of the goats.

As soon as the animals are put out to grass, or to brouse on the leaves of the trees, the quality of the milk becomes inferior. The prices of the goat and its products during the pre-war period and at the present time are as follows:

Milk-yielding goat	35	80 to 100
Dry goat	5	15 to 20
Kids	4 to 7	10 to 30
White cheeses (salted and dried)	0.30	1
Blue cheeses (covered with mould)	0.35	1.20
Ripe cheeses (finished in earthenware pot)	0.45 to 0.50	1.50

These figures would give a gross return of 250 to 300 fr. per head: this means a high profit. It must, however, be remembered, that goats need liberal feeding, careful supervision, and unremitting attention, which if adequately recompensed, would mean a considerable outlay.

897 - **An Experiment with Fattening Pigs to Compare Cooked with Raw Potatoes.** — *Department of Agriculture and Technical Instruction for Ireland Journal*, Vol. XX, No. 2, pp. 190-193. Dublin, 1920.

PIGS

The high cost of fuel, of manual labour, etc., has been the reason why many farmers hesitate to undertake the fattening of pigs with cooked food, especially potatoes, which however is a customary proceeding in Ireland. The Department of Agriculture has therefore undertaken a series of tests in order to ascertain if it is possible to fatten pigs successfully on a diet of raw potatoes. These tests were carried out at 5 centres, and at each centre the pigs were divided into 2 lots, as for as possible homologous in appearance, and the total number of pigs was 34. The average age of the pigs at the commencement of the tests was 15 weeks and the tests covered a period of 110 days.

Lot I were given cooked potatoes; Lot 2 raw pulped potatoes. In all other respects the two lots were treated alike The 2 lots consumed the same quantity of feed, and particulars regarding the live weight increase are given as follows:

Lot	Number of pigs	Average weight at beginning	Average weight at close	Average increase	Average Daily Gain
		cwt. qrs. lb.	cwt. qrs. lb.	cwt. qrs. lb.	lb.
Lot 1 (cooked potatoes)	17	— 3 2	2 0 20	1 1 18	1.43
» 2 (raw potatoes)	17	— 3 4	2 0 6	1 1 2	1.29

Results show that the 17 pigs which received cooked potatoes made an increased gain in live weight of almost 16 lb. per head (equals a total gain of 266 lb.) as compared with the 17 pigs which received raw potatoes. Naturally, against the pigs which were fed on cooked potatoes must be set the cost incurred in cooking the latter. Nevertheless, taking into account the market conditions when the experiment was made, the value of the increased live weight was obviously superior to the expenses in-

curred in cooking the potatoes, and the following conclusions may be-drawn :

(1) At the present price of pork, a substantial profit is obtained by the cooking of potatoes for fattening pigs.

(2) Moderately good results may be obtained from the use of raw potatoes; but in this case the fattening period is extended.

898 – Effect of Calcium on the Composition of the Eggs and Body of Laying Hens. POULTRY
— BUCKNER, G. D., and MARTIN, J. H., in the *Journal of Biological Chemistry*, Vol. XLI, No. 2, pp. 195-203. Baltimore M. D., Feb. 1920.

The authors have determined the effect produced by grit, oyster shell, and limestone, fed with the ordinary ration used for laying hens; and also the ultimate effect on the constitution of the hen, of the continued laying of eggs in the absence of calcium other than that contained in the food.

Four lots of 10 white Leghorn pullets each received the same ration, namely : 1) a dry mash composed of 6 parts maize meal + 3 parts bran + 3 parts middlings + 5 parts meat meal + 4 parts charcoal ; 2) a grain mixture of 16 parts wheat + 16 parts cracked maize + 8 parts oats. These foods were supplemented : in Pen 2, with grit ; in Pen 3 with grit and oyster shell ; in Pen 4 with grit and limestone ; Pen 1 served as a control test. The experiment extended over 6 months.

A series of Tables shows : 1) the analyses of the materials fed, the mortality and egg record ; the analyses of shells of eggs from the various pens ; the analyses of the contents of eggs from the various pens ; the analysis of a anormal hen compared with that of a hen in Pen 2 that had collapsed and died ; the analyses of carcasses and leg bones of hens from all lots, at the end of the experiment.

From a study of these figures the following conclusions may be drawn :—

(1) Laying hens whose supply of calcium is limited to that naturally contained in the food, continue laying until there is a general depletion of magnesium, phosphorous, and calcium in their bones and carcasses.

(2) As long as the hens permit the formation of an egg shell, the contents thereof remain reasonably constant, thereby allowing an average supply of calcium, magnesium and phosphorous sufficient for the normal development of the embryo of the chicken.

(3) Ten weeks elapse before there is any noticeable change in the general condition of hens receiving no mineral matter other than those naturally contained in the food ration such as that fed during these experiments.

(4) The lack of calcium is not the fundamental cause of the formation of shell-less eggs.

(5) The percentages of calcium and phosphorus in the bones of the hens in all lots were fairly constant, thus indicating a stable equilibrium between the 2 elements.

(6) The continued laying of eggs taking into account the calcium restrictions, does not materially alter the percentage mineral composition of the egg shells or their contents. There is, however, a gradual thinning of the shell.

(7) Under the conditions governing this experiment, the addition of limestone or oyster shell to the ration, increases the production of eggs 69.4 % as shown by the average production of Pens 1 and 2 when compared with that of Pens 3 and 4.

BEE-KEEPING

899 – **Bee-Keeping in Isolated Hives.** — ROBERT-AUBERT, in *L'Apiculture*, Year 64, No. 7, p. 155. Paris, July, 1920.

Bee-keepers, whose stock is attacked by foul-brood, are usually those who take their honey too early and use composite hives arranged in such a way that they always obtain relatively large quantities. Taking the honey and replacing the frames of these hives for the bees to clean are two operations that encourage the queen to lay at the very time when she ought to be prevented from so doing. If the honey supply continues, no harm is done, but if the honey-season is finished, which is generally the case in districts where foul-brood is rife, there is a great risk that the bees seeing their emptying frames, will let part of the brood die on account of want of honey.

The author has substituted for this pernicious system one which 25 years' experience has proved most satisfactory. He uses LAYENS hives with 20, 22 and 25 frames. In May, he pays his first visit, cleans the hives, divides any food that is left, and replaces useless frames wih sections containing bees-wax. Having done this, he does not open the hives again until after September 1, unless the season is a good one, in which case, he visits them again, to take the honey from the side opposite the brood. This operation takes place once every 3 years. In September, he removes the superfluous honey, and as the bees only concern themselves with the part of the hive where they are going to winter, this hardly disturbs them at all, and the replacing of the frames to dry only gives them one day's work.

The result of 25 years' bee-keeping with isolated hives according to this simple method is that the honey supply has never failed and the author has taken honey every year. The average yield in Oise during these 25 years was from 22 to 25 kg., per hive per annum. His great triumph is that, even in bad seasons, it has never been necessary to feed the bees. The latter were thus allowed to live naturally, they received no food, the brood did not die, and there were no signs of foul-brood.

M. ROBERT-AUBERT is of opinion that if all bee-keepers followed his example, many more hives could be kept and much larger quantities of honey obtained without losing the brood. Bee-keepers who take too much honey, whose broods, die, and who are obliged to feed their bees on a large scale every year, are evidently in the wrong.

SERICULTURE

900 – **Crossing Experiments with Varieties of Silkworm Having Bivoltine Females.** — PIGORINI, L. (R. Stazione bacologica sperimentale at Padua), in *L'Italia agricola*, Year 57, No. 5, pp. 129-146. Piacenza, May 15, 1920.

Breeds used in the experiments. — The following 19 crosses were made:

Small, bivoltine, greenish-white female with males of an annual breed viz., golden Chinese, white Japanese, yellow Ascoli and yellow Gran Sasso.

White bivoltine female with annual males, viz., white Japanese, and yellow Gran Sasso.

White, bivoltine female with gibbous caterpillars with annual males, viz., golden Chinese, white Japanese, yellow Ascoli, and yellow Gran Sasso.

White, bivoltine Chinese female with annual males, viz., golden Chinese, white Japanese, and yellow Ascoli.

Mixed white bivoltine female with annual males, viz., golden Chinese, and white Japanese.

Yellow bivoltine female with annual males, viz., golden Chinese, white Japanese, yellow Ascoli, and yellow Gran Sasso.

The results of the crosses were studied in 101 small separate rearings, each lot consisting of hybrids from the same laying.

Objects of the experiments. — The characteristics of the cocoon were investigated in these researches. The weight dimensions, form, amount of silk and its properties were all studied.

The number of cocoons examined were :

for total weight	15 173	cocoons
for size and shape	2 474	»
for weight of outer silk and fibrin	1 479	»
for length of reelable silk and standard	1 082	»
for strength and elasticity (3 597 determinations)	351	»

The technique of the various determinations has been improved by the author.

Results. — These are given in a series of tables and summarised as follows :

In addition to the well-known fact that in crosses made with a bivoltine, female bivoltism persists in all cases, the hybrids obtained by the author showed parental characters as well as intermediate and non-intermediate characters.

Of the intermediate characters, some occurred according to the average number calculated, others deviated from it more or less, sometimes approaching nearer to the paternal or maternal characters respectively.

The non-intermediate characters have slightly higher values than those of the parents, but smaller values.

The observations may be arranged in a schematic form as follows :

A. — Intermediate Characters.

(a) *Attaining the average.*

I. — *Size.* This was calculated by determining the long diameter. The calculated average was 177 ; the average ascertained was 176. Partly by means of the observation of the calculated averages and the averages found, and partly by noting the slight deviations of the latter from the respective averages, the author concluded that the phenomenon was constant.

He mentions special cases of crosses with a golden male, in most of which the dimensions of the hybrid are not intermediate, but exceed those of the parents.

II. — *Shape.* The method employed, which consists in indicating the size by a sign or a series of numbers that express the ratio of the diameters, necessitates the separate consideration of crosses between more or less strangled cocoons, or between strangled and non-strangled cocoons, such as in the present case, where a golden Chinese male was used. In both cases, the value found coincided with the average calculated values.

III. — *Percentage of crude fibrin in the raw silk.* As a rule this amounts to 101 % of the general calculated average. This figure remains approximately the same in all the groups. Mention, however, should be made of the case of crosses with a Japanese male, in which the percentage often exceeds the calculated amount, and in most cases exceeds the fibrin percentage of the parent producing most fibrin.

IV. — *Standard of the thread.* Taking this as a whole, it may be said that the standard proved to be 99 % of the average calculated, that is to say it coincided with it. It should, however, be observed that crosses with Eastern breeds slightly lowered the standard, while crossing with local breeds raised it.

(b) *deviating from the average.*

(b_1) *below the average,* inclining towards the maternal characters.

I. — *Weight of outer silk.* This is much below the calculated average, being only 77 % of the latter. This inferiority is constant and is found however the crosses are arranged. The character thus tends to approach the maternal character, and it is permissible to suppose that the latter is dominant as regards the paternal chracter. It must, however, be remembered that the breeding conditions may have exerted some unfavourable effect.

II. — *Length of reelable silk.* Taken as a whole, the value found was 83 % of the calculated value. For the rest, what has already been said about the weight of the outer silk holds good here also. This character may be regarded as depending on the previous one.

(b_2) *above the average,* and tending towards the paternal character.

I. — *Strength of thread.* This is 111 % of the calculated average. This phenomenon is constantly observed in all the hybrids.

B. — NON-INTERMEDIATE CHARACTERS.

(a) *superior to the characters of each of the parents.*

I. — *Elasticity of thread.* — This is observed in the majority of cases and always in partial groupings. It may further be said that the arrangement of the groups of hybrids according to the degree of elasticity of the thread follows the order of the females as regards this character, which shows the special influence of the females.

(b) *superior to the characters of the parents and approaching their sum.*

I. — *Colour.* — Taking the total of the cases studied, this attained 84 % of the sum of the parents' character. The order of the succession of the groups of hybrids according to colour, does not reproduce that of their parents. It is not possible to speak with the same certainty as has been done for the characters previously described, with regard to various other characters such as *vigour of larvae, live-weight of cocoons,* and *the num-*

ber of double cocoons. The author is, however, able to state that the hybrids are chiefly affected by the vigour of the bivoltine race ; that the live-weight of the cocoons largely depends upon paternal influence, seeing that it was greater when the females were crossed with local males than when the male parent belonged to an Eastern variety. The occurrence of double cocoons was clearly reduced to one-half (from 12.9 to 7 %) by crossing with an annual race.

VARIOUS ANIMALS

901 – **Note on the Description of Elephants.** — SCHEIN (First-Class Veterinary Inspector), in the *Bulletin économique de l'Indochine*, Vol. XXIII, New Series, No. 140, pp. 26-41, + figs. Hanoï-Haïphong, Jan.-Feb., 1920.

Few authors have written about elephants, and so far Veterinary Captain EVANS is the best authority. In addition he has had the advantage of studying and writing about the elephants of Burma, which largely come from South Indo-China, Cambodia, and South Annam, and are thus the brothers of those examined by the author. But he has not given a method by which elephants may be described, and the author has filled in this blank by the article under consideration.

The primitive races Moïs and others, could recognise an elephant after not having seen it for a very considerable time, but they could not give an accurate description of it. The author has followed the standard method of listing the points of a horse. viz : — Stud number and mark, name, sex, skin and colouring, shape, head (nose, teeth, skull, ears), back, tail, legs, hoofs, height, age, special points (approximately: very young, young, adult, old, very old). The author describes these points in detail, and gives numerous illustrations. In addition, he gives a sample of a scoring card for elephants, and diagrams of an elephant and the chief parts, all of which will greatly simplify descriptive work in this connection.

902 – **Domestication of the African Elephant in the Belgian Congo, (Api Station)** (1) — LEPLAE, E., in *Bulletin agricole du Congo Belge*, Vol. X, Nos. 1-4, pp. 207-269, figs. 10. Brussels, March-December, 1919.

The Indian or Asiatic elephant (*Elephas maximus*) seems to be descended from the mammoth (*E. primigenius*), whereas it is supposed that *E. antiguus* was the ancestor of the African elephant.

Although there is probably only one species of elephant in Africa, a certain number of varieties, or sub-species, differing chiefly in the shape of their ears, have been found in that continent.

These varieties, according to the publications of the British museum of Natural History, are as follows :— (1) The Cape elephant (*E. Africanus capensis*) ; (2) the western variety of the Cape elephant (*E. a. toxotis*) ; (3) the Matabeleland elephant (*E. a. Selousi*) ; (4) the West African elephant (*E. a. cyclotis*) ; (5) the elephant of the Masaï (*E. a. Knockenhaueri*) ; (6) the Aberdare elephant (*E. a. Peeli*) ; (7) the Lake Rudolph elephant (*E. a. Cavendishi*) ; (8) the Abyssinian or E. Sudan elephant

(1) See *R.*, May, 1919, No. 633. (*Ed.*)

(*E. a. oxyotis*); (9) the elephant of N. Somaliland (*E. a. Orleansi*); (10) the W. Sudan elephant (*E. a. Rotschildi*). In the British Museum Handbooks the dwarf Congo elephant (*E. a. pumilio*) and the Lake Albert elephant (*E. a. albertensis*) are also mentioned.

In the Belgian Congo, there are various zoo-geographical regions, hence it is natural that different races of elephants should exist in the country. Hitherto, however, it has not been possible to determine them accurately, owing to the necessary documents being somewhat difficult to obtain. It is the same in all the other African Colonies, and the elephants there have been relatively little studied.

The race living in the Lower Congo is most likely, according to M. Schouteden, *Elephas africanus cyclotis*. It is hoped that, before long, an opportunity of verifying the matter will present itself.

In the North of Uelé, the Sudan elephant (*E. a. oxyotis*) is found. *E. a. Cottoni* lives in the great forest and in Ituri, while near Lake Albert, and as far as Semliki, *E. Albertensis* is met with; this is probably the same race as that found near Lake Edward.

At Katanga, there is a variety of which little is known as yet. It is not possible at present to identify it from museum material. The circumference of one of the fore-feet of an adult elephant killed in 1912, near Nieuwdorp was 1.26 metres, which corresponds to a height of 2.52 m. at the withers.

A very large elephant has been found near Lake Leopold II; its skull, which is a magnificent one, is at Tervueren, but fresh material for study is awaited. Besides this giant race, there is also a dwarf variety, *E. a. Frausseni*, which lives in herds. Another variety of elephants, a half-dwarf one, lives near Lake Albert; in 1916, the author had a male and a female specimen shot for the Museum of Tervueren.

The author deals successively with the following matters: Trade in elephants in Burma, their classification, food, diseases (pneumonia, colic, cerebral congestion, heat-apoplexy and sun-stroke [the elephant being by nature a nocturnal animal, cannot stand very high temperatures well]; anthrax, trypanosomiasis, a common disease in Burma which does not seem to occur in Africa; piroplasmosis, rare; apthic stomatitis; tetanus and tuberculosis, rare; the elephant seems immune to rinderpest); the capture of elephants in British India (the author describes a hunt in which he took part in Ceylon in 1910, when 17 wild elephants were captured).

When the Api elephants are not working, they spend their day in the following manner. They go out to feed at 5 in the morning, each accompanied by a driver, and return about 5.30 p. m., when they are given a little manioc, some potatoes, and a bunch of bananas.

On working-days, they begin their labours at 4 a. m. and if they have to go far, to fetch tree trunks for instance, they set forth at midnight, or at 1 or 2 in the morning. In any case, the elephants stop working at 11 a. m., rest, bathe, and then graze all the afternoon.

The elephant-hunts, which were interrupted in 1914 by order of Commissioner BERTRAND, used to last 2 months at a time, 3 elephants about 1.60 m. high being captured. The captives are allowed one year to get accustomed to their new conditions, and then trained for 10 to 12 months, when they are put to work with the others.

In 1918, Lieut. MAGNETTE drove a cart with 6 elephants to Buta and back. The 700 kilometers were accomplished without accident, but not without difficulties. There would be no trouble in using elephants outside the Station of Api, provided they were gradually accustomed to the new surroundings and persons.

FARM ENGINEERING

AGRICULTURAL MACHINERY AND IMPLEMENTS

903 - **Continuons Knife Mowers.** — LARUE, P., in *La Vie agricole et rurale*, Vol. 9, No. 19, pp. 334-335. Paris, May 8, 1920.

The mower knife works with an interrupted movement, the grass being cut by the action of the blade edge passing between the teeth of the comb. The action is similar to that of pruning shears, and needs more power and is not as clean as that of the double-blades of garden shears or tinman's sheard. But a satisfactory movement of the blades of shears in the grass is not practicable.

M. J. d'HEUR, of Daubs (France), has evolved a set of continuous action shears. To do this, he replaced the toothed cutter by a blade having steel teeth set "en échelon" and with vertical cutting edges. Two blades, moving in opposite directions one over the other, act as clippers, cutting the grass.

Continuous movement is obtained by using an endless steel band, a sort of bandsaw whose parallel blades move in the space between the combs used in the machine. The band passes over a small pulley at the end of the knife blades and is actuated by another pulley driven off the road wheel of the machine.

A lateral roller assures the stability of the machine.

A single driving wheel is found to be very efficient and does away with the need for a differential.

904 - **A Seated Drag-Hoe** — LARUE, P., in *La Vie agricole et rurale*, Vol. 9, No. 19, p. 333. Paris, May 8, 1920.

In classical machinery for cultivating the soil, the working parts slid through the earth, the machine was carried on wheels and the driver walked behind.

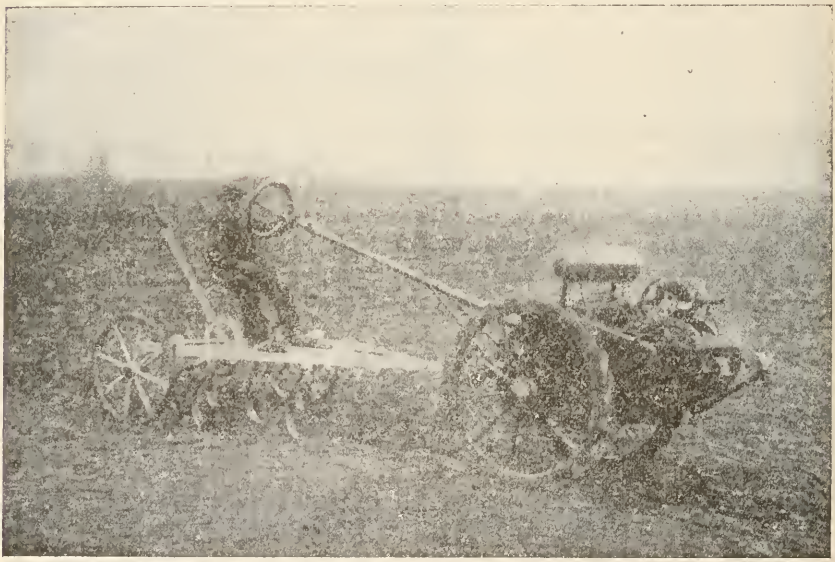
M. BAILOR has constructed a tillage machine in which the working parts rotate, the supports slide and the driver sits.

The whole machine representers a small disc harrow mounted on 2 runners with a steering runner behind. The depth is regulated by means of a lever held by a ratchet.

Oblique weeder blades in front give stability and prepare the work for the discs.

905 – **The Blanchard Improved Fore-Carriage.** — DESSAISAIX, R., in *Journal d'Agriculture pratique*, Year 84, No. 22, p. 411. Figs. 1. Paris, May 27, 1920.

The first model of M. BLANCHARD'S double brabant plough was actuated by a motor and two windlasses fixed over the back axle (1), but many improvements and alterations have been made in the latest design of machine put on the market under the name of the *Agro* (90, Rue Saint-Lazare, Paris, 9e).



BLANCHARD Improved Fore-carriage.

The appended figure gives a general idea of the machine working as a fore-carriage tractor, pulling a flexible-toothed cultivator provided with a driving seat and all controls.

When pulling, the motor actuates the two driving wheels, whose tires are provided with grips.

This machine is capable of hauling : — An 11 toothed cultivator, a 60 toothed harrow with roller, a mowing machine having a 1.5 m. blade, a binder or a double brabant for light ploughing and stubble skimming.

The single cylinder motor (bore 96 mm. × stroke 120 mm.) develops 8 HP. at 1400 R.P.M. The cylinder is ribbed and is air cooled by a rotary fan. A pulley is provided so that other machines may be driven by belt.

(1) See *R.* March, 1918, No. 333 (*Ed*).

The wheels are 90 cm. in diameter, and the tyres are 0.8 cm. wide The track can be increased from 70 to 80 cm.

With the windlass a cable 5 cm. in diameter is used, having a breaking strain of 1500 kg. Each windlass holds 250 m. of cable whose anchorage to the ground is maintained by a chain 8 m. long. held by 6 iron pegs. Using the cable, the speed is about 2 m. p. h., and working as a tractor from 2 1/4 to 2 1/2 m. p. h. (reverse 1 1/2 m. p. h.), depending on whether the diameter of the wheels is increased by the grips or not.

906 – **A Turbine Sorter for Seeds.** — See No. 859 of this *Review*.

RURAL ECONOMICS

907 – **Research Work of the Swiss Peasants' Secretariat on the Swiss Agricultural Yields from 1914-1918.** — *Schweizerische Landwirtschaftliche Zeitschrift*, Year 47, Part 11, pp. 215-216; Part 13, pp. 267-268; Part 16, pp. 350-351; Part 20, pp. 435-437; Part 45, pp. 992-994; Part 46, pp. 1006-1008; Part 47, pp. 1033-1034; Part. 48, pp. 1049-1050; Part. 49, pp. 1079-1080. *Cf.* also *Untersuchungen betreffend die Rentabilität der scheweiz. Landwirtschaft, Bericht des schweizerischen Bauernsekretariates an das schweiz. Landwirtschaftsdepartement, Erntejahre* 1915-1919, Vols. 30-33. Berne, 1916-1919.

The *Review* of January, 1916, under this heading, contained several extracts from the 16th. Report presented by the Swiss Peasants' Secretariat to the Swiss Department of Public Economy. The present study reviews briefly the principle distinctive economic results that characterise the yields obtained by Swiss Agriculture during the war, in comparison with preceding seasons.

VARIATIONS IN THE GROSS YIELD PER HECTARE OF CULTIVATED LAND IN THE LAST FOUR SEASONS. — Table I gives the chief data relating to the average gross yield per hectare worked out in figures for the investigation farms whose accounts were audited by the Swiss Peasants' Secretariat for the period March 1, 1914 to February 28, 1915, and March 1, 1917 to February 25, 1918.

In order to summarize the results, the general averages of 288, 259, 200, and 253 farms for the years 1914-15, 1915-16, 1916-17, 1917-18, respectively are shown in Table I.

The influence of the size of these farms on the gross yield is remarkable. It will be of interest to give in Table II, in order to complete the analytical data of Table I, the results in round figures of the gross yields per hectare, in order of importance, obtained during the four years investigated. As can be seen in Table I, the noteworthy increase in gross yield per hectare during the war should be attributed to nearly all the productive branches of the farm, but in different degrees.

The increase of cultivation depends in the first place on the greater stocks of cereals, potatoes and forage present on the farm during the successive years.

TABLE I. — *Variations of the gross yield per hectare during* 1914-15, 1916-17, 1917-18 *on Swiss farms andited by the Swiss Peasants' Secretariat* (1).

Productive branch of the farm	1914-1915 Average of Farms 288			1915-16 Average of Farms 259			1916-17 Average of Farms 300			1917-18 Average of Farms 353		
	Gross yield per hectare cultivated	Gross percentage yield	Increase in Percentage	Gross yield per hectare cultivated	Gross percentage yield	Increase in percenage	Gross yield per hectare cultivated	Gross percentage yield	Increase in percentage	Gross yield per hectare cultivated	Gross percentage yield	Increase in percentage

(1) In this table and in the rest of the article, values are given in Swiss Francs. (*Ed.*)

TABLE II. — *Variations in gross yield per hectare of cultivated ground obtained for farms, with accounts audited by the Swiss Peasants' Secretaria and classified in their order of importance during the years* 1914-15, 1915-16, 1916-17, 1917-18.

Year	Farms of 3-5 hectares	Farms of 5-10 hectares	Farms of 10-15 hectares	Farms di 15-30 hectares	Farms of more than 30 hectares
	fr.	fr.	fr.	fr.	fr.
1914–1915	1 021.62	828.64	771.63	659.45	616.58
1915–1916	1 164.84	1 001.98	916.94	805.99	742.15
1916–1917	1 285.52	1 130.00	1 077.06	1 026.07	856.46
1917–1918	1 734.32	1 518.48	1 284.17	1 239.12	1 021.56

There is, in addition to this a constant increase in receipts obtained from the sale of cereals and potatoes. The receipts brought in by fruit farming per hectare is noteworthy, and is mainly due to higher unit prices.

It is also interesting to note the increased receipts produced by the forests ; the average, and large peasant farms with a considerable wooded area benefited most from this increase.

In Table III the results obtained from the Cattle rearing are examined in detail in order of size and compared with the pre-war results.

TABLE III. — *Gross yield from cattle-rearing per hectare on various farms arranged in order of importance.*

Year	3-5 hectares	5-10 hectares	10-15 hectares	15-30 hectares	more than 30 hectares	Average
1908	156.50	96.24	100.70	71.08	45.05	94.25
1912	234.76	147.15	126.71	113.23	94.45	141.84
1914	196.81	133.86	117.80	116.64	108.31	130.33
1915	274.23	209.48	186.02	176.86	152.88	199.40
1916	360.30	293.51	251.24	254.85	221.43	278.66
1917	197.80	149.54	131.47	122.88	99.73	142.08
Media	367.01	335.94	279.46	254.08	241.82	305.21

The increase in receipts from cattle breeding is explained by the increased unit prices and by more intensive breeding and by a rapid influx of fresh animals and elimination of the older ones.

In the two last years, the increase of the gross receipts from dairy farming is noteworthy, although they decreased from 1912 to 1914. Milk production diminished chiefly on account of the unit prices of the last 2 years, which prevented this productive branch of Swiss agriculture from contributing enough to increase the production per hectare.

Pig breeding which suffered a decline in 1914, because of the lack of concentrated food, has again developed during the following years and, especially in the last one, has contribued greatly to increase the gross receipts per hectare.

Production for home and market. — Production for the home and market during the war, was particularly interesting for it shows up the efforts made by the producers to supply the demands of the market.

A considerable part of the yield was thus absorbed by the market, whilst that taken for home consumption, although showing a large increase mainly due to increased unit prices, was not wholly as important as that absorbed by the market. This increase naturally varied with the different products, and also for the different classes.

Table IV gives the averages for all the farms investigated during the years in question.

Table IV. — *Production, domestic consumption and the market during the war per hectare cultivated.*

Year	Home consumption per hectare	Market production per hectare	Gross yeld per hectare
	fr.	fr.	fr.
1901	146.75	355.15	501.98
1910	155.15	583.30	738.45
1913	154.45	569.35	723.80
1914	178.50	662.60	841.10
1915	184.40	755.42	939.82
1916	220.72	876.31	1 097.03
1917	302.41	1 092.93	1 405.34

The data given in Table IV show that the home consumption of the products has increased considerably since 1901, but, taking the unit prices into account, this consumption has decreased in favour of production for the market.

Net revenue obtained by Swiss agriculture during the war. — The net revenue of the farm represents the interest on the capital invested, whether it belongs to the cultivator or to the investor. It is calculated by deducting from the gross yield, the cost of labour, the cash expen diture, depreciation of stock, remuneration for the work, done by the farmer and his family, and all products used on, or put into, the land. In this calculation neither debts nor capital charges are entered. The notable fluctuation of the net revenue during and previous to the war indicates the need for a careful examination of the index of the projects of Swiss agriculture since 1901.

Table V gives the general averages for all the farms studied instead of averages for groups of farms classed according to size, for it is important that the general result should be kept in mind.

TABLE V. — *Net revenue obtained by Swiss farms associated with the Secretariat, in the years* 1901-1917.

Year	% interest on capital	Net Revenue per hectare of Unwooded land	Net Revenue per 100 fr. of working expenses
	fr.	fr.	fr.
1901	1.9	94.60	23.23
1905	3.3	155.60	32.70
1910	3.7	189.92	34.62
1914	3.7	200.43	38.81
1915	6.1	340.41	56.79
1916	7.9	446.49	68.63
1917	10.4	621.09	79.20
1901–05	3.07	141.15	31.39
1906–13	3.65	188.36	36.02
1914–16	5.94	329.11	54.74
1914–17	6.89	402.11	60.86

The causes which determined the increase of the unit yield also apply equally well for the net revenue. Working costs however have not risen in proportion to the gross unit yield, so that it leaves, in the last four years a continually increasing margin of profit on the invested captal. During the war the smaller increase in expenses as compared with the yields was due not only to a smaller increase in the cost price of the means of production, particularly fertilisers, forage, etc., but also to a lesser use of such means, and to a decrease in the cost of maintenance, repairs, etc.; this lesser use is obviously due to the high cost of labour and raw materials. Again, during the earlier years, whilst pre-war materials were still being used, and at pre-war cost, the extension of arable land and the high prices of the products contributed greatly to the increase in net unit revenue of the farms for those years.

In order to interpret the data accurately, it must be born in mind that most of the farms are in the hands of the peasantry, and that the owner, besides supervising the enterprise, works just the same as any member of his farm.

On the other hand the researches of the Secretariat are intended to explain facts, just as any scientific research would, and it is only occasionally that they furnish any data that could serve as a basis for valuations or estimated values which with regard to land values or the wages of the farmer and his family, could be made in different ways according to the precise aim of the valuation or attribution of value.

CAPITALISATION PER HECTARE. — In the researches of the Swiss Secretariat, the interest on Capital is taken at 4 % of the net return less

the portion set apart as working capital, called in German "Pächterkapital" "tenant capital ,, which is taken as interest at 4 % on the estate. In compiling the accounting statistics of the Secretariat this value is compared with that of the inventory value as entered in the books, which derives from previous purchases, costs of production, and work in view, etc.

The inventory value is taken as the average between that of the amount of the inventory and the capitalisation value.

The capital is also increased by interest from funds.

The progressive increase of the unit value of capitalisation since 1901 is illustrated in Table VI.

The value of capitalisation is, amongst the indices of the economic result of Swiss agriculture, that which has most felt the influence of the economic system employed and the direction followed by production. This is amply proved by the flourishing state of arable cultivation during the last few years. The farms using a triennal rotation of crops, with unpastured clover fields on the Jura Mnts. derived the most benefit from fluctuations.

Grass and forage have benefited from the increased to the revenue from fruit farming, and forestry has shown a steady increase in its capital value, especially during latter years.

TABLE VI. — *Unit value of capital and inventory as shown by the Swiss Secretariat for the year* 1911-1917.

Year	Stock Value	Capital Value	Stock Value	Capital Value
	per hectare worked, working capital not included		per land value per hectare buildings, etc. not included	
	fr.	fr.	fr.	fr.
1901–1905	4 401.05	2 680.80	2 320.50	1 682.00
1906–1913	4 556.55	3 561.85	2 337.50	2 248.45
1914–1916	4 697.05	6 959.20	2 318.05	5 025.75
1916	4 704.00	9 842.85	2 335.90	7 601.05
1917	4 770.15	14 053.00	2 420.45	11 751.60

In the Alps, cattle breeding has had a very good influence on all the classes of farm, and the upper valleys have obtained similar results with the breeding and sale of cattle.

Dairy farming has contributed little to the net revenue and capital value, and has actually diminished owing to the high cost of production; only farms exclusively producing forage crops can have been especially effected. There was an improvement in the Alpine regions that produce butter and cheese, chiefly during the summer months. Table VII shows the increase in capital per hectare, in the various branches of agri-

TABLE VII. — *Percentage increase of the various factors influencing the capital value per hectare during the war years (1914-17) compared with the years 1906-13, as entered in the farm accounts controlled by the Swiss Peasants Secretariat.*

Type of Agricultural Economy	Capital in Livestock per hectare exclusive of forests	Cost of labour per hectare	Total working cost per hectare	Gross yield per hectare	Produce of Livestock per 100 fr. invested in livestock	Net revenue per hectare	Net revenue per 100 fr. capital invested in livestock	Value of the capitalisation per hectare
Triennial rotation of crop	+ 36.57%	+ 16.15%	+ 21.09%	+ 53.53%	+ 10.86%	+ 176.57%	+ 138.54%	+ 243.77%

Farms on the Jura Mnts, inclusive of pasturage	+ 27.68	+ 38.62	+ 12.25	+ 32.13	+ 4.78	+ 78.07	+ 117.53	+ 96.98

cultural economy comparing the increase in the averages for the years 1914-17 to those of the pre-war years 1906-13 and giving the analytical data regarding these changes.

The data given in Table VII show clearly that all the farms no matter what their system of agricultural economy or specialisation, have greatly increased the receipts. Least of all comes dairy farming which has progressed not so much owing to milk productions as to subsidiary branches of production.

THE COST OF LABOUR AND OF THE HOUSEHOLD. — The cost of manual labour includes the wages, at a fixed rate, of permanent and casual labour together with the cost to the farmer of his supervision and work as well as that of his family.

The variation in cost of manual labour before and after the war are shown in Table VIII.

TABLE VIII. — *Average cost of labour in francs per hectare.*

Year	Hectares cultivated	Employers working Expenses	Coaf of habour and food
1901	257.35	185.50	71.85
1910	328.40	224.30	104.10
1913	331.23	222'79	108.44
1915	343.62	216.10	127.52
1916	370.89	232'89	138.00
1917	470.81	300.75	170.06

For the last year (1917-18) the increased cost of labour as compared with that for 1916-17 is given in Table IX.

TABLE IX. — *Increase in labour costs in* 1917-18.

Hectares	Cost per family per hectare	%	Cost in wages per hectare	%
	fr.		fr.

Cost of supervision	0.06	4.96	—	—
Total increase	1.21	100.00	0.78	100.00

Economic revenue obtained from Swiss agriculture. — This revenue is the total of all the income of the persons who collaborate in agricultural production. It is interesting to note the influence of the war on this index of production which is the most important from an economic standpoint. This index on account of its importance, is given for various sizes of farms in % of the active capital, and that per hectare cultivated. Tables XIII to XVI illustrate this and the distribution of revenue per person contributing to the production.

Table XIII. — *Return on* 100 *fr. of working capital* (*in francs*).

Size of Farms	1914	1915	1916	1917	Average 1903-1905	Average 1906-1913	Average 1914-1917

The labourers wages have increased from 94.33 fr. per hectare in 19 to 146.50 fr. in 1917. The return on the farmer's capital has increase on an average, from 98.60 fr. (in 1908-13) to 477.40 fr. i 1917.

Rates and taxes, which represented 11.50 % of the income betwe 1908 and 1913, have increased to 12.74 % in 1917 having reached 15.29 in 1916, the year when the war supertax was imposed.

TABLE XV. — *Distribution of the returns in % of the income, amongst the persons contributing to the production.*

The expenditure per hectare, for the years 1914-1917 in taxes, interest on loans, etc., and in working expenses, salaries, etc., is shown in Table XVII.

The working profit, which was $^3/_5$ of the total revenue in 1913, diminished to $^2/_5$ in 1917, whilst the capital returns increased from $^2/_5$ to $^3/_5$ during the same period.

908 – **Agricultural Book-keeping in Canada.** — *Communication from* Mr. J. K. DOHERTY *Head of the Bureau corresponding with the International Institute of Agriculture. Department of Agriculture. Ottawa.*

The following is a brief summary of the reports, sent to the Canadian Department of Agriculture, by the local authorities, on agricultural book-keeping in the Provinces.

British Columbia. — In this province farmers rarely keep accounts. The Department of Agriculture has sent out circulars to the secretaries of the Farmers' Institutes asking them to undertake propaganda on this subject among their members. So far the results have been so poor that the University authorities have decided to give courses of instruction in agricultural book-keeping.

Alberta. — The Department of Agriculture here has carried out investigations on the Demonstration Farms as to cost prices, and in order to check the results obtained, and to find out the average profits and cost the Department has kept the books of a number of farmers in the Province. The Province also provides the Agricultural Colleges with a manual giving a good simple method of book-keeping.

Saskatchewan. — The Department of Agriculture has started a book-keeping competition for crop statistics amongst its correspondents, on the understanding that all those who enter must send their books up for examination once a year.

The College of Agriculture gives courses in Agricultural book-keeping, but that is all.

Ontario. — Book-keeping in Ontario has not received much encouragement, and all that is done is to recommend its use as a necessity. The Department of Agriculture distributes gratuitously a simple method of book-keeping consisting of a register for receipts and expenses and an inventory. The problem of ascertaining cost prices has not yet been taken in hand.

The Department is now considering a thorough system of book-keeping which will be distributed shortly to the farmers, who will thus be able to collaborate in supplying data for "Farm Business Survey Work".

The State Banks have also greatly helped, during the last few years by supplying their agricultural clients with an amplified account book in which to enter cash transactions relative to farm business.

Quebec. — Two little books have been prepared, one containing a simple system, and the other a more complete one. These are sent to traders and farmers who have some knowledge of book-keeping. The local agricultural officers distribute the books to the farmers and explain how the accounts should be kept ; they examine the books at the end of the year. This method has given excellent results so far.

New Brunswick. — No definite plan has yet been adopted, but district representatives have carried out some propaganda and are distributing a book prepared by the Commission of Conservation.

Nova Scotia. — A course in agricultural book-keeping is held at the Agricultural College. No other steps have been taken.

AGRICULTURAL INDUSTRIES

INDUSTRIES DEPENDING ON PLANT PRODUCTS

909 – **The Rapid Aging of Barbera Wine.** — Martinotti, F., and Garino-Canina, E. (R. Stazione enologica d'Asti), in *Giornale vinicolo*, Year XLVI, No. 25, pp. 192-194. Casale-Monferrato, June, 1920.

Although it can be said that the artificial aging of Barolo, Chianti, and Barbaresco wines is an accomplished fact, this does not apply to other types of wine. If, however, this treatment only saved 50 % of the time, it would be of decided advantage.

The authors have tried the Monti process in their experiments in aging Barbera wine. If the latter is cooled almost to freezing-point, a current of filtered air passed through it repeatedly for a given time, and subsequently exposed to a temperature of between 24 and 30° C, a deposit is formed, which is then removed. It is advisable to add 8 % of old wine.

Experiments were made as long ago as the spring of 1918, on wines coming from Montaldo Scarampi, and Montegrosso d'Asti, the classical districts of the Barbera vines. Three vintages were studied, those of 1915, 1916, and 1917.

In each case, 2 hectolitres of wine were placed in a demi-john and kept in a refrigorator at —4° C. Much time was required in order to reach the desired degree of cold. After this, the wine was aerated for 15 min. on 8 consecutive days. Glass tubes with fractionating bulbs at the end were used, and the air was filtered through plugs of cottonwool, after having first been bubbled through 95° alcohol. The refrigeration and aeration produced a thick deposit which separated by decantation. The wine was subsequently exposed for 2 months, June and July, to a temperature of 20-30° C, when a slight precipitate was again formed and removed. The wine was put in the cellar and bottled in the spring of 1919.

Three lots were made every year : No. 1, control, untreated ; No 2, refrigerated, aerated, and heated wine ; No. 3, the same test as No. 2, with the addition of 4 % of old Barbera wine from the same districts.

In April 1920, the wines were analysed and tasted.

No. 2 of the 1915 vintage was a bright, ruby coloured wine, and more mature by at least a year than the control, whereas No 3, although of the same colour, and apparently at least 2 years more mature than the control, was inferior to No. 2.

No. 2 of the 1916 vintage seemed a little more mature than the control, while No. 3 was the least delicate of the three, and perceptibly aged.

No. 2 of the 1917 vintage had a finer aroma and flavour than No. 3, and its maturity was a little above the normal, approaching that of No. 3. As No. 1 had altered during the experiments, it was neglected.

It should also be noted that the 1915 wine had the old "barolo" bouquet of 12 year-old Barbera wines of this district.

In 1916, there was a great decrease in the total acidity, chiefly due to the breaking-down of the malic acid, with the formation of 2 gm. lactic acid. This applies to lot No. 3 as compared with Nos. 1 and 2.

The authors, who intend making further experiments on Barbera, Valpolicella, and Gattinara wines, give the analyses which they have already obtained in the course of their work.

910 – **The Effect of Phosphates on Alcoholic Fermentation.** — Garino-Canina, in *Le Stazioni sperimentali agrarie italiane*, Vol. LIII, Nos. 1-3, pp. 67-78,1 Diagr, Bibliography of 12 works. Modena, 1920.

That phosphorus is of great importance for grape ferments is shown by the fact that about 59 % of the ash of saccharomycetes consists of phosphoric anhydride. Phosphorus is important to the technique of fermentation in general, for in some rare cases, owing to the natural absence of phosphates, it may be the determining cause of the process. It plays a special part in making "filtrati dolci", and sweet sparkling wines, in which one or more substances are wanting which are necessary to the life of the saccharomycetes. Wine contains from 125-510 mgm. P_2O_5 per litre, and generally, though not always, fine wines are rich in phosphorus.

Previous investigators have already tested the effect of tricalcium phosphate, ammonium phosphate (Astruc); potassium phosphate (Meyer, Elion) ; to the must the author proposed to make a contribution to the study of the question by first investigating the action of phosphates upon

the saccharomycetes, and afterwards upon fermentation properly so-called.

He used a culture medium composed of: 100 gm. saccharose + 2 gm. tartaric acid + 1.5 gm potassium carbonate + 0.75 gm. potassium sulphate + 0.25 gm. magnesium sulphate + 0.10 gm. calcium chloride + 2.5 gm. asparagin + distilled water to make up 1000 gm. To this the author added increasing amounts of potassium sulphate: from a minimum molecular concentration of 0.000052 to a maximum of 0.036. When the fermentation was finished, he collected the saccaromycetes on a tarred filter, weighed them, and analysed the liquid filtrate.

The results are set forth in tables and illustrated by a diagram. On examining them critically, it can be seen that phosphorus, even when added in very small quantities, has a decided effect upon the development of the saccharomycetes. The maximum result was obtained with the molecular concentration 0.0104; this corresponds to about 1 part per 1000 of bi-potassium phosphate.

The effect was less favourable when larger amounts were used. The weight of the yeast also increased in proportion to that of the phosphorus added. In confirmation of ASTRUCS' observation, those samples to which the phosphorus had been added had a high volatile acidity.

The author made a second series of experiments upon the action of phosphates on alcoholic zymase using pure yeast that had been prepared under strictly aseptic conditions. He found that the maximum effect is obtained with 2 parts per 1000; this amount brings about fermentation after 2 minutes. The degree of fermentation was in inverse proportion to the amount of phosphate introduced.

The same experiments have been repeated with the prepared yeast "zimina" (called by the Germans "Dauerhefe"), which has the same properties as yeast-juice. The results confirmed those obtained with living yeast.

These experiments prove the extreme importance of phosphorus, even in minimum quantities, and show that experts had good reason for advising the addition of ammonium and potassium phosphates to liquids to be used for the preparation of yeast. This is especially advisable in making sparkling wines, for insufficient pressure and effervescence in these wines is sometimes due to lack of phosphates.

DISEASES OF PLANTS

DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN

911 – **Alteration of Grapes, in Brazil.** — PUTTEMANS, A., in *Bulletin de la Société de Pathologie végétale de France*, Vol. VII, Part 1, pp. 34-36, 1 fig. Paris, 1920.

The author draws attention to a disease attacking grapes is Brazil which he previously recorded in 1906.

It makes its appearance in some years towards the end of November, a little before the vintage, on the bunches of the « Isabelle » vine (*Vitis Labrusca*), which has long been cultivated on a large scale in the states of São Paulo and Rio de Janeiro. Vines growing as espaliers against the wall, and those in the vineyard suffer equally. On the infected bunches, which are usually the finest and most compact, berries of a livid colour are seen here and there, and these subsequently become dry and shrivel, large wrinkles appearing on their surface. Some of the grapes surrounding these berrries show the same alteration and it would seem at first sight that the disease is due to a parasite transmitted in contact from one berry to another. The malady seems to be localised in the berry for if an infected grape falls — which easily happens — the pedicel shows no sign of alteration.

A more careful examination reveals the fact that the disease is due to a want of equilibrium in growth produced by the too rapid swelling of the grapes, which is not accompanied by the simultaneous lengthening of the pedicels, or secondary ramifications of the bunch.

In fact, in the case of very compact bunches, the berries as they increase in volume tend to recede from the centre of the bunch, and exert a pull upon the pedicels which increases with the rapid swelling of the grapes. This pull, which is exerted simultaneously by several of the berries of the small secondary bunches that form the large composite bunch, ends by detaching the former from the rachis.

Very frequently, the berries in the centre of the bunch, which usually atrophy more or less, now grow in an almost normal manner, and this tends to push the berries covering them still further from the centre.

In any case, the small secondary bunches borne by the principal one, although nearly detached, still adhere by a strip of tissue, and this traumatism (change of colour and withering of the grapes) is all the more rapid when the detachment is almost complete, and atmosheric conditions are favorable.

As regards the damage done, it is not a rare thing to see a third, or even half, of the small secondary bunches thus affected and if the disease spreads to a large number of them, the yield may be considerably reduced, at any rate in certain seasons.

It seems that the phenomenon may be explained by the prevalence of special climatic conditions at the time of the ripening of the fruit. In November in Brasil, there are sometimes very rapid changes of temperature amounting to as much as 40° C and the rainfall may exceed 50 mm. in 24 hours. The abrupt change from heat to humidity may cause irregular growth such as has been mentioned above.

A certain amount of thinning early in the season, as is usually practised with hothouse grapes in order to obtain fine table-fruit, is the only remedy or palliative for this disease.

912 – **The Destruction of the Elm by Poison-Gases in War.** — GRAFFIN, R., in *Comptes rendus des séances de l'Académie d'Agriculture de France*, Vol. VI, No. 24 (June 23-30 1920), p. 609. Paris, 1920.

The elm has proved extraordinarily susceptible to the injurious effects of poison-gases, more so indeed, than any other forest tree.

In the *massif* of the Argonne chain running from the Valley of the Bar to the Meuse (Vouziers to Stenay), there are many dead elms that show no trace of having been struck by missiles, or otherwise injured.

Elms are equally susceptible whether they are growing singly or in a coppice, and their age makes no difference.

If a dead tree is found there to-day in a stand, the probabilities are that it will prove to be an elm, although this corner of Argonne was not bombarded until November, 1918, and then only for a short time, at the season when the trees had shed their leaves.

DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS

913 – ***Bacterium atrofaciens* n. sp., Injurious to Wheat, in the United States and in Canada.** — MC CULLOCH, L., in *Journal of Agricultural Research*, Vol. XVIII, No. 10, pp. 543-552, pl. 2. Washington, D. C., Feb. 16, 1920.

DISEASES OF VARIOUS CROPS

In the course of examination of various collections of wheat of the crops in 1917 and in 1918, a new bacterial wheat disease was discovered in the United States (New York, Michigan, Kansas, Missouri, Minnesota, North Dakota, South Dakota, Oklahoma) and in Alberta, Canada.

This disease affects the leaf, ear, and grain of wheat. On the ears, the glumes show at the base a dull brownish black tinge. Sometimes, this dark area extends over nearly the whole surface of the glume ; but usually only the lower third or less is darkened, and often no discoloration is visible on the exterior. Glumes that present a normal colour on the outer surface may have the inner surface discoloured. In every case, dissection of the spikelet reveals more signs of disease on the inner surfaces than on the onter. Often a narrow dark line at the junction of the spikelet and the rachis is the only outward sign of disease. The grain enclo-

sed by diseased glumes shows varying degrees of undevelopment. The fact that the grains are often well filled out seems to indicate that the disease sometimes appears late in the course of growth. In diseased grain the base varies in colour from a scarcely noticeable brown to charcoal black. In the discoloured areas, bacteria are found in great abundance, which have been isolated and pure cultures obtained. The organism in question studied by the author from the point of view of cultural characters is considered to be the cause of the wheat disease in the pre-mentioned regions. It was a hitherto undescribed organism, and it is here designated as *Bacterium atrofaciens.*

Inoculations on young wheat plants have given rise to numerous leaf infections. Fewer mature plants have been available for inoculation of ears and besides this, weather conditions were somewhat unfavourable. However, enough infections were effected to determine the positive pathogenicity of the organism for glumes and kernels. The organism has also been re-isolated from the glumes and kernels of inoculated ears, and a second series of inoculations effected on the ears and spikelet leaves. Infection was evident also in this second case and it was possible to re-isolate the bacteria once again.

914 – **Self-Sown Wheat in Relation to the Spread of Rust, in Australia.** — WATERHOUSE, W. L., in *The Agricultural Gazette of New South Wales* Vol. XXXI, Pt. pp. 3, pp. 165-166. Sydney, May 2, 1920.

Report of periodical observations made from June 1918 to March 1919, in the Government Experiment Farms in New South Wales with a view to securing evidence on the question as to how rust of wheat survives after the heat of the Australian summer, and how the next year's crop comes to be infected.

The summer of 1918-1919 was one of the hottest on record in the districts under investigation ; drought conditions were general and no rust epidemic was reported anywhere in the State.

It should be remembered the destructive rust of the wheat crop in Australia is the black stem rust (*Puccinia graminis*). A second form, known as the brown spring rust (*P. triticina*) occurs, but it does not usually do much damage.

In June, 1918, on the leaves, stems and ears of the self-sown wheat, and in abundance on the fields reserved for this crop, a large amount of *P. graminis* in the uredo and teleuto stage was found, as well as uredospores of *P. triticina.* These uredospores were tested and proved viable. No sign of *P. graminis* was found on the cultivated crop ; although pustules of *P. triticina* were plentiful on the seedling leaves.

At the end of August, 1918, the self-sown wheat was badly attacked by rust, but on the leaves of the cultivated crops, only uredospore pustules of *P. triticina* were found. One paddock that had previously contained a self-sown wheat crop that had been attacked, and later on had been ploughed, produced many wheat plants growing up between the furrows attacked by both forms of rust ; *P. graminis* and *P. triticina.*

Towards the end of November, on the green parts of cultivated wheat, viable uredospores of both rusts were found, though practically no damage had been done to the crop. "Volunteer" wheat, particularly around haystacks, was red with *P. graminis* on all parts of the plants above ground. The field under consideration had been ploughed, reploughed and cultivated, but in spite of this, a few stray "volunteer" wheat plants carrying viable uredospores of both rusts were still to be found.

The latest inspection was made at the end of March, 1919. The summer had been exceptionally dry and very hot ; no second growth had occurred, the stubble having been killed out by the dry weather in most places. A light rain in February had encouraged germination of much of the shed grain, but on these seedlings no rust was discovered. Only in one place was rusted wheat found, this was in a paddock which had laid fallow for nearly a year, ploughed a couple of months previously, and at the time of this visit was being cross-ploughed and harrowed in preparation for sowing the wheat. Here, in the centre of several much-grazed tufts of wheat that had assumed a somewhat perennial nature, were found uredo pustules on leaves, inner surface of sheaths and stems. In the cases examined the rust proved to be the brown spring rust, but it is by no means improbable that the black summer rust was also present in some of the tufts. In an adjoining paddock, no rust pustules were found on the early sown crop of wheat. Numerous pale patches were observed on many of the seedling leaves.

While these observations are far from complete, they nevertheless show the importance of self-sown wheat as an agency in the spread of rust by means of the uredospores.

915 - ***Sphacelotheca Reiliana*, New Maize Smut in Washington, U. S.** — Dana, B. F., and Zundel, G. L., in *Phytopathology*, Vol. X, No. 6, pp. 328-330, figs. 4. Baltimore, M. D., June, 1920.

During the autumn of 1919, *Sphacelotheca Reiliana* (Kühn) Clinton was seen in the neighborhood of Pullman ; this smut is identical with that found usually on *Sorghum* spp. but was not previously known to occur in Washington.

Two widely separated fields were attacked, one field showing 40 % of smutted plants. "Thayer's yellow dent" maize was the variety grown in both cases, the seed having been selected from local stock for a number of years.

Sori or smut masses were observed in ears and tassels only. In one field the latter were most commonly affected, and in the other the reverse was evident. In addition to this, some cases of sterility accompanied by proliferation were observed both in the ears and male inflorescence giving rise to abnormal and dwarfed development.

Occasionally a normal ear was produced on a plant showing a diseased tassel. Many plants were on the contrary seen where the ear was smutted and the tassel normal. However, in one field where a special study of symptoms was made, the ears were affected generally where smut masses were noticed on the tassels.

916 - ***Peronospora parasitica* in Turnip Roots, Indiana, U. S.** — GARDNER, M. W., in *Phytopathology*, Vol. X, No. 6, pp. 321-322, pl. 1. Baltimore, M.D., June, 1920.

Among turnip roots (*Brassica Rapa*) in storage and in the local market in Lafayette, Indiana, an occasional root was found in February, 1918, showing an internal region extending from the crown to the root with a tissue varying in colour from a light brown to a distinct black, although quite firm and turgid.

After cutting sections of one of the affected roots and placing the same in a damp chamber in the refrigerator, upon the cut surfaces of the discoloured tissue, there occurred a luxuriant development of conidiophores and conidia of *Peronospora parasitica*.

A series of inoculations were made in the conidia of the seedlings of turnip, *B. campestris* var. *Napo-Brassica* and radish. From these it was observed that the turnip seedlings were readily infected and showed abundant sporulation of *Peronospora* on the cotyledons. No infection occurred on *B. campestris* var. *Napo-Brassica*, nor on uninoculated turnips and radishes used as controls.

The occurrence of living mycelium of Perenosporaceae in turnip roots in late winter appears to indicate that it may also hibernate over the winter in turnips which remain in the field.

917 - ***Blepharospora terrestris*, a Phycomycete Parasitic on White Lupin, and New to Italy.** — PEYRONEL, B., in *Rendiconti delle sedute della Reale Accademia dei Lincei*, Classe di Scienze fisiche, matematiche e naturali, 1st. Half-year, 1920, Vol. XXIX, Part. 5, pp. 194-197. Rome, 1920.

In December, 1919, some young plants of *Lupinus albus* suffering from rot of the roots and hypocotyl region were sent for examination to the Phytopathological Station at Rome from the estates of Pantano and Pratolongo (in the neighbourhood of Lake Regillus). All that remained of the root system was the tap-root and a few secondary roots, and there was no sign of the root-tubercles. The entire surface of both the roots and the lower part of the stem was of a dark-brown colour and soft to the touch ; all the leaves, except a few at the top of the stem, were withered.

The author found by microscopic examination of the affected parts that the roots and nearly the whole hypocotyl were infected and completely disintegrated by a mycelium which, from its morphological characters, appeared to be that of a phycomycete. In the cortical tissue of some quite young plants, he discovered the oospores of the fungus.

With the object of increasing the material for study, and of observing the behaviour of the fungus, the author prepared two series of lupin cultures in cylindrical pots without any drainage hole. As soon as the plants put out their first leaves, he watered them in such a way that the soil was always covered with a layer of water 1-2 cm. deep. One series of the seedlings he kept for a control ; amongst the others, he planted some infected lupin plants (that had been kept in water). The result of the experiment was that the seedlings growing with the infected plants all died, while the control seedlings remained perfectly healthy.

In the root tissues of the dead plants, the author found only mycelium, but in the cortical tissues, there was a large number of oogonia and ripe oospores, the latter being identical with those present in the material forwarded for examination.

On the submerged cotyledons of the dead seedlings, he subsequently discovered a thick external mycelium floating on the water, and as microscopic investigation revealed, bearing large zoosporangia.

The observations hitherto made, allow of the identification of the fungus in question as *Phytophthora terrestria* Sherbakoff, found in Florida.

Before the author had discovered its identity with *Ph. terrestria* he had been struck by the extraordinary similarity between the fungus he was studying and *Blepharospora cambivora* Petri, now believed, as is well-known, to be the specific agent of the " Ink Disease " of Chestnuts. It is evident, according to the author, that the species described by Sherbakoff has all the characters of the genus *Blepharospora* as defined by Petri, although it is very distinct from *Bleph. cambivora*. The author proposes the name of *Bleph. terrestris* (Sherb.) Peyr. for the fungus examined by him.

M. Peyronel is induced to believe that the fungus in question is not a recent importation from America, but a ubiquitous species already existing in Europe, and usually living as a saprophyte in very damp soils, but capable, under favourable conditions, of adopting a parasitic mode of life.

No control measures can at present be suggested beyond the destruction of infected plants, and the disinfection of the soil with carbon bisulphide or formalin. It is also advisable to grow a herbaceous plant, for some such as a years cereal, that is immune to the disease, instead of lupins.

918 - ***Ustilago Coicis* on *Coix Lachryma-Jobi* in the U. S.** — Thomas, C. C., in *Phytopathology*, Vol. X, No. 6, pp. 331-332, figs. 1. Baltimore, M. D., June, 1920.

On a speciman of *Coix Lachryma-Jobi*, grown in the Plant Quarantine Greenhouse of the United States Department of Agriculture obtained from seed coming from Kalasungay, Mindanas (Philippine Islands), was noticed towards the end of December, 1919, the appearance of " Coix smut" (*Ustilago Coicis* Bref.), a disease not hitherto reported in North America.

Every grain affected is converted into a black spore mass, slightly increased in size, which, however, in some cases may reach to almost double the size of a normal grain. The grain may be badly deformed or it may be almost normal in outward appearance. The spore mass is surrounded by a membrane and is more or less hidden by glumes. The leaves and portions of the culms adjoining the diseased grains are distorted and bent.

The life history of the parasite is unknown and it is difficult to say in this case whether it was introduced by spores on the seeds or by dormant mycelium within.

919 - ***Polyporus igniarius* Injurious to the Vine, in Tunisia.** — Kien, E., in *Revue de Viticulture*, Year 27, Vol. LII, No. 1347, pp. 289-290. Paris, 1920.

Numerous cases of the death or partial withering of vines at the pruning season were observed in the neighbourhood of Tunis in 1919, and still

more frequently in 1920. The varieties chiefly affected were " Carignan " and " Alicante ".

The author's investigations have shown that the diseased vines were always infested by a mycelium which is probably that of *Polyporus igniarius*, and the author recommends the disinfection of the pruning-knife by passing it through a flame, before going from one vine to another.

920 - ***Monilia fructigena* and *M. cinerea*, Brown Rot Diseases of Fruit Trees (*Pyrus* and *Prunus* spp.) in Great Britain.** — WORMALD, H., in *Annals of Botany*, Vol. XXXIV, No. 134, pp. 143-171, pl. 2, bibliogr. of 30 works. London, April, 1920.

In Great Britain there are two species of *Monilia* parasitic on fruit trees of the genera *Pyrus* and *Prunus*, namely, *M. fructigena* Pers., (=*Sclerotinia fructigena* [Pers.] Schröt.), and *M. cinerea* Bon.

The two species are to be distinguished by the colour and size of the pustules, by the dimensions of the conidia, by the mode of growth on sterilised culture media, by the mode of branching of the germ tube of conidium, and by the mode of parasitism.

M. fructigena causes a fruit rot of apples, plums, and cherries and on apple trees may produce cankers by invading the branch through the fruit.

M. cinerea occurs also on apple, plum and cherry trees and causes disease as follows: — apple trees : blossom wilt and canker disease ; — plum trees : fruit rot, blossom wilt, canker, and wither tip of young shoots ; — cherry trees : fruit rot, blossom wilt, and may kill twigs by penetrating through the flowers.

In *M. fructigena*, conidia production is inhibited during winter; *M. cinerea* on the other hand begins to develop new pustules about the beginning of December and produces conidia freely during winter and spring.

The winter conidia of *M. cinerea* are considerably smaller than those produced in the summer.

The form of *M. cinerea* parasitic on apple trees is biologically and physiologically different from the form found on plum and cherry trees. *M. cinerea* f. *Mali* produces an apple blossom wilt ; it readily secretes an enzyme which oxidises tannins ; *M. cinerea* f. *Pruni*, when plum blossoms are inoculated with conidia, this attacks only the flowers actually inoculated and does not attack the axis of the inflorescence ; it secretes the oxidising enzyme far less freely than the apple.

The oxidising ensyme is secreted freely by *M. cinerea* f. *Mali* when growing in a liquid culture media, on diseased apples, and on diseased apple spurs.

The American form of *Monilia* is more nearly related to *M. cinerea* than to *M. fructigena*, but in cultures it can be distinguished from the European form of *M. cinerea* by its mode of growth and by the numerous fructifications produced on all the culture media on which it has been grown up to the present time.

921 - ***Pucciniopsis Caricae*. Leaf Blight of the Papaya (*Carica Papaya*), in Florida.** — STEVENS, H. E., in *The Quarterly Bulletin of the State Plant Board of Florida*, Vol. IV, No. 3, pp. 98-100, Gainesville, Flo. April, 1920.

A leaf blight of the papaya (*Carica Papaya* Linn., has recently been reported at St. Cloud (Florida), where it was learned from the owner of the plants attacked that the disease first made its appearance in 1920 and spread very rapidly. The disease was also observed on some of the plants in a neighbouring farm.

This is not a new disease and has been previously reported in Porto Rico, Cuba, British Guiana and Sanibel Island, Fla. This appears, however to be the first record of its presence on the mainland of Florida, and it might prove to be a serious pest to the papaya in the southern part of the State should the disease become widely distributed.

The disease, which is caused by *Pucciniopsis Caricae* Earle, is easily recognisable by the round black, pustular spots on the under surface of the leaf which enclose the septate spores of the fungus. On the upper surface, the infected areas appear as small brown circular spots, distinctly outlined. From a few to several hundred spots are likely to be present on a single infected leaf.

Severe attacks will engender defoliation of the plants resulting in death or a very much weakened plant.

If the disease is discovered in time, it can probably be easily controlled by the use of Bordeaux mixture. Three or four sprayings at intervals of 10 days to 2 weeks apart on both sides of the leaves should be sufficient to put down a mild attack. In cases of severe attacks, all of the older infected leaves should be removed and destroyed. The remaining foliage should be thoroughly sprayed with Bordeaux mixture at weekly intervals, until the new leaves that develop are entirely free from infection. If the badly infected plant is a young one, it will be more economical to destroy the same and re-commence with another healthy plant. All the seedlings should be closely watched, especially if they are grown in the vicinity of old diseased plants. In such cases frequent application of Bordeaux mixture will be necessary to protect them from disease.

When the disease appears, efforts should be made to eradicate it as quickly as possible.

922 - **On the Presence of Oak Oidium in Brazil.** — PUTTEMANS, A., in *Bulletin de la Société de Pathologie végétale de France*, Vol. VII, Part I, pp. 37-40. Paris, 1920.

In a garden of the town of São Paulo, the writer first observed oidium on October 1, 1912, on trees of *Quercus pedunculata* of about 15 years of age. The fungus was heavily parasitised by *Cicinnobolus Cesatii*.

A very large number of oaks growing in different public and private gardens were inspected the next day, and only in rare cases were they found to be attacked ; a week later, however, oidium was distinctly visible on most of these trees.

Shortly afterwards, M. MAUBLANC informed the author that he had found the same fungus at Campinas (about 100 km. from São Paulo) ; in April 1913, the author himself saw it at Petropolis and Nova Friburgo

(State of Rio Janeiro) on specimens of *Q. palustris* Du Roi amongst others ; about the same date, M. MAUBLANC met with it also in Argentina.

It should be mentioned that, at São Paulo during the second half of 1912, a damp period hot and very rainy succeeded one of abnormal cold ; this state of affairs was very favourable to the development of the fungus, which under such conditions, causes serious injury, even to large trees.

The sudden appearance of oidium in Brazil, five or six years after it had been so common in Europe, is no doubt a proof that it was introduced from that continent.

As for the mode of its introduction, the author does not think it likely that the perithecia of the fungus were transported (1), for these organs have always been extremely rare everywhere ; he also thinks that it is impossible that the disease should have been introduced into Brazil by young imported oaks, seeing that the oak is so easily propagated by the acorns which the trees of the country produce in abundance.

Leaving out of account the transport of living ocean or windborne conidia, which however might occur, there only remains to consider whether, the common, conidial form of the fungus might not have been carried by some fast ship. Experiments made regarding the duration of the germinative power of oidium conidia, as compared with the time necessary (8-9 days) for their transport to Brazil (port of Rio de Janeiro) from the nearest infected region (Madeira, where oidium was reported in 1908), have led the author to believe that as the germinative power of the conidia has been known to last ten days, this form of the parasite could well have been carried by a trans-Atlantic liner, and this might have occurred very many times during the four years between the discovery of the disease in Madeira, and its appearance in Brazil.

INJURIOUS INSECTS AND OTHER LOWER ANIMALS

MEANS OF PREVENTION AND CONTROL

923 - ***Coccinella sanguinea*, a Beetle Preying on Aphids in Cuba.** — SUAREZ, C., in *Revista de Agricultura, Comercio y Trabajo*, Year III, Vol. III, No. 2, p. 75. Havana, 1920.

Coccinella sanguinea, popularly known as " cotorrita roja ", is a very common beetle throughout the island of Cuba.

The author had the opportunity of observing the larvae feeding on the aphids that attack various cultivated plants: — *Gossypium* sp., *Meibomia leiocarpa*, *Hibiscus Sabdariffa*, *Citrus* sp., etc. He found that the insect reproduces itself throughout the year, but chiefly during periods of drought when aphids are especially plentiful The author gives a short morpho-biological description of the beetle from the egg to the adult stage

(1) *R.*, February, 1920, No. 264. (*Ed.*)

924 - ***Coracias indica*, Beneficial Bird to Agriculture,, in India.** — FLETCHER, T. B. and INGLIS, C. M., in *The Agricultural Journal of India*, Vol. XV, Pt. I, pp. 1-4,, 1 col. pl. Calcutta, Jan. 1920.

The Indian Roller or Blue Jay (*Coracias indica*), occurs in considerable numbers throughout the Plains of India and Ceylon, and is easily recognised when on the wing owing to the brilliant colour of its feathers.

The breeding season takes place in Bihar from March to the end of June, and in January in Ceylon. The nest is made in a the holes of a tree or building, and four or sometimes five eggs are laid.

Besides being an ornament to the landscape, *C. indica* is an extremely useful bird, as its food consists almost entirely of large insects, such as grasshoppers (*Acridae*), crickets (*Gryllidae*), and beetles (*Coleoptera*), and occasionally small mice, frog snakes, or even toads.

An examination by C. W. MASON of the stomachs of 18 birds between January and October at Pusa, led to the discovery of 412 insects eaten by these birds; 4 only were beneficial, 111 injurious, and 297 neutral. Of the injurious insects captured by *C. indica*, 52 were grasshoppers, 18 crickets, 22 caterpillars, mostly cutworms (*Noctuidae*), so that the benefit obtained by the destruction of these injurious insects far more than counterbalances the fact that very few beneficial insects were taken.

The bird is protected under the Wild Birds and Animals Protection Act, throughout the whole year in Bihar, Orissa and in Delhi. In spite of this, Europeans frequently shoot them especially in the neighbourhood of military cantonments, for the sake of the brilliantly coloured wings.

925 - ***Prodenia litura* and *Cirphis loreyi*, Caterpillars Injurious to Crops of Northern Gujarat, India.** — JHAVERI, T. N., in *The Agricultural Journal of India*' Vol. XV, Pt. 2, pp. 181-184. Calcutta, March, 1920.

In the early part of the monsoon of 1919 after the long and almost unprecedented drought which had resulted in the famine of 1918-19, the farmers were alarmed to find their crops of maize, *Pennisetum typhoideum*, *Paspalum scrobiculatum*, and also chillies and rice etc., attacked by swarms of small dark brown caterpillars which appeared likely to do very serious damage.

These caterpillars, identified as *Prodenia litura* and *Cirphis loreyi* — recognised as well known pests capable of serious damage in many parts of the tropical world — seemed in this case to be confined to the parts of Gujarat where a light soil occurs. They were observed in Surat, Kaira, and in the Panch Mahals and in Barodo, where although known previously, had never been found in such abundant quantities.

The first sign of attack was usually a partial destruction of the leaves; sometimes on an examination of the latter, a group of caterpillars was traced. In the case of cereals, they were often found in the funnel composed of the leaf-sheaths round the central shoot of the plant.

The reason for the exceptional attack in 1919 can probably be attributed to the absence of rain for a very long period.

The caterpillars pupate in the ground chiefly in the higher land, at a depth of 2-3 in. Under conditions of normal moisture, it remains in

his state from 1 to 6 weeks, but with the exceptional drought in 1919, it is quite possible that the pupae may have remained much longer in their concoons. At any rate, the first rains of the second week in June were followed by a remarkably large emergence of moths which laid eggs on many plants, but particularly on the early sown crops and on the grasses which were just springing up. As each female moth laid about 500 eggs in several small masses along a leaf, and as these eggs hatch in about 4 days, it will be easily understood that by the end of June, the small caterpillars were spreading over all the suitable crops growing at the time. As the caterpillars developed, they were found feeding in the early morning, evening and night. During the hot part of the day, they were concealed in the soil or at the base of the leaves of the plant attacked.

The majority of caterpillars which had made their appearance at the end of June, disappeared in the third week of July; those which had become fully developed retired to pupate in the soil; others were badly attacked by tachnid flies. These latter parasites were found as small maggots on the viscera of the caterpillars, while their eggs were noticed on the surface. At this time, too, there was a good deal of heavy rain, and on examination of the soil of the higher lands, the majority of pupae were found to be in state of decomposition, probably as a result of the wet conditions in which they found themselves. Partly, therefore, as a result of the parasites, and partly on account of the rains, the much dreaded second brood, which should have appeared early in August, never gave rise to the alarm which had hitherto prevailed.

The observations made in connection with the attack in 1919 have brought to the fore a number of preventive measures which will if widely practised, lead to successful results in the future. In the first place, the land should be ploughed up before the advent of the rains, or still better, as soon as the previous crop is harvested. By this means, the pupae in the ground will be turned up and either dried out by exposure to the sun or devoured by insectivorious boids. The moths, at least of *C. loreyi* are moreover easily attracted to light, and if a numbrer of lamps are placed in the fields, each standing in a tray of kerosine and water, or if some fires made of brushwood are lighted for a few days after the first rains and the corresponding emergence of the moths, a very large number will be destroyed before they have had a chance to lay eggs.

Also it is equally advisable to delay for a few days the sowing of the the crops. It is a frequent practice to sow immediately after the first rains. This was done in 1919, and the crops so treated were those most attacked. Crops sown a fortnight later were, on the contrary hardly, attacked at all. In special cases, in addition to the precautions enumerated above, children may be employed to collect and burn the leaves on which the egg masses are found and on which also the swarms of very young caterpillars are feeding. In the case of seed beds or fields containing valuable crops, a trench should be dug round the seed bed or field in which green plants can be put in the evening. The large caterpillars sheltering in it can be destroyed the following morning.

926 – ***Trachelus tabidus*, Black Grain-Stem Sawfly of Europe, Injurious to Wheat and Other Cereals, Introduced into the United States.** — GAHAN A. B., in *United States Department of Agriculture, Bulletin* 834, pp. 1-18, fig. 1, pl. 2, bibliogr. of 56 works. Washington D. C., May 19, 1920.

During the summer of 1918 it was discovered that another exotic insect liable to cause considerable damage to agriculture, has become established in America. A complaint was received by the Bureau of Entomology, Washington, D C., from a correspondent at Gaithersburg (Maryland) regarding the work of certain attacks which had caused serious damage to ripening wheat, and steps were immediately taken to investigate the outbreak with the result that this insect was identifield as *Trachelus tabidus* (Fabricius) Jurine; this sawfly belonging to the genus *Cephidae* has already been referred to in European literature (England), and goes by the popular name of "black grain stem sawfly".

In the Old World Continents, the species occurs throughout most of central and southern Europe, south-eastern Asia, ad northern Africa.

In America, the insect was found, before 1918, in New Jersey, Virgiania, Delaware, Maryland, Pennsylvania and New York.

It is probable that the species has even now spread and is likely to spread over a very wide area of the New Continent just as it did the Old.

Various cereals, especially wheat, but also barley and rye, have been attacked, and the Russian records are more specific and confirm this statement.

In America only wheat and rye have thus far been recorded; it appears certain that wheat is the food plant preferred. It is not improbable that *Tr. tabidus* also attacks plants other than those mentioned.

The author gives the synonymy of the insect, and describes the adult and the hibernating larva, and also makes preliminary observations with reference to the life history of the sawfly.

The larvae burrow downwards through the stem pith hollowing it out to the base; before preparing to hibernate, this larva severs the stem from the inside at or very near the surface of the ground, leaving the epidermis of the straw intact sufficient to allow it to stand erect; the first slight bending of the ripened straw causes it to snap off and fall, having the same effect as a strong wind.

An efficacious chalcidoid parasite of *Tr. tabidus* has been notified in America; reared from a species which has apparently never been described, belonging to the genus *Pleurotropis*.

It is recommended to plough in the stubble containing the larvae so deeply that the maturing adult will be unable to escape. Wheat, barley and rye should be followed by some crop which will not serve as a host plant, such as maize or market crops.

927 – ***Cephus cinctus*. Hymenopteron Injurious to Wheat, Rye and other Cereals in the United States.** — AINSLIE C. N., in *United States Department of Agriculture, Bulletin* 841, pp. 1-27, figs. 16, Washington. D. C., May 7, 1920.

The Western Grass-stem Sawfly (*Cephus cinctus* Norton), an indigenous species of the (United States is becoming a serious menace to the grain crops in the Northwestern States.

It appear that various species of *Elymus* and *Agropyron* have been the original host plants of the larvae. Since their feeding habits have been modified by changing agricultural conditions, to the host plants already mentioned may be added the following : *Hordeum jubatum, Bromus inermis, Phleum pratense, Deschampsia* sp., *Calamagrostis* spp., *Festuca* sp., wheat, durum, spelt, rye and probably barley. On wild *Gramineae* and on wheat, the insect has also been observed in North-west Canada.

The egg is always laid in the stem of the host plant either in the hollow of the stem, or in a split made by the saw of the insect. The larva when it escapes from the egg begins almost at once to feed upon the parenchymatous tissue by which it is surrounded in the interior of the stem, excavating for itself a gallery both above and below the spot where the egg formerly lay. When mature the larva makes for the extreme base of the stem, where it does not delay in beginning its preparations for hibernation. Usually at or slightly above ground level, it cuts round and inside the stem, but never severs the stem completely, although this is so weakened that the upper part of the stem above the cut, bent over by the wind, breaks off altogether when dry. After cutting its characteristic groove within the stem, the larva continues to remain there and forces a mass of debris into the bore just below the groove and in this manner plugs the upper end of the stubble that is to be left in the ground after the upper stalk has been broken away. In this way, the larva moves freely until the time of pupation arrives the following summer.

Under normal conditions, when *C. cinctus* lived exclusively in grass stems, the larvae were attacked with varying degrees of success by two or more species of parasites which apparently had not followed the sawfly during its course on the wheat and on other coltivated grasses. The most common parasite is the chalcid *Pleurotropis utahensis*, Cwfd. ; the braconid *Microbacon cephi* Gahan also attacks the larvae in grass stems.

The most effective artificial means of control that can be suggested. at present is perhaps deep ploughing and burying at least 5 to 6 in., deep the stubble attacked by the larvae, to hinder the adults emerging. The ground should in addition to this be adequately rolled.

In certain parts of the United States, the occurence of *C. cinctus* appears to have been confused with that of its congener *C. pygmaeus* L., a stem borer injurious to wheat and probably imported from Europe only a few years previous to the first mention of *C. cinctus* in the United States. The habits of the two species are very similar. As for as it is now known *C. pygmaeus* is not found west of the Mississipi ; while *C. cinctus* has oft, en been found west of this river.

928 – ***Schoenobius incertellus, Chilo suppressalis,*** and ***Cnaphalocrocis medinalis,*** **Microlepidoptera Injurious to Rice in Indo-China.** — VINCENS, F., in *Bulletin agricole de l'Institut scientifique de Saïgon*, Year II, No. 4, pp. 97-105, 2 plates. Saïgon, April, 1920.

The author describes the lepidoptera most commonly found in the Cochin-China rice-fields, which are especially frequented by *Schoenobius*

incertellus Wlk, *Chilo suppressalis* Wlk, and *Cnaphalocrocis medinalis* Guénée (fam. *Pyralidae*).

Of the three, *Sch. incertellus* and *Ch. suppressalis* alone do appreciable injury to rice. Both of them, when in the caterpillar stage, destroy the green shoots, causing abortion in many panicles, but whereas *Sch. incertellus* attacks the whole rice-field, *Ch. suppressalis* concentrates its efforts on circular patches which increase little in size. *Sch. incertellus* over-winters at the base of the stubble left standing after the harvest, and *Ch. suppressalis* lives and reproduces itself on the wild herbaceous plants growing in the rice-field after the crop has been harvested.

To lessen the damage wrought by these two insects, the author advises the following measures.

(*a*) The cutting-down and burning of the weeds that have sprung up in the rice-field and the surrounding fields. This should be done before sowing and planting out.

(*b*) The lighting at intervals (during the vegetative period of the rice) of large fires of brushwood on moonless nights, when the presence of the adult forms of *Sch. incertellus* has been observed in the rice-field. The uprooting and burning of all infected rice-plants forming large yellow patches in the field should be carried out.

(*c*) After the harvest, the straw remaining in the field should be burnt and the soil lightly hoed, in order to break up and aerate the surface soil, and uncover the lower parts of the stubble that the fire has not reached.

Although *Ch. medinalis* is more frequently met with than the other two insects in Cochin-China rice-fields, fortunately it does but little harm, owing probably to the attacks of its numerous parasites. The caterpillars attack the laminae of the rice leaves making longitudinal furrows throughout their length ; along these they devour the green tissues only sparing the lower epidermis. The leaves thus look as if they were striped longitudinally ; later, they are badly torn parallel to the vein, which tends to rupture the delicate, exposed epidermis. It is clear that leaves thus deprived of much of their chlorophyll tissue make less starch, and that the culms bearing them will produce panicles consisting of grains with a lower starch content, but it would be necessary for the insects to be unusually plentiful for them to cause any loss that is really appreciable at the harvest.

Hence, the losses caused by *Cn. medinalis* are too limited for it to be worth while controlling this insect. As however, the adults are attracted by light, a certain number are always destroyed by the fires lighted to kill the adult forms of *Sch. incertellus*.

929 - ***Nezara viridula*. The Southern Green Stink Bug, Injurious to Cultivated Plants in Florida** (1). — DRAKE, C. J., in *The Quarterly Bulletin of the State Plant Board of Florida*, Vol. IV, No. 3, pp. 41-94, figs. 33, Gainesville, Fla, April, 1920.

It often happens that *Nezara viridula*, L., becomes a serious pest to cultivated plants in Florida. Its depredations are also well known

(1) See also *R.*, Feb., 1913, No. 194 ; *R.*, May, 1913, No. 609 ; *R.*, Mar., 1917, No. 298 ; *R.* Aug. 1918, No. 927. (*Ed.*)

in other southern States, but particularly in the Gulf States. The insect is of foreign origin and is almost universally distributed throughout the tropical and sub-tropical regions of the entire world. Its ravages have also been reported in Australia, India, West Indies, Austria and other countries.

Both nymphs and adults of *N. viridula* obtain food by puncturing the tissues of plants and then extracting plant juices. All parts of the plant are attacked, but tender young shoots and maturing fruit are much preferred.

Amongst the numerous plants attacked are tomato potato, sweet potato, beans, *Vigna sinensis*, *Raphanus* sp., *Brassica* spp., *Hibiscus esculentus*, etc. In autumn and early winter, the insect sometimes becomes a serious pest in citrus groves, feeding especially upon the fruit, young seedlings and young shoots of older trees. Similar infestations have been reported for pecan groves (*Carya Pecan*).

From observations made at Gainesville, Florida, it was ascertained that hibernation is imperfect, and about one-half of the individuals remain upon plants in the field throughout the winter months; no breeding takes place during this period. Eggs have been found out of doors the second week of April and as late as December 12. The eggs are deposited in clusters, mostly on the under surface of the leaves. Some females deposited no eggs, while others laid one, two or, even three egg clusters. One single female laid 212 eggs, three clusters of 78, 70 and 64 eggs respectively. No eggs were found in her ovaries at death. In the field, 40 egg clusters collected consecutively, contained an average of a little ove r88 eggs per cluster. Each cluster consisted of from 46 to 126 eggs.

The minimum period for incubation was 4 days. The minimum time for the 5 nymphal stages was 24 days, which points to the conclusion that only 28 days is required from the time the eggs are laid until the adult stage is reached. Field records indicate that there are 4 generations annually at Gainesville and probably 5 in the southern portion of Florida. Development was more rapid during the summer than in either spring or autumn, the temperature having an important bearing upon the period of development of both eggs and nymphs.

Six predaceous enemies have been recorded in the field, the bug, *Euthyrhynchus floridanus* being the most important. Three parasites of the adult and 2 egg parasites have been reared. Out of 800 adults of *N. viridula*, collected in the field during the latter part of May and the beginning of June, 38 % were killed by two dipterous parasites, 31 % by the tachinid fly, *Trichopoda pennipes*, and the rest by *Sarcophaga sternodontis*. The egg parasites were not common at Gainesville; and are represented by species as yet undescribed.

In most cases, parasitised specimens of *N. viridula* failed to deposit eggs before they died. Breeding experiments conducted in the insectary show that, if the eggs are nearly or fully developed within the ovaries of *N. viridula* when the eggs of *Tr. pennipes* are deposited on her body, a female will sometimes deposit eggs after being parasitised. In this

case, not more than one egg cluster is laid before the insect is destroyed. Pairs have been collected while feeding and copulating in the field during the late afternoon, and both sexes died from the effects of parasitism the ensueing night.

When important crops are infested, hand collecting seems to be the best control method. The cutting of the cover or soiling crop will usually keep the insects under control in citrus groves, also in pecan groves.

In cases of severe attacks in citrus groves, it has been demonstrated that hand collecting with large nets can be done successfully and profitably. In using such nets, the work should be done in the early morning or on cool days, when the temperature is below 70° F. At a higher temperature, many of the adult bugs will save themselves by taking flight before they drop into the nets.

Amongst the wild and cultivated plants, the insects generally show a decided preference for leguminous and cruciferous plants. During the autumn, winter (individuals that do not seek protection to hibernate) and early spring, the bugs often congregate upon crucifers such as *Raphanus* spp., *Brassica oleracea* var. *acephala*, *B. chinensis*, *B. Napus*, *B. Rapa*, etc. Some of these plants might serve as a valuable trap crop during these seasons. Experiments at Gainesville, during the summer, show that *Raphanus* and *B. oleracea* var. *acephala*, both growing in the same row, will serve as a trap crop to protect tomatoes.

The seed should be sown about November 1, so that *Raphanus* will be forming pods while the fruit of the tomato is developing and ripening. The insects should be collected by hand.

Leguminous plants (*Vigna sinensis*, *Crotalaria usaramoensis*, haricots, etc.) are much preferred to other plants in the summer and early autumn, especially during the pod formation period. Probably *C. usaramoensis* offers one of the greatest possibilities as a trap and propagating centre for the natural enemies of the bug, during the summer. The plant itself is probably not more or perhaps as attractive to the bugs as *V. sinensis* but the blossoms are very alluring to the *Nezara* parasites. The principal parasite, *Tr. pennipes* ti evidently a constant visitor to the flowers of *C. usaramoensis*. From 10 to 80 % of the specimens of *Nezara* collected on *C. usaramoensis* bore eggs of *Tr. pennipes*. For this reason, it seems evident that this plant should be grown during summer and thus increase the number of parasites. The long blooming and pod-formation period adds much to the value of this leguminous plant as a trap and propagating centre for the natural enemies of *N. viridula*.

930 – **Some Lepidopterous Pests of Sugar Cane in Queensland.** — JARVIS E., in *Queensland Bureau of Sugar Experiment Stations, Division of Entomology, Bulletin* No. 9, pp. 5-16. pl. 1. Brisbane, 1920.

The author records the presence in North Queensland of a few Lepidoptera notified as injurious in the larval stage, to the leaves of the sugar cane. These include :

1) *Cirphis loreyi* Dup. ; 2) *Mocis frugalis* F. ; 3) *Melanitis leda* L. ; 4) *Padraona hypomoloma* Lower ; 5) Undetermined species of Fam. *Psy-*

chidae near gen. *Hyalarcta* ; (6) *Anthela acuta* Walker ;(7) *Ophiusa melicerte* Drury.

The author gives a concise description of these insects in conjunction with biological data ; he also mentions advisable methods of control of certain species.

931 – ***Maculolachnus rosae*, an Aphis Injurious to Rose-Bushes in France.** — GAUMONT, L., in *Bulletin de la Société entomologique de France*, 1920, No. 2, pp. 26-31, Figs. 4.Paris, 1920.

Cultivated and wild rose-bushes are not only attacked by the common and very destructive aphis, *Macrosiphum* (*Siphonophora*) *rosae* L., but also by another which, according to the author, has as yet been little studied.

This insect belongs to the group *Lachnina*, described under the mame of *Lachnus rosae* by CHOLODKOWSKY as a parasite of rose-bush roots in Thuringia.

The author foud this aphis in 1915 and 1918 on wild roses near Wesserling (Upper Alsace), and was able to follow its entire life-cvele, which he describes in the present article. It is often found on cultivated roses in the centre of France around Montargis. M. MARCHAL observed it in 1910, at Fontenay-aux-Roses (Seine).

The injury caused by this insect is quite as serious, though not as apparent, as that done by *Macrosiphum* (*Siphonophora*) *rosae*, Sprays containing nicotine are very useful in the control of these pests.

On account of the systematic characters of this aphis, the author considers it is necessary to establish a new genus for it. It will therefore be known as *Maculolachnus rosae* (Cholodk).

932 – ***Aspidiotus uvae*, Grape Scale in California.** — ESSIG, E. O., in *Monthly Bulletin of the Department of Agriculture, State of California*, Vol. IX, Nos. 1-2, pp. 37-39, figs. 2.Sacramento, California, Jan.-Feb., 1920.

There appears to be no published record of the occurence of grape scale (*Aspidiotus uvae* Comst), in California. Specimens were collected from the American vine of the Catawba variety at Oakland, November 7, 1919. The scales of this pest were abundant upon the old canes as well as on the one year old wood, and were usually hidden under the bark of the host plant.

Various other scale insects have been notified as attacking grapes in California, namely : *A. hederae* Vall., *A. camelliae* Sign., *A. perniciosus* Comst., *Icerya purchasi* Mask., *Pseudococcus bakeri* Essig, *Ps. citri* Risso, *Ps. longispinus* Targ., *Pulvinaria vitis* L., *Coccus hesperidum* L., *Lecanium corni* Bouché, *L. persicae* Fabr., *L. pruinosum* Coq., *Saissetia oleae* Bern., *Chrysomphalus aurantii* Mask., *Lepidosaphes ulmi* L.

Although the scale insects found attacking the grape appear to be numerous, practically none of them are of any importance in commercial viticulture, but some are at times very troublesome in small household vineyards.

933 - ***Anomala undulata,*** **Injurious Beetle on the Mango (*Mangifera indica*), in Florida.** — MOZNETTE, G. F., in *The Quarterly Bulletin of State Plant Board of Florida*, Vol. IV, No. 3., pp. 95-98, figs. 1. Gainesville, Fla., April, 1920.

When the mango is in bloom it may be visited by swarms of the beetle *Anomala undulata* Mels. which when present in considerable numbers may cause serious damage to the plant. Up till now, this species has attracted attention of growers in the Dade County south of Miami (Florida).

The insect was first brought to the authors' notice in February, 1919, when a grower at Larkins, Florida, reported the serious damage caused by *Mangifera indica* to his own mango blossoms. Upon examination, the author discovered that the flowers were severely attacked, the insect having damaged all portions of the blossom in many cases completely encircling the same or cutting it entirely off. Usually, however, the beetles confined their attacks to the floral clusters about the spikes. The beetles were often seen to congregate at the base of the floral spikes where they gnawed away the outer tissues, in some cases, gathering at the tops of the spikes, destroying everything that came into their path.

During the day, the adult beetles were to be found in a quiescent stage in holes in the soil from whence they passed in the early morning up the trees, feeding on the blossoms.

To give an idea of the abundance of these beetles observed feeding on the mango, the author states that at Larkins, under a tree that had been shaken only once, approximately 1300 adult beetles were collected.

The larvae feed probably on the roots of some native or cultivated plant. Up to the present, the author has been unable to find either the larval form or the host plant.

The author has also noticed this species feeding on avocado blossom (*Persea gratissima*). The species had also been found distinctly injurious to beans at Redlands (Florida), and engendered defoliation. In addition to this, the same beetle has been recorded as infesting a variety plants of both herbaceous and woody.

The best means of control as regards the mango, consists in spraying the blossom spikes with either powdered arsenite of zinc or arsenate of lead diluted with: Bordeaux mixture and sufficient soap to assist in the wider diffusion of the combination spray.

934 - ***Ehrhornia cupressi,*** **Coccidae Injurious to *Cupressus macrocarpa* in California.** — HERBERT, F. B., in *United States Department of Agriculture, Bulletin* 838, pp. 1-22, figs. 5, pl. 6. Washington, D. C., June 5, 1920.

Cupressus macrocarpa is one of the most popular shade and ornamental trees in California It is planted separately or in hedgerows and often trimmed into set shapes; due to its well developed and thick habits it makes a good wind-break in exposed areas. It is used expecially along the coast and in the sandy citrus areas of San Bernardino County. It is also cultivated as an ornamental tree in many other parts of the world,

The cypress bark scale, *Ehrhornia cupressi* attacks a large number of trees in California, causing serious damage, particularly to the thickly

planted hedgerows and windbreaks. In the San Francisco Bay region this insect ranks first among the pests of *C. macrocarpa*.

It was found in the course of thorough investigation that tnt his scale insect was not originally found on *C. macrocarpa*, but on *Libocedrus decurrens* which occurs in the mountains of California, Nevada, and southern Oregon. From this host plant it has probably spread to *C. macrocarpa* by the transport seedlings of *L. decurrens* or timber to the regions infested.

The characteristic injury caused by this insect begins to makes its appearance on one or two branches and slowly spreads to the rest of the tree. The leaves turn first yellow, then red or brown, giving the tree a dilapidated appearance. After a few years the whole tree dies.

The scale does not depend solely on *C. macrocarpa* and *L. decurrens* for food, but also attacks *C. arizonica*, and *C. guadalupensis*. At Santa Rosa (Calif), a dead male was found on a *Cedrus Deodara*.

The larvae after they are hatched consist of small oval bodies, pale yellow in colour, and active only for a short time after hatching. They attach themselves to crevices in the bark, and are soon enveloped in a white cottony secretion. As they reach maturity they become reddish-brown in colour and nearly spherical in shape.

Oviposition begins in the spring and continues throughout the summer. The eggs hatch into larvae in less than an hour and soon attach themselves to the host. The females reach the adult stage in the autumn, then hibernate, and start laying in the spring. The males appear towards the end of autumn for mating purposes and then die.

Various insects are acknowledged as parasites of the bark scale, none of which however are sufficiently abundant to be a really efficient means of control. Consequently remedial measures have to be adopted. According to the results obtained as the result of spray tests, a 12 ½ % solution of a " miscible oil " spray (1) (33° Baumé) is recommended. The proportions are as follows : 1 part miscible oil to 7 parts water. To obtain complete control, it is necessary to spray twice, one in August and once in the latter part of September.

935 – **Infestation of the White Pine Aphid, *Lachnus strobi* on *Pinus Strobus* in Massachusetts, U. S. A.** — PEIRSON, H. B., in *Psyche*, Vol. XXVII, Nos. 2-3 pp. 62-63. Boston, Mass., April-June, 1920.

Whilst in the Harvard Forest, Petersham, (Massachusetts), the attention of the author was called to a somewhat isolated clump of white-pine trees (*Pinus Strobus*), 40 to 50 years old, which were dying.

On two sides of the clump, which consisted of a dozen trees were young white pine plantations.

A careful examination showed that the trees were being killed as the result of an extremely heavy infestation of black aphids which upon identification proved to be *Lachnus strobi* Fitch., the White Pine Aphid. Many of the larger limbs were barren of foliage, whereas on others the

(1) Soapy emulsions diluted with water. Cf. SANDERSON A. D. Insect Pests of Farm, Garden and Orchard, New York, 1912, p. 50. (*Ed.*)

foliage was brown, the individual needles each showing many puncture marks made by the aphid when feeding.

The tree were first examined on October 10, 1919, at which time the aphids were laying their eggs on the green needles, in a series of straight lines, generally consisting of 5 or 6 eggs per line, but it was not at all uncommon also to find 10 or 15 attached end to end.

As many as 27 eggs were found on a single needle. At this particular period, large numbers of the aphids were still feeding, and these had congregated on the needles and small twigs. The survival of the insects in spite of heavy rains and low temperatures was remarkable; subsequent investigations showed them feeding up till about November 1.

936 - ***Pityophthorus bassetti*** **n. sp. and *P. occidentalis* n. sp., Coleoptera Parasites of *Picea Engelmanni* in Colorado, United States.** — BLACKMAN, M. W., in *Psyche*, Vol. XXVII, N. 1, pp. 1-5, figs, 1. pl. 1, Boston, Mass, 1920.

Morphological details of two new species of *Pityophthorus*: *P. bassetti* and *P. occidentalis*, parasitic on *Picea Engelmanni*, according to observations made in 1915 at Pitkin, Colorado.

P. bassetti can be obtained by breeding according to report, and will also breed successfully in *Abies balsamea*.

In the case of *P. Engelmanni*, the larvae bore into the bark within touching the sapwood ; while in *A. balsamea* on the contrary, the larvae mines are excavated partly from the sapwood.

GENERAL INFORMATION

937 – **The Antimalarial Rôle of Livestock and Poultry.** — LEGENDRE, J., in *Comptes rendus de l'Académie des Sciences*, Vol. CLXX, No. 12, pp. 766-769, Paris, March 22, 1920. RURAL HYGIENE

Observations made in Tonkin, Madagascar and in France which confirm the important part played by livestock from the point of view of mosquito bites (1).

The horse, and as a general rule, most mammiferous animals are more readily attacked by mosquitoes than human beings ; rabbits are preferred to pigs ; poultry are only occasionally attacked. Domestic animals attract mosquitoes and therefore guard human beings from malarial infection.

The important efficacious rôle played by the rabbit from this point of view is decidedly worthy of attention, owing to the fact that if it is not possible always to breed big stock, there is never any hindrance to rabbit breeding. Poultry keeping has no value in this respect ; not only do the mosquitoes avoid poultry, but the eggs are never even laid in the drinking troughs.

938 – **The Action of Radium Emanation on the Vitamines of Yeast.** — SUGIURA, K., and BENEDICT, S. R., in *Journal of Biological Chemistry*, Vol. XXXIX, No. 3, pp. 421-433, diagr. 1. Baltimore M. D. October 1919.

As a result of practical experiments with white rats, the authors have come to the conclusion that growth-promoting factors may be inactivated partially by means of exposure to radium emanation. It is possible that the therapeutic effect of radium upon neoplasms may be due in part, at

(1) See analogous observations made by M. ROUBAUD ; R., Jan. 1920, No. 1 (*Ed.*)

least, to this destruction of growth-promoting substance. In these experiments it was found that 2 % of yeast content added to the synthetic ration (consisting in feeds composed of a single chemical substance) seemed to be sufficient to promote normal growth in young rats.

EXPERIMENTAL AND ANALYTICAL WORK

939 – **Resolution and Scheme of a Convention with Regard to the Creation of an International Scientific Commission on Food Supplies.** — *Commission Scientifique Interalliée du Ravitaillement*, pp 1-11. Brussels, 1919.

When peace was signed, the Allied Food Commission which was founded to advise the Allied Governments on all problems of food supply arising from the war, naturally ceased to exist, and when, in the last quarter of 1919 the final reports had been published, the organisation was dissolved (1).

However, the Delegates present at the meeting held in Brussels on May 22, 1919, in accordance with a resolution adopted at the Rome-Naples meeting, held in December, 1918, again decided to call the attention of the various Governments to the utility of retaining an international institution, whose task would be to establish scientific relations between the various organisations engaged in the study of problems relating to food.

This institution would have the following aims :—

(1) To study the production and distribution of foods for human and animal consumption.

(2) To gather data and statistics with regard to the needs of man under all conditions as regards age, sex, work, climate, social conditions, etc. as well as data on the relationship between various diseases and deficiencies of food whether qualitative or quantitative.

(3) To ascertain the chemical composition and calorific value of foods.

(4) To popularise and spread information relating to the best methods of using natural food supplies for human consumption.

As far as possible, the proposed international organisation would co-operate with institutions already in existence for the purposes above named.

In addition, according to the scheme of the convention for the foundation of an International Commission, presented by Dr. Rulot, Belgian Delegate, and M. Alquier, Head of the Permanent Central Secrétariat of the Inter-allied Commission and passed on May 29, 1919, the Allied Food Commission should be recognised by the adhering Powers as the Official headquarters of scientific study and research on alimentation, in order to co-ordinate and assist all sciences relating to food and facilitate practical applications ; it would be supported by contributions from adherent States. Each State would appoint one or more delegates to the Commission, the delegates to be assisted by a national secretariat.

A permanent Central Secretariat would be formed to maintain close

(1) Commission Scientifique Interalliée du Ravitaillement. Rapport Général. Les Ressource et les Besoins Alimentaires des Pays Alliés. *Rapports I et Annexes II et III*. Paris-Rome, Oct.-Déc. 1918. (*Ed.*)

contact between all Administrations, Institutions and Associations having the same objective as the Commisson.

In brief, the functions of the Commission should be :—

(*a*) To collect and study all information of a scientific, practical and administrative nature concerning, on the one hand, the human food supply and on the other the production and distribution of foods.

(*b*) To consider the standardisation of scientific methods and of unit systems of food production and utilisation, and to consider the choice of a unit method by which scientific work of this kind can be compared.

(*c*) To encourage systematic investigation in the adherent States and to initiate scientific missions.

(*d*) To contribute, with the help of the competent Administrations, Institutions and Associations, to the development, teaching, and propagation of science applied to feeding problems and to issue useful publications to this end.

(*e*) To enable all States represented on the Commission to profit to the fullest extent from the practical results obtained by science, so that each State can take measures when and where necessary for the common good.

The resolutions passed by the Commission are in no way binding on any of the participant States.

CROPS AND CULTIVATION

940 - **Predicting Minimum Temperatures from Hygrometric Data.** — Warren Smith, in *Monthly Weather Review Supplement* No. 16, pp. 6 19, figs. 24. Washington, 1920. AGRICULTURAL METEOROLOGY

In the Monthly Weather Review for August, 1917, the author discussed the prediction of minimum temperatures on radiation nights by the use of the following linear equation

$$y = a + b R,$$

using R as representing the evening relative humidity and y as the variation of the night minimum temperature from the evening dewpoint. This equation was applied to hygrometric data obtained at special fruit stations in Ohio, and the results were found to be very satisfactory. According to the records kept at other stations after an attempt to use this equation, the results were not entirely satisfactory. In such cases in reporting the evening relative humidity and the variation of the minimum temperature from the evening dewpoint, it was found that the dots were arranged in the form of a curve, instead of along a straight line, hence the impossibility of applying the linear equation

The next step taken by the author was to determine the coefficients of equation for a parabola curve. The equation of a parabola may be written thus :

$$y = a + b x + c x^2$$

and in order to facilitate matters, the equation might be written as follows :

$$v = x + b y + c z$$

in which x y and z are the coefficients to be determined ; b is the evening relative humidity, c = the square relative humidity, and v = the variation of the minimum temperature from the evening dewpoint.

With a view to working out the formula for predicting the minimum temperature the first step is to chart the available data on squared paper on which the evening relative humidity is indicated at the bottom of the diagram, and differences between the dewpoint temperature and the minimum are noted at a prescribed point. A dot is entered on the diagram for each day covered by the record. If the dots arrange themselves in a straight line, the linear equation will be $y = a + b\,R$, and this has already proved successful in Ohio. If on the other hand the dots form a curve, the data may be represented by the parabola curve formula.

A judicious selection is made of certain " star " points as for example points 1, 2, and 3 in figure 2 of the article reviewed. At 1, the relative humidity is 5 %, and the variation of the minimum temperature from the dewpoint equals 48°. At 2 the relative humidity is 15 % and the variation 28°.

At 3 the relative humidity is 40 % and the variation 9°.

With these data the normal equations are written as in the following table :—

b	v	c
5	48	25
15	27	225
40	9	1600

From this table, the three equatons for solving the unknown factors x, y, and z are expressed as follows :

$$(1) \qquad x + b_1 y + c_1 z = v_1 y$$
$$(2) \qquad x + b_2 + c_2 z = v_2$$
$$(3) \qquad x + b_3 y + c_3 z = v_3$$

The coefficients b_1, b_2 and b_3 represent the 3 values of b in Table 1, viz 5, 15 and 50 ; the values of c and v are the corresponding values of these factors in the given Table.

To determine the values x, y and z, it is preferable to adopt the " direct solution method "

Insert the values under b, v and c in equations (1) (2) and (3) and solve for z as follows :—

$$(1) \qquad x + 5y + 25z = 48$$
$$(2) \qquad x + 15y + 225z = 27$$
$$(3) \qquad x + 40y + 1600z = 9.$$

Subtracting equation (2) from equation (1) we get

$$(4) \qquad -10y - 200z = 21$$

Subtracting (3) from (2) we have

$$(5) \qquad -25y - 1375z = 18$$

Multiplying (4) by 5 and (5) by 2, we get, respectively

(6) $-50y - 1000z = 105$

(7) $-50y - 2750y = 36$

Subtracting (7) from equation (6) we have

(8) $1750\,z = 69$

$z = 0{,}03943.$

The next step will be to substitute the value of z in equation (4) or (5) and solve for y.

Substituting in (4) we get :—

(9) $-10\,y - (200 \times 0.03943) = 21$

$-10\,y = 21 + 7.886$

$-10\,y = 28.886.$

$y = -2.8886$

Substituting in (5) it becomes

(10) $-25\,y - (1375 \times 0.03943) = 18$

$-25\,y = 18 + 54.21625$

$-25\,y = 72.21625$

$y = 2.88865$

Substituting the values of y and z in equations (1), (2) and (3) we get the following:—

(11) $x + (5 \times -2.886) + 25 \times 0.03943) = 48$

(12) $x + (15 \times -2.886) + (225 \times 0.03943) = 27$

(13) $x + (40 \times -2.886) + (1600 \times 0.03943) = 9.$

Carrying out the calculation, we have for each equation, respectively

$x = 61.45725$

$x = 61.45725$

$x = 61.456$ or an average of

$x = \mathbf{61.457.}$

By using these values, we find that:—

$x = 61.46$

$y = -2.89$

$z = 0.0394$

According to the equation

$$v = x + by + cz.$$

the probable variation of the minimum temperature from the evening dew-point (v) can be determined on radiation nights with a fair degree of accuracy.

The parabolic curve will be traced on the diagram by utilising the points already selected and calculating others by this equation. For a relative humidity of 10 %, for example, by inserting the known values of b and c, and the above-determined values for x y and z it becomes

(14) $v = 61.46 + (10x - 2.89) + (100 \times 0.0394).$

and working out the calculation, we find that

$v = 36.5^{\circ}$

By the same method the value of v for other relative humidity figures is calculated, and then the curve AB can be drawn.

If trials fail to give a satisfactory parabolic curve, it will be evident that sufficient care was not taken and that the graph is not a parabola but some other curve.

For El Paso (Texas), the parobolic curve in fig. 2 in the article under consideration corresponds exactly with the calculations.

Having discovered the particular dependable formula, the practical work will be facilitated by computing a table giving the necessary values of the minimum temperature based on the known values of b and the dew-point as indicated in the following table.

El Paso, Texas.

$$v = x + by + cz$$

$$x = 61{,}457 \quad y = -2{,}889 \quad z = 0{,}03943.$$

b	c	b y	c z	v
5	25	− 14.445	0.986	48.00
6	36	− 17.334	1.3184	45.44
7	49	− 20.223	1.9306	43.16
8	64	− 23.112	2.5216	40.87
9	81	− 26.001	3.1914	38.65
10	100	− 28.89	3.943	36.51
20	400	− 57.58	15.767	19.44
30	900	− 86.67	35.487	10.27
40	1600	− 115.56	63 088	8.99
50	2500	− 144.45	98.575	15.58

The author continues by giving the values and diagrams for the following localities: Boise (Idaho); Chicago University; Cincinnati (Ohio); Grand Junction (Colorado); Montrose (Colorado); Phoenix (Arizona); San Diego (California).

In all these localities, the curve is represented by a parabola obtained in each case by means of the equation $v = x + by + cz$.

An inspection of these curves shows a distinct similarity between them in many cases, and seems to indicate that the equations and factors determined for one place can be used at another place with a similar climate and topographic surroundings

With the variation in climate and in topographical surroundings, even if the curve appears the same, the values of x, y and z are variable. For example, some of the values are as follows :—

Cincinnati (Ohio)	x + 41.1	y = 0.95	z = 0.00275
Montrose (Colorado):	x = 50,8	y = — 2,04	z = 0,016
San Diego (California):	x = 48,3	y = — 1,1935	z = 0,00656
Boise (Idaho)	x = 39.6	y = — 1.482	z = 0.012

An exhaustive study was made by the author to see whether better results could be obtained by using some other hygrometric factors (instead of relative. humidity).

Definite results were only obtained when the factor showing the depression of the dewpoint below the current temperature was used and was compared with the variation of the minimum temperature from the dewpoint, and it is hoped that this method may prove useful in connection with forecasts.

941 – **Effect of the Relative Length of Day and Light and other Factors of Environment on Growth and Reproduction in Plants.** — GARNER, W. W. and ALLARD, H. A., in *Journal of Agricultural Research*, Vol. XVIII, No. 11, pp. 553-606, tables 14, pl. 16, bibliogr. of 26 publications. Washington D. C., March 1, 1920.

Results of experiments concerned chiefly with the effect of daily duration of the light exposure on the general growth and development of plants.

A darkened chamber was employed in which the plants growing in small boxes were readily handled.

In the various tests, the length of exposure to light varied from a minimum of 5 hours per day to a maximum of 12 hours. For the 5 hours exposure, the plants were placed in the dark house at 3 p. m. and left there until 10 a. m. the following day; for the 7 hour exposure to light, plants remained in the dark from 4 p. m. until 9. a. m. and for the 12-hour exposure from 6 p. m. to 6 a. m. In certain special cases the plants were kept in the dark house from 10 a. m. to 2 p. m.

In the course of experiment, the plants were exposed to the light :—

1) from the germination of the seed or in the earlier stages of growth, and continued until maturity ;

2) till the flowering period ;

3) after the flowering period until maturity.

The following species were employed in these tests : — *Soja max* L. (Piper) ; *Nicotiana Tabacum* and *N. rustica* L., *Aster linariifolius* L., *Mikania scandens* L., *Phaseolus vulgaris* L,, *Ambrosia artemisiifolia* L. ; *Raphanus sativus* L. ; *Daucus Carota* L., *Lactuca sativa* L., *Hibiscus Moschentos* L. ; *Brassica oleracea capitata* L. : *Viola fimbriatula* S. M. ; *Solidago juncea* Ait.

In addition to the experiments with the dark house, a series of plantings were made at intervals of approximately 3 days in order that the effects produced by different dates of planting might be compared with those produced by artificially shortening the length of the daily exposure to light.

LENGTH OF DAILY LIGHT EXPOSURE IN RELATION TO VEGETATIVE DEVELOPMENT. — In general, the extent of growth was proportional to the length of the daily exposure to light.

The following Table demonstrates this biometric relationship fo soybeans and the aster.

Apart from the reductions in rate of growth and slight chlorosis, the tobacco, soybeans, and aster showed no ill effects, physiologically speak-

Length of daily exposure	Average height of plants				
	Soybeans				*Aster*
	Mandarin	Peking	Tokyo	Biloxi	
	Inches	Inches	Inches	Inches	Inches
10 a. m. to 3 p. m., 5 hours (I)	6 to 7	5 to 6	7 to 8	6 to 7	—
9 a. m. to 4 p. m., 7 hours (II)	9 to 10	8	7 to 8	11	8 to 10
Sunrise to 10 a. m. and 2 p. m. till dark, 8 1/2 to 11 hours (III)	—	20 to 26	24 to 25	38 to 40	11 to 12
6 a. m. to 6 p. m., 12 hours (IV)	14 to 15	14 to 15	17 to 18	23 to 24	8 to 10
Full daylight, 12 1/2 to 15 hours (V)	18 to 20	40 to 44	42 to 44	54 to 58	14 to 15

ing, from the reduced length of illumination; *Hibiscus*, however, was not able to make any appreciable growth when this period was reduced to 9 hours, and *Lactuca* was much more seriously affected.

Length of daily light exposure in relation to sexual reproduction. — The results obtained with soybeans are particularly interesting. This included 4 varieties ranging from early to very late in maturing. The average number of days from germination to flowering was approximately 27, 56, 70 and 105 respectively for the Mandarin, Peking, Tokyo and Biloxi.

Length of daily exposure	Time from germination to flowering (Days)			
	Mandarin	Peking	Tokyo	Biloxi
5 hours (I)	23	23	24	27
8 hours (II)	21	21	24	26
Do	—	22	27	28
8 1/2 to 11 hours (III)	—	40	62	79
12 hours (IV)	21	21	28	28
12 1/2 to 15 hours (V)	26	62	73	110
Do	28	51	66	90

When the daily illumination consists of a 12 hours exposure, the vegetative period is apparently only slightly shortened in the Mandarin variety, but in the very late Biloxi variety, this period is reduced to less than 1/4 that of the control plants. In reality, all 4 varieties become equally early maturing ones under these conditions. Further shortening of the light exposure period had no remarked effect; apparently therefore the minimum formative period will be approximately 21 days for the Mandarin and Peking varieties, 24 days for the Tokyo, and 26 days for the Biloxi.

As regards the tobacco, the contrast in behaviour between the Connecticut Broadleaf and Maryland Mammoth, and Stewart 70-Leaf Cuban varieties is very striking. Neither sexual reproduction nor the vegetative period in the Connecticut Broadleaf is materially affected by changes in length of exposure to light, either lasting 12-15 hours or limited to 7 hours.

The Maryland variety can only be forced into flowering during the summer months by artificial shortening of the duration of the daily exposure to light. If this lasts 12 hours, this occurs after 75-85 days, and if reduced to 7 hours, after 52-59 days. The Cuban variety was affected in a similar way, while *Nicotiana rustica* shows no material change

From the studies undertaken by the author, it has been found that in a number of species, the plant can only attain the flowering and fruiting stages when the length of day falls within certain limits, and, consequently, these stages are reached only during certain seasons of the year. In the latitude of Washington where the tests were made, some species and varieties respond to relatively long days. The Mandarin soybean demonstrates this fact in that the time required by it to reach the flowering period cannot be greatly reduced by shortening the length of artificial exposure to light. On the other hand, certain varieties respond to relatively short days, for example, the Biloxi soybean is a dintinctively "short day" variety and the Maryland Mammoth Tobacco flowered only during the summer months when submitted to artificial light during part of the day, etc. Still further species appeared indifferent to the length of exposure.

In the absence of the favourable length of day for sexual reproduction, vegetative development may continue more or less indefinitely, thus leading at times to the phenomenon of gigantism: LODEWIJKS discovered a giant type of Sumatra tobacco, grown under the influence of the 12-hour equatorial day, which may reach the height of 24 ft., either without flowering or forming only a very limited number of flowers and seeds. These forms of gigantism disappear if the plant is brought under the influence of short days such as prevail in the temperate zone during winter. For example, the Maryland Mammoth tobacco retains a normal appearance during winter.

On the other hand, under the influence of a suitable length of exposure to light, precocious flowering and fruiting may be induced, and certain varieties may act as early or late maturing.

The relationships existing between annuals, biennials and perennials are dependent to a large extent on the length of day in the locality concerned, and by artificial regulation of this factor, the normal annuals may complete two cycles of alternate vegetative and reproductive activity in a single season. For example: the Biloxi soybean, was kept in the dark house up till the flowering period, and consequently, when restored to normal conditions, the seed pods ripened rapidly, the leaves faded as if the plants were dying; the effect of the long summer days was to encourage the development of new shoots which flowered in the early part of September.

Experiments reported indicate that light intensity is of secondary importance so far as concerns the attainment of the flowering stage.

Effect of shading soybeans.

Treatment	Average Height	Air-dry weight per stalk defoliated	Yield of beans per stalk	Yield of hulls per stalk	Percentage of beans in seedpods	Date of flowering
		gr	gr	gr		
Plants shaded . . .	3 ft. 5 in.	5.4	10.5	5.4	66.1	Aug. 7
Plants not shaded .	2 ft. 3 in.	9.4	17.0	9.0	65.2	Aug. 7

The effect of direct light on the growth and development of the plant and on the yield is evident ; the date of flowering was not in the least affected.

Variations in the water supply, ranging from optimum to a condition of drought sufficient to induce temporary wilting, did not however influence the date of flowering.

It may therefore be concluded that the " length of the day " is an important factor in the natural distribution of plants, and should be taken into account in connection with crop production. Fruiting may be cut short by the effect of too long or too short a day. By introducing a species from one latitude into another, or by changing the time of sowing, good results may be obtained, but may also bring about misleading results. These are matters of vital importance both to the plant breeder and the agronomist. To obtain maximum yields, it is essential that the date of sowing be so regulated that the optimum length of day coincides with the critical stage of the floral development.

Conclusions. — Sexual reproduction can be attained by the plant only when it is exposed to a specifically favourable length of day (this varies widely with the species and variety). A length of day unfavourable to reproduction, but favourable to growth, tends to produce gigantism or indefinite continuation of vegetative development. However, exposure to a length of day favourable alike to development and reproduction, encourages the uninterrupted type of flowering and fruiting.

The authors suggest the term *photoperiod* to designate the favourable length of day for each organism, and *photoperiodism* to designate the response of the organisms to the relative length of day and night.

942 – **New Methods for Determining the Correlation Coefficients Between the Growth and Yield of Winter Wheat in Ohio, U. S.** — Blair, T. A. in *Monthly Weather Review*, Vol. 47, No. 12, pp. 841 847. Washington, Dec. 1919.

Concerning the methods of computing the relationships between weather and biological value (vitality, growth, yield, etc.), the author has made use of a linear regression equation by which the biological value is expressed as a function of a fixed number of weather elements (3 to 6).

The equation may be expressed as follows :

$$Y = a + b_1 x_1 + b_2 x_2 + b_3 x_3 + b_4 x_4 + \ldots \quad (1)$$

in which Y is the biological value; $x^1, x^2, x^3, x^4 \ldots$ are the various weather elements (mean temperature, total precipitation, percentage of sunshine, etc.) expressed numerically; a, b_1, b_2, b_3, $b_4 \ldots$ are numerical quantities, having a constant value for a given equation to be determined from the data.

The equation may first be simplified by the elimination of a as follows: the normal equation for a (obtained by multiplying each of the equations under consideration by the coefficient of a, in this case unity, and taking the sum) may be expressed thus:—

$$\Sigma Y = n a + \Sigma b_1 x_1 + \Sigma b_2 x_2 + \Sigma b_3 x_3 + \Sigma b_4 x_4 + \ldots \quad (2)$$

from which

$$a = \frac{\Sigma Y}{n} - \frac{\Sigma b_1 x_1}{n} - \frac{\Sigma b_2 x_2}{n} - \frac{\Sigma b_3 x_3}{n} - \frac{\Sigma b_4 x_4}{n} + \ldots \quad (3)$$

Substituting this value in the original equation gives:—

$$Y - \frac{\Sigma Y}{n} = \left(x_1 + \frac{\Sigma x_1}{n}\right) b_1 + \left(x_2 + \frac{\Sigma x_2}{n}\right) b_2 + \left(x_3 + \frac{\Sigma x_3}{n}\right) b_3 + \left(x_4 + \frac{\Sigma x_4}{n}\right) b_4 + \ldots \quad (4)$$

Now as $Y - \frac{\Sigma Y}{n}$, $x - \frac{\Sigma x_1}{n}$, are in each case the differences between the values for the individual years, and the average values of the same quantities, that is to say, are the departures from the means. Designating these departures by y, D_1, D_2, D_3, D_4 (y = departure from average yield; D_1 = departure from mean temperature, October to November etc.) we have for the final form of the equation:—

$$y = b_1 D_1 + b_2 D_2 + b_3 D_3 + b_4 D_4 + \ldots \quad (5)$$

From equation (5), the normal equations become:—

$$\Sigma D_1 y = b_1 \Sigma D_1^2 + b_2 \Sigma D_1 D_2 + b_3 \Sigma D_1 D_3 + \ldots$$
$$\Sigma D_2 y = b_1 \Sigma D_1 D_2 + b_2 \Sigma D_2^2 + b_3 \Sigma D_2 D_3 + \ldots$$
$$\Sigma D_3 y = b_1 \Sigma D_1 D_3 + b_2 \Sigma D_2 D_3 + b_3 \Sigma D_3^2 + \ldots$$

It is then necessary to prepare tables of the data used, together with the departures, squares of departure, and products of departures appearing in the normal equations. These equations should be solved simultaneously for the values of b_1, b_2, b_3, b_4. Where the number of equations exceeds 3, the solution is more easily performed by writing the required values in the form of determinants, and reducing these to the second order, before expanding.

This method possesses distinct advantages over that of partial correlation coefficients, especially as regards the effect of the several factors considered, expressed directly in an equation from which a general idea is at once obtained as to the relative importance of each of the factors under consideration.

Winter wheat in Ohio is sown in September and harvested in July. Being given, however, the length of the growing season and the multiplicity

of factors that may be expected to affect the growth of wheat, the author compares the relative values of weather factors, affecting the condition of winter wheat from sowing to harvest:— (1) from sowing time to December 1; (2) from December 1 to April 1, (3) from April 1 to May 1; (4) from May 1 to June 1.

The Bureau of Crop Estimates gives the estimated condition of the various crops on the first day of December, April, May, and June. This is expressed as a % of the normal (represented by 100). The normal is defined as "a condition of perfect health unimpaired by drought, hail, insects,

or other injurious agencies" and is somewhat better than the average but always inferior to the optimum condition as indicated by figures over 100.

The condition reports are available for a 25 year series (1893 to 1917) (see Table) and deal with the relative values of weather factors and the development in growth of winter wheat at various dates.

The Table illustrates the relative values of the condition on December 1 and the condition of the crops later.

Columns 12 to 25 (not reported owing to lack of space) contain squares and products of departures from which the following sums are obtained :

$$\sum D_1^2 = +131 \qquad \sum D_2 D_3 = +4.01$$
$$\sum D_2^2 = +37.44 \qquad \sum D_2 D_4 = -52.8$$
$$\sum D_3^2 = +58.24 \qquad \sum D_3 D_4 = -137,2$$
$$\sum D_4^2 = +1.048 \qquad \sum D_1 y = +128$$
$$\sum D_1 D_2 = -1.3 \qquad \sum D_2 y = +109.2$$
$$\sum D_1 D_3 = +2.7 \qquad \sum D_3 y = +173.6$$
$$\sum D_1 D_4 = +63 \qquad \sum D_4 y = -627$$

Normal equations

$$128 = 131\, b_1 - 1.3\, b_2 + 28.7\, b_3 + 63\, b_4$$
$$109,2 = -1.3\, b_1 + 37.44\, b_2 + 4.01\, b_3 - 52.8\, b_4$$
$$173.6 = 2.7\, b_1 + 4.01\, b_2 + 58.24\, b_3 - 137.2\, b_4$$
$$-627 = 63\, b_1 - 52.8\, b_2 - 137.2\, b_3 + 1.048\, b_4$$

Solving :

$$b_1 = 1.1 \qquad b_2 = 2\,3 \qquad b_3 = 2.1 \qquad b_4 = -0.3.$$

Substituting in equation (3) : $a = 33.8$.

Substituting in equation (1) :

$$Y = 33.8 + 1.1\, x_1 + 2.3\, x_2 + 2.1\, x_3 - 0.3\, x_4.$$

Substituting the values of x_1, x_3, x_3, x_4, for individual years (see Table), we get the calculated condition of December 1 as given in column 26.

In the linear equation the numerical values are expressed relative to the units employed, namely :— inches, degrees, percentage, etc. To obtain an idea of the relative importance of the coefficients b_1, b_2, b_3, b_4... the unit must be eliminated by multiplying each by its standard deviation, ; the values are then $b_1\,\sigma_1$, $b_2\,\sigma_2$, $b_3\,\sigma_3$, $b_4\,\sigma_1$, and these give an idea of the relative values of the various factors to which they refer.

The values of b_6 calculated for the entire season under consideration, leads to the following general conclusions : —

1) to ensure vigorous growth of winter wheat, temperatures should be above normal from October to March inclusive (especially in March), and temperatures below normal in May ;

2) precipitation above normal from September to November, inclusive, below normal from December to March ;

3) he amount of sunshine in October, November, March and May, and the amonht of snow in March are relatively unimportant factors.

As regards the yield apart from the general conditions of development,

in some cases opposite effects have been notified. This is thought to be due to the fact that at certain critical stages of growth the vigour prevents a heavy yield of seed.

In every case, after examination of each month's record and at recognised fixed intervals, a diversity of fairly low correlations will be noted in the various localities. The existence of the critical stages having been established, the results are not surprising. These stages may extend over a single season, and as these may occur at quite different times, even within limited areas, the same meteorological phenomenon can determine very different effects according to the condition of development of the plant under inspection.

After due consideration of these points, the author examined the data (meteorological and yield) in Fulton County for the following periods: April 6 to 15 ; April 16 to 25 ; April 26 to May 5 ; May 6 to 15 ; May 16 to 25 ; May 26 to June 4 ; June 5 to 14 ; June 15 to 24 ; June 25 to July 4.

The resulting regression equation obtained for the 3 thermic values (t_2 t_3 and t_8) was as follows:

$$Y = 0.53 + 0.14\, x_2 - 0.51\, x_3 + 0.52\, x_8.$$

The reason for these high coefficients may be attributed to the fact that the above mentioned periods (after due investigation) coincide with the critical stages of growth of the winter wheat, namely : —

1) April 16 to 25 corresponds with the latter part of the tillering stage ; in order therefore to ensure good stooling in the Fulton County, relatively warm weather is needed ; hence the existence of a positive correlation between temperature and yield at this period ;

2) April 26 to May 5 corresponds with the beginning of the rapid growth in height and formation of internodes (jointing stage) ; at this time, cool weather is essential to avoid excessive vigour which would be liablel to have a detrimental effect on the grain yield ; hence the large negative relation ;

3) June 15 to 24 corresponds to the stage and to the early stages in the caryopsis development. If this process is normal, warm weather is desirable ; hence the existence of a distinctly positive correlation.

Results obtained in the Counties of Madison, Franklin and Pickaway in Central Ohio (much further south than Fulton County) confirm the possibilities of limiting the grouping of values to short periods (decades)

$$Y = 2.97 - 0.46\, x_1 - 0.58\, x_2 + 0.42\, x_3 + 0.33\, x_4 - 1.97\, x_5 \qquad (7)$$

in which x_1 = temperature, May 1-11 ; x_2 = temperature, May 22-31 ; x_3 = temperature, June 1-10 ; x_4 = temperature, June 21-30 ; x_5 = precipitation, May 12-21.

The first decade of May corresponds with the jointing period, and in this case a very marked negative relation exists as in Fulton County. The same may be said for the period, which in central Ohio, occurs in the early part of June ; in this case as in Fulton there is a distinct positive correlation.

On the other hand, in central Ohio, situated much further south, in a warmer climate, there is a negative relation at the flowering period while Fulton County where the climate is cooler, fails to show this relation definitely.

The following general conclusions may thus be drawn :—

1) For the State of Ohio, as a whole, a warm March and June, and a cool and dry May, are favourable conditions for a high yield of winter wheat ; all other monthly temperature and precipitation values may be disregarded ;

2) certain periods appear to correspond with critical stages in growth, particularly as regards temperature ; *e. g.* April, May and June ;

3) in Northern Ohio (Fulton County) and in central Ohio, the weather should be cool during the jointing stage and warm when the ear is forming ;

4) in Fulton County, during the last part of the stooling process it should be warm ; it should be cool in central Ohio during flowering, and warm when the grain is ripening ;

5) in Fulton County and probably also in other counties subject to heavy snow falls, where the snow remains long on the ground it is decidedly detrimental.

943 – **The Effect of Weather on Alfalfa Hay and Alfalfa Seed Growing in Western South Dakota and in Utah, U. S.** — I. Johnson, H. N., in *Monthly Weather Review*, Vol. XLVII, No. 5, pp. 325-329 + 3 figs. — II Alter, J. C., *Ibid*, pp. 330-332. Washington, May 1919.

I. — The climate of western South Dakota is especially favorable for growing alfalfa ; as 73 % of the annual rainfall (15 to 20 in.), falls during the period from the beginning of April till the end of September ; the percentage of sunshine is high, end extends over a long period, the rate of evaporation is comparatively low and moderate temperatures usually prevail.

The soil is deep, rich, and retains moisture well. Alfalfa needs a considerable amount of water during the growing period, but fair weather while the hay crop is being harvested. Special weather forecasts are issued during the cropping season in the interests of farmers which enable them to determine how much hay can be cut and cured before the rain is likely to occur.

Seed is usually produced from the second crop when the season is relatively dry. If there is considerable rainfall, the second crop is also utilised for hay, and a third crop is frequently possible. If it is too dry after the first crop has been harvested, growth is checked, and there is a danger of frost injury to seed in the early autumn.

A frost-warning service is therefore established and is widely utilised by seed growers.

II. — The first crop of alfalfa is usually cut for hay in Utah, and the second crop is allowed to run to seed. The seed crop should have sufficient moisture during its early growth to produce a vigorous healthy plant, but the weather should be dry and not too warm while the plants are in bloom.

The dry spell must not be too extended, however, as the seed must have sufficient moisture while setting to give normal size and weight.

Definite comparisons with the yield show that the best results are obtained when the spring temperature averages from 3° to 5° F. a day above normal, and from 2° to 4° F a day below normal.

It takes nearly twice as long to grow and mature a seed crop as it does a hay crop. Seed is usually ready for harvest in Utah one or two weeks in advance of the first autumn frosts. Temperatures of 26° to 28°F will seriously damage partially ripe and unripe seed burrs : hence the importance of minimum temperature forecasts, especially in years when the formation and development of the seeds has been hindered for some reason or other.

The usual practice is to cut as large an area as possible on the receipt of frost warnings, but the first cold period is often followed by several weeks of fine ripening weather.

The use of irrigation and mulches has been fairly well demonstrated in many districts, and efforts should be made to protect the plants from frost damage without cutting, as soon as the warning is received.

The cost is entirely compensated for by the value of the seed and the consequent high prices obtained for the grain produced.

944 – **Effect of Climate of Tonkin on the Yield of Different Varieties of Coffee.** — See No. 985 of this *Review*. (*Ed.*)

SOIL PHYSICS, CHEMISTRY AND MICROBIOLOGY

945 – **Résumé of Work Connected with the Relations Existing between Soil and Water Content.** — KEEN, B. A. (Goldsmiths' Company's Soil Physicist, Rothamsted Experimental Station) in *The Journal of Agricultural Science*, Vol. X, Pt I, pp. 44-61, tables 13, figs. 2. Cambridge, Jan., 1920.

The relations existing between soil and its moisture content are subject to so many variable factors that separation for purposes of discussion is only possible in a very general way. According to the author, the former classification of soil water as : (1) hygroscopic moisture ; (2) capillary water ; (3) gravitation water, is too empirical for a theoretical basis in connection with colloidal hypothesis. In this paper, therefore, results are specially noted as given in the comparatively few recent papers in which the colloidal hypothesis is accepted, although those dealing with the old theory are also mentioned.

Investigations are reviewed under the following headings :

I. *Soil moisture in general.* — (*a*) The maximum water capacity and pore space ; (*b*) the permeability of soil ; (*c*) capillary effects and the "water retaining capacity"; (*d*) capillary movement of soil water ; (*e*) hygroscopic moisture in soils. From the numerous experiments carried out by soil experts special attention can be given to the results obtained by CRUMP, showing that the organic material has considerable influence on the total amount of water held. Over the whole of the experiments, it was found that the ratio water content was very nearly constant for any one type of soil. This constancy persisted when varying depths of soil were separately examined, in spite of the considerable difference in actual moisture content. Also, it was noted that capillary effects are very dependant upon the nature

of the surface pore spaces (1). The flocculated structure induced by acids and lime, and the deflocculation with alkalis were shown directly to affect such physical factors as the drainage conditions, aeration, and the capacity of the soil to hold the soil solution, and control its movement through the soil (PATTEN and WAGGAMANN).

With regard to the hygroscopic moisture, the author suggests that the subject could be profitably re-opened in the light of present knowledge of colloidal phenomena. Reference is made to the historical summary of work of hygroscopicity given by ALWAY, KLEINE and MC DOLE (2).

II. *Attempts to obtain a more complete theory of soil moisture relations.* — Investigations have followed, in the main, two lines, those on the " wilting coefficient " and on the " moisture equivalent ", and the latter gives a better quantitative comparison of soils than the water retaining capacity mentioned above. Experiments by SHULL with *Xanthium* seeds, point to the fact that the wilting coefficient must be regarded as a measure of the water in the plant, and not in the soil at the time of wilt, and the cause of wilting is due to the slow movement of soil moisture.

III. *Surface forces in soils and the colloidal hypothesis.* — The point which needs emphasis in all studies of soil solutions (3), is the recognition that the system soil + solution must be treated as a whole. In this section, the papers discussed are characterised accordingly. Experiments show the importance of emphasizing the above point. A change in the moisture content is reflected in the resulting alteration of all the complex variables involved. Conclusions based on an examination of soil solution after it has been removed from the soil, cannot be regarded as necessarily quantitative, and it is open to doubt whether they are always qualitative. Hence the advisability of study from the colloidal point of view.

946 – **Soil alkali** (4). — HARRIS, F. S. *Circular* No. 41, *Utah Agricultural College Experiment Station*, pp. 1-8. Logan, Utah, Jan., 1920.

In general it may be said that soils containing more than 0.5 % soluble salts where the larger part is composed of chlorides, carbonates or nitrates, and 1 % where sulphates predominate, are unsuitable for crop production without reclamation. These figures are of course modified by many conditions.

The crops to raise on alkali land depend on the degree of salinity of the soil, the uses that can be made of the crops, the markets, and other economic conditions as well as the climatic factors. Among the ordinary farm crops the smaller grains can usually be raised to about the best advantage, As a type of cropping for Utah alkali land, three crops were found suitable. used in rotation on damp medium alkali, namely:— sweet clover, sugar

(3) See *Soil Conditions and Plant Growth* 3rd edition, 1917, p. 104 by E. J. RUSSELL (Longmans). (*Ed.*)

(4) See *R.*, May 1919, No. 564. (*Ed.*).

beets, and barley. Legumes as a class do not do well and maize and potatoes are also not usually successful.

To prevent alkali from becoming more serious, the author suggests: (1) The cutting off of seepage water from higher land; (2) reduction of evaporation from the surface land by cultivation and a consequent rise of salts from lower depths; (3) constant cropping; (4) the use of manure to reduce surface evaporation; (5) the proper use of irrigation water.

Native vegetation and a chemical analysis of the soil to a depth of at least 6 feet make an excellent combination in determining the degree of contamination of alkali land.

947 – **Soil Reaction as Influenced by Green Manures** (1). — HOWARD, L. P. (Rhode Island Agricultural Experimental Station), in *Soil Science*. Vol IX No, 1, pp. 27-29, tables 7, Bibliogr. of 15 publications. Baltimore, Jan. 1920.

A brief review by the author of the literature dealing with the practice of green manuring serves to indicate that the quantitative evidence for and against this question is very limited. This is followed by results of work on soil samples collected at various periods during the season at Rhode Island Station 1915 and 1916, showing the changes in acidity, and also in organic matter on a legume and non-legume plat. Samples were taken at frequent intervals from the date of ploughing, and lime measurements then made.

This work showed that variations are maintained in dried soils as manifested in their ability to retain different amounts of ammonia.

The net result over the period of 2 years indicates a decreased acidity except in the legume plat and suggests that the rye caused an increased requirement of 33 lb., while the legume caused an increase of 370. It should be noted that the last application of lime was made in 1914 in 1 ton of finely ground limestone per acre when considering net changes in lime requirement during 1915 and 1916.

With regard to hydrogen-ion concentration in soils (1) it is significant that with the rye plat the variations follow in a general way the fluctuations in lime requirement.

In the uncropped soils treated in the laboratory with an equal weight of green rye as compared with clover, the rye increased the lime requirement 300 to 400 lb., or about twice as much as the clover, and the increase was maintained from July to December.

The author considers it advisable to state that these results were scarcely an index of the net cumulative effect exerted by the cover crops through a longer period of time.

948 – **Formation of Nitrate in a Soil Following the Growth of Red Clover and of Timothy.** — LYON, T. L., BIZZELL, J. A. and WILSON, B. D., in *Soil Science*, Vol. IX. No. 1, pp. 53-64. Tables 8, Bibliogr. of 10 publications. Baltimore, Jan. 1920.

The authors first give a brief review of former experiments, but state that the results reported leave some doubt whether the legumes used in-

(1) See *R.*, June 1918, No. 626, and *R.*, July 1918, No. 739. (*Ed.*)

creased the nitrifying power of the soil for dried blood, as compared with the influence of non legumes, except when crop residues alone were concerned, and favour of the legumes was unanimously expressed. The authors deal with the question in a new way and the experiment described involved the leaching of soil on which different crops were growing.

Twelve cylinders were fitted with soil of medium fertility and good drainage qualities, limed and fertilised with acid phosphates, muriate of potash and dried blood. Six were planted with timothy and six with red clover. The soil of all the cans was inoculated with a pure culture of *Bacillus radicicola* from clover nodules. Each also received 1000 cc. of an infusion made by stirring 1 lb., garden soil with 3 litres of tap water to insure an active nitrifying flora.

During the growing period, the soil was leached with distilled water periodically. After these crops were removed, the soil was allowed to remain in fallow for a month Oats and maize were then planted, but cylinders kept free from vegetation. Leaching was continued from time to time and nitrogen determinations made in every case.

The experiment brings out certain data which may be significant. Under the same conditions of soil and treatment, clover caused a greater production of available nitrogen than timothy. The effect is shown in the nitrate content of the drainage water and the total nitrogen content of the oats and maize. Furthermore, only a minor part of the total nitrogen probably remaining in the roots of the clover crop was nitrified before the rate of nitrate production in the clover soil fell to that of the timothy soil.

949 – **The Washing out of Nitrates by Drainage Water from Uncropped and Unmanured Land** (1). — Russell, E. J. and Richards, E. H. (Rothamsted Experimental Station). in *The Journal of Agricultural Science*, Vol. X, Pt I, pp. 22-43. tables 7. figs. 6. Cambridge, Jan. 1920.

The authors have based their work on analyses made by the late N. H. J. Miller. In 1870 the famous drain gauges were constructed at Rothamsted by Lawes and Gilbert, and a series of measurements were begun of the amount and nitrate content of water draining through uncropped and unmanured land. The soil in the gauges is still in its natural condition.

Broadly speaking results show that uncropped land steadily and persistently loses nitrogen in the form of nitrates. If the curve showing the rate of fall continued its present course and without further slowing down, no less than 150 years would be needed for exhaustion of the nitrogen. So far as can be ascertained the nitrogen lost from the soil appears wholly as nitrate in the drainage water. Measurements of the amount of nitrate washed out from the gauges and its relation to external conditions between the years 1877 and 1915 in 4 year periods show that the quantity of nitrogen as nitrate washed out for every inch of rain was till 1901 1.0 to 1.2 lb., per acre, and since then fell to 0.73 lb.

Rainfall obviously shows a closer relationship than any other single factors to the nitrate in drainage water. The relationship between the

(1) See *R.*, Jan. 1917, No. 8. (*Ed.*)

amounts of rainfall and percolation, and the washing out of nitrates, show that this is more marked in summer than in winter, according to the figures as plotted for individual months. Further figures showing the effect of very dry years and very wet years on losses of nitrates from soil, signify that these losses are nearly proportional to the rainfall. Closer inspection of the data, however, shows that exceptional seasons have after effects which persist the following season.

The effect of temperature is less obvious, but a relationship is seen between the nitrate in the drainage water and the sunshine of the preceding summer. The loss tends to be higher after a hot summer than after a cold one.

The curve showing the rate of washing out of nitrate from the soils of the drainage gauge is very different from the curve for the rate of accumulation of nitrate in soils under fallow conditions. Records show that the loss exceeds 30 lb., per acre in the latter case, compared with 20 lb., from the drainage gauges. The chief difference between the field soil and the gauges apparently lies in the fact that the field soil, even though unmanured and lying fallow for one year, receives annual additions of easily decomposable organic matter in the form of weeds and stubble of the preceeding years' crop, while the soil of the drain gauge does not. At the present time the figures are :

	Percentage of nitrogen in top 9 inches
Drain gauge	0.099
Broadbalk unmanured plot	0.088

Lb., per acre (top 9 inches)

	20 inch. gauge	60 inch. gauge
Present in 1880	3500	3500
Present in 1917	2376	2328
Loss from top 9 in	1124	1172

The total amount of nitrogen in the drainage water from the gauges during the period of 38 years (1877-1915) in which continuous determinations have been made, shows the close similarity between the 1170 lb. of nitrate washed out from the 20 inch. gauge and the 1141 lb., washed out from the 60 inch. gauge, and thus indicating that the nitrate comes only from the surface layers, and not at all from the lower depths. Analysis of the soil at the beginning and end of the experiment, shows how much nitrogen has been lost from the top 9 inches of soil.

Determinations have also been made during 27 years, of chlorine in rain water and in drainage water. This affords by far the best check on the accuracy of working. If the records are accurate, the total amount of

chlorine found in the drainage water should equal that found in rain water for the same period. A table shows how complete is the agreement, the average per annum of chlorine per acre in rain water = 16.35 lb., and also the same figure is given for the amount in drainage soil (20 inch. gauge).

Records prove that the nitrate in drainage water accounts for practically all the nitrogen lost from the soil, and the chief, if not the sole action, in this soil, where there is no manure, crop residues or fresh supply of organic matter, is the production of nitrate. The nitrogen cycle becomes more complex when organic matter is added.

950 – **Loss of Nitrogen in the Soil due to Spring Rains.** WAIBULL, M., in *Landtmannen, Tidskrift for Landtmän*, Vol. XIII No. 26, pp. 422-423. Stockholm, June 26, 1920.

The present article gives the results of a series of experiments made at the Agricultural Station at Alnarp (Sweden) with a view to establishing the extent to which the heavy spring rains cause soil erosion and wash away the nitrates.

The nitrate content of the drainage water was determined in the following plots under rotations: (1) Spring cereals (barley, oats, and wheat-rye mixture) given no nitrogenous fertilisers, on sandy clay soil; (2) sugar-beet treated at the beginning of May with 160 kg., of calcium nitrate on the surface; (3) Pansar wheat treated at the beginning of April with 100 kg., of calcium nitrate on the surface; (4) field peas treated at the beginning of April with 60 kg., of calcium nitrate in sandy-clay soil, (5) forage crops, not manured, on sandy-clay soil. The total area of the plots was about 60 hectares, the soil was slightly alkaline, and the subsoil, of drift clay, was almost always calcareous.

The rains during April and May of that year were very heavy, especially, in May, the average fall per month being 266 mm. (about 10 inches), which is double the average; the worst days were May 6 with 29 mm. and May 25 with 59 mm.

The following table gives the number of grammes of nitrogen per hectolitre of drainage water from the various plots: —

	Spring cereals	Beet	Wheat	Peas	Fodder
May 15 . . .	1.85	1.9	1.5	1.4	undetermined
May 26 . . .	1.90	1.8	0.75	1.4	0.7

The quantity of nitrate, washed away in this water from 1 kg. of soil was, in kg. per hectare:

Spring cereals	37 kg.	=	280 kg.,	of	calcium	nitrate
Beet	36 »	=	280 »	»	»	»
Wheat . . .	15 »	=	110 »	»	»	»
Peas	28 »	=	210 »	»	»	»
Forage crops .	93 »	=	70 »	»	»	»

It will be seen that the greatest loss was sustained by sugar-beet and the spring cereals, followed closely by peas. Wheat sustained a smaller loss and forage crops still less. All the losses are considerable, however, and must have a bad influence on the crops. But, in order to answer this question, the nitric nitrogen content of the soil must be ascertained.

Towards this end the author compares the nitric nitrogen content in 1920 with the averages for 1907-1911. The following table gives the average content per million parts in the soil for the period 1907-1911, and for the year 1920.

Plot	Middle of May		Ende of May		Begenning of June	
	1907-11	1920	1907-11	1920	1907-11	1920
Spring cereals . . .	9	9	8.5	3	3.5	3
Sugar beet	2.5	11	10.5	8	7	6
Wheat	2.5	2.5	1	1.5	3	1
Peas	8	5	7	3.5	6.5	2.5

During the first half of May, 1920, in spite of the heavy April rainfall, the nitric-nitrogen content of the soil was nearly up to the normal average of the years 1907-1911 : on the other hand, at the end of May and even during the first days of June, the difference was considerable, especially with the wheat and peas, the amount being only ⅓ of the normal.

951 – **Protozoan Fauna of Soils of New Jersey.** — Fellers, C. R. and Allison F F., in in *Soil Science*, Vol. IX, pp. 1-25, Pl. 4, Bibliogr. of 40 publicatons. Baltimore, Jan. 1920.

A review of previous investigations in soil protozoa has already been given (1), but in the present case the principal thesis is connected especially with the *character* of soil microfauna, and embodies the main results obtained from an extended period of research and observation carried out on many soils with several media, and at different sesaons. The depth of soil taken for samples, excludes the strictly surface forms. Poor sandy acid or forest soils contained the least number of protozoa species in comparison with fertile soils (2) or those with high water holding capacity.

Of the 104 species identified, the ciliates were the most numerous, followed in order by flagellates, rhizopods and heliozoa. In point of actual numbers in the soil, however, flagellates easily rank first.

The author reviews the opinions previously given with regard to the new theory of distribution of protozoa in the soil to replace the former " egg and germ " theory. His own work supports the views of Koch and Waksman (3), namely, that in ordinary soils there are very few living protozoa even though the same soil may contain thousands of cysts per gram. In the examination by the author of some hundred fresh samples, only two were found to contain living protozoa. It is concluded that in soils not con-

(1) See *R.*, June 1917, No. 619

(2) *R.*, May 1915, Nos. 579 and 589.

(3) *R.*, Feb. 1916, No. 269. (*Ed.*)

taining moisture much in excess of the physical optimum, protozoa exist mainly in a non-trophic state and are characterised by simple, hardy forms, capable of encystation, or otherwise, to withstand extremes.

In soils saturated with water for several hours, or in standing water, the limited numbers found have very little importance from the standpoint of soil fertility. In fresh water the fauna was much more varied than in the soil, and included rotifers, crustaceans, diatoms, suctoria, sponges, etc.

Much controversy has arisen concerning the question in general but under certain conditions it cannot be denied that protozoa might be able to decrease the fertility of a soil by destroying the beneficial soil bacteria.

In the plates appended to this paper the more common soil protozoa and algae are roughly pictured.

952 – **Ectotrophic Mycorhizal Connections between *Boletineae* and Certain Trees.** (1). — PEYRONEL, B, in *Le Stazioni sperimentali agrarie italiane*, Vol. III, Parts 1-3., pp. 21-31. Modena, 1920.

AGRICULTURAL BOTANY, CHEMISTRY AND PHYSIOLOGY OF PLANTS

Much has been written on the subject of mycorhizae, but as NEGER says, the results obtained are not proportionate to the labour expended.

Researches have been chiefly directed to the humicolous *Tuberales*, *Hymeniales*, and *Gasterales*, and to the *Hyphomycetes* and *Mucorineae* of the forest soil, as being the possible source of the ectotrophic mycorhizae.

Many writers have regarded mycorhizae as the mycelium of humicolous *Hymenomycetes*, because a number of *Agaricineae* and *Boletineae* only grow in the neighbourhood of certain forest trees. The researches of MÜLLER and MANGIN have proved that, in the mycelium of some of the ectotrophic mycorhizae of forest trees, there occur the fibuliform connections regarded as peculiar to *Basidiomycetes*.

The author had already stated that many species of cap-fungi are found growing at the foot of trees with ectotrophic mycorhizae, whereas except for a chance group of meadow and dung fungi, they are never seen near trees without mycorhizae, or with endotrophic mycorhizae.

There is, however, but little direct and trustworthy information regarding the genetic relation between humicolous *Hymenomycetes* and ectotrophic mycorhizae.

The distribution of these *Hymenomycetes* in the Vaudois valleys has convinced the author that a large number of these fungi, especially *Agaricineae* and *Boletineae*, are connected with trees.

The dry season had greatly hindered the development of cap-fungi, but the few observations the author was able to make convinced him of the existence of mycorhizal connections between *Larix decidua* and *Boletinus cavipes*, *Boletis elegans*, and *B. laricinus* on the one hand, and between *Populus tremula* and *Boletus rufus* on the other. The best opportunity for the study of these connections occurs when the fungus fructifications grow on the edge of a flat stone, lightly covered with soil. The author cut out a fairly large clod of earth and removed it on a shovel to the laboratory. There he carefully examined the mycorhizae under the microscope, follow-

(1) See also *R.* Sept. 1915. (*Ed.*)

ing the mycelial hyphae from their point of origin to the place where they pass into the stipe of the receptacle, or into the club-shaped fructifications. *Boletinus cavipes* is a very good subject for study, on account of the thickness of its hyphae.

The best places to make observations are the sides of foot-paths, and the borders of streams flowing near larches and aspens. Little can be done where the soil is rich in humus.

The ectotrophic mycorhizae of *Larix decidua* produced by the three above-mentioned *Boletineae* have the same appearance and structure. In direct light, the mycelium is white, whilst the hyphae are hyaline, thin, and septate, as is shown by the microscope, and are very much alike in all three species of fungus.

The author did not find on the roots of *Populus tremula* the distinctly coraliferous ramifications of the mycorhizae that occur on the larch, but the mycelium of *B. rufus* which produces them has the same characters as that of the three species of fungi producing mycorhizae on the larch.

953 – **Certain Relationships Between the Flowers and Fruits of the Lemon.** — Reed H. S. (Professor of Plant Physcology, University of California), in the *Journal of Agricultural Research*, Vol. XVII, No. 4, pp. 153-165, tables 10 + 1 fig. Washington D. C., July 15, 1919.

The author attempts to discuss :— 1) the seasonal distribution of the fruit buds ; 2) the size and productiveness of the inflorescences ; 3) the time required for the growth of fruit and the relation of this time to the season at which the buds appear ; 4) the numerical ratio of flower buds to mature fruit.

A small group of Lisbon lennon trees were selected for study, and these occupied a large industrial orchard and received no special treatment during the 2 years when the observations were being made.

Approximately 66 % of the fruit buds appeared during March and April ; 13 % in November ; 17 % between April and November, and about 3 % during the winter months.

The distribution of buds on an inflorence showed no tendancy to follow the normal curve of errors. Few-flowered inflorescences predominated numerically over many-flowered inflorescences. A bud on a small inflorescence had a greater chance of developing into a mature fruit than one on a large inflorescence. The competition between individual buds on larger inflorescences seemed to be too severe to allow all to survive.

The time required for the fruit to reach maturity varied from 7 to 14 months according to conditions. Fruit which was set in May, June, and July reached maturity soonest. The season at which fruit was set appeared to influence, but not wholly determine the time which was required for maturity.

The records for 4440 buds showed that 51.98 % set fruit, 21.71 % reached a diameter only of $^1/_4$ inch, and 6.62 % reached the stage of maturity.

A fruit set in the spring had the best chance of survival and of re-

aching maturity. The chances of reaching maturity diminished as the season advanced.

954 – **Ripening of Pears and Apples as Modified by Extreme Temperatures.** — OVERHOLSTER, E. L. and TAYLOR, R. H., in *The Botanical Gazette*, Vol. LXIX, No. 4, pp. 272-296 tables 5, bibliogr. of 8 publications. Chicago, April 1920.

This work was undertaken as a result of previous experiments carried out by SHAMEL (1) who believed that it was the high relative humidity which was the controlling factor in retarding the ripening of pears, but the factor of high temperatures was also present. Hence an experiment was outlined by the authors to endeavour to determine whether high temperatures, or humidity, or both, where responsible. Bartlett, and Easter Pears, and Yellow Newton apple were chosen for investigation purposes. Comparative results showed that temperatures between 87.7° F and 110°F caused an appreciable delay in ripening of green first crop Bartlett pears. This was directly proportional to the increased degree of heat within the limits of 87° to 104°F. Second crop pears placed at a temperature of 101° F, and surrounded by a relative humidity of below 50 %, remained unripe 4 weeks after similar pears had become fully ripe at room temperature and humidity The flavour of pears subjected to temperatures higher than 85°F showed slight acidity and lack of juice.

There was a comparatively large loss from rot with fruit kept at high,. temperatures + high relative humidity.

If the pears have nearly reached a stage of complete ripeness, the temperatures above 70°F do not check the ripening process, but the ripening and breakdown are more rapid with each appreciable rise in temperature. Unripe Easter pears behaved in the same way.

Experiments with the apples showed that ripening is not delayed by temperatures above 32°F and then takes place with increased rapidity. This is true with temperatures up to a point which result in the disorganisation of the protoplasmic contents of the cells.

The authors suggest that these results indicate that the pears might be allowed to remain on the trees somewhat longer in an excessively hot season than with a normal season, and that in the case of apples, the necessity of quickly cooling after harvesting is emphasized.

955 – **Chemical Analysis of Carob Bean** — — I CONDIT, I. F., The Carob in California, in *College of Agriculture, Agricultural Experiment Station, Berkeley, California, Bulletin* No 309, pp. 431-440, figs. 6. Berkeley. 1919. — II. JAFFA, M. E., and ALBRO, F. W., Nutritive Value of the Carob Bean, *Ibid.*, pp. 441-452. figs. 2. bibliogr. of 23 works.

Th Division of Nutrition has completed the analyses of a number of samples of carob beans, from various sources and the results showing the percentage composition of the pods and seeds are presented herewith.

(1) See *R.*, August 1917, No. 771. (*Ed.*)

I. *Pods and Seeds.*

	Water	Ash	Protein	Ether extract	Sugars: Reducing	Sugars: Sucrose	Nitrogen free extract	Crude fibre
	%	%	%	%	%	%	%	%
Minimum	9.12	1.57	3.26	1.00	3.25	6.39	26.99	4.98
Maximum	19.81	3.46	15.22	3.82	18.69	41.56	43.57	17.42
Average	13.28	2.57	6.75	2.17	11.08	19.44	39.80	9.29
II. *Pods.*								
Minimum	3.70	1.75	2.02	0.22	3.00	7.02	24.48	3.14
Maximum	24.70	3.87	7.18	4.02	20.54	43.62	48.36	15.31
Average	11.50	2.72	4.50	2.37	11.24	23.17	36.30	8.78
III. *Pods. Calculated to Water Free Basis.*								
Minimum	—	1.96	2 27	0.26	3.98	7.82	26.69	3 40
Maximum	—	4.10	7.72	4.51	25.07	47.56	51.30	15.90
Average	—	3.09	5.03	2.62	12.61	26.45	40.56	9.78
IV. *Seeds.*								
Minimum	8.89	2.32	14.44	1.83	—	—	55.66	6.90
Maximum	13.63	3.60	19.69	3.06	—	—	62.54	8.34
Average	11.74	3.18	16.46	2.50	—	—	58.61	7.50

The nitrogen free extract and non sucrose content of the pods proves the presence of other carbohydrate compounds than sugar in the carob, but the exact nature of these compounds is as yet unknown, save for the fact that about 1 % of amide has been discovered.

PLANT BREEDING

950 – **Riccio Wheat (Winter Awnless Very Early Variety).** — STRAMPELLI, N. in *Italia agricola*, Year LVII, No. 7 p. 208 + 1 plate. Piacenza, July 15, 1920.

Another excellent, very late type (1) of the hybrid *Wilhemina Tarve* × *Rieti* is No. 76 m. This was also crossed in 1913 with Akagomughi, and among the varieties obtained, was No. 560-1916, which received the name of " Riccio ".

It has the following characters :

Ear red, awned, square, slightly inflated, maximum density 36, average number of fertile spikelets 21, minimum 10, maximum 23.

Spikelets with 4-5 fertile flowers, and 6 in the centre of ear ; average number of caryopses per ear about 70, maximum 85.

Glumes oval-inflated, truncated, keeled, with 3 almost equal ribs brown-red at the edge, short rostrum.

Paleae ovate-lanceolate, surmounted by a rostrum that becomes a small awn (5-10 mm) in the last spikelets near the top of the ear.

Caryopses oval, slightly globular, a little asymmetrical, of a fine wheat yellow ; their size varies with their position in the ear; lobes circular in sec-

(1) See *R.*, July-August, 1920 No. 732. (*Ed.*)

tion, central side convex; average length 5.8 mm.; average breadth 3.5 mm.; dorso-ventral diameter 2-8 mm. ; weight of 1000 caryopses 36.87 gm.

Fracture starchy, glutinous.

Culms, strong, hardly 85-90 cm. in height.

Tillering poor.

Ripening very early : in 1917 harvesting began on June 12, in 1918 on June 14, and in 1919, the wheat was ripe on June 30, whereas " Rieti " was harvested on July 15.

Yield : 31-60 quintals per hectare in 1919

As Ardito and Riccio are very early wheats, catch-crops can be more easily grown than with later varieties, but they were specially created for soils inclined to drought, where the grain is subject to scald.

957 – **Natural Wheat-Rye Hybrids in the United States.** — LEIGHTY, C. E., in *The Journal of Heredity*, Vol. XI, No. 3, pp. 129-136, figs. 4 Washington March, 1920.

In 1918 the author discovered 19 natural wheat-rye hybrids on Arlington Experimental Farm, and others at the Virginia Agricultural Experiment Station.

At Arlington, in order to reduce the chances of cross-pollination between the different varieties of rye, in the intervening spaces between the rye plots different varieties of wheat were sown. At the flowering stage the wind carried the pollen from a rye plot like a dust cloud that could be followed by the eye for a considerable distance, and coming into contact with the wheat plots.

It is in this way that quite frequently natural wheat-rye crosses occur in which the rye is invariably the pollen parent.

CHARACTERISTICS OF THE HYBRIDS. — The hybrids were always taller than the surrounding wheat plants, but always slightly shorter than the rye. The " height " may be taken then as intermediate.

The spikelets were nearly always from 1 to 3 cm. longer than those of wheat, and the number of rachis nodes was usually from $^1/_5$ to $^1/_2$ greater than in wheat. Here again the hybrids appear to be intermediate.

All rye varieties were awned and so the characters found were what would be expected in F_1 hybrids between wheat and rye.

The peduncle of the rye is usually rough and pubescent or hairy for some distance below its junction with the spike or head. It is also solid for the same distance downwards. Plants with entirely smooth peduncle are occasionally found.

Wheat has on the other hand a smooth, hollow peduncle of a greater diameter than that of the rye.

The hybrids, with the exception of three possessed more or less rough and pubescent peduncles, but less so than is usual with the rye parent. The three exceptions had however smooth peduncles as in wheat. As regards the diameter, this seemed to present intermediate characteristics and as a rule there was strong evidence of both wheat and rye parentage in the peduncles of hybrids. Wheat-rye hybrids are usually sterile.

Amongst the 19 plants found by the author at Arlington, 7 only pro-

duced one or more kernels ; it is inevitable that the plants here described are first generation hybrids (F_1) produced by natural fertilisation of wheat flowers with rye pollen.

Forty seeds were produced by the 19 hybrids plants (about 1 % set seed). Vigorous plants of F_2 are being grown from a portion of this seed.

The natural hybridisation of wheat and rye is now known to have occurred in 5 different localities of the United States: — in Northern and South-western Virginia, in Tennessee, in Georgia, and in Oklahoma.

958 – **Studies in the Heritable Characters of Maize " Brachytic Culms ".** — KEMPTON, J. H., in *The Journal of Heredity*, Vol. XI, No. 3, pp. 111-115, figs. 3. Washington D. C., March, 1920.

This variation consists of a shortening of the internodes on the main culm and lateral branches without a corresponding reduction in number and size of other organs. It made its appearance in 1917 in the F_2 progeny of the Chinese × Algerian hybrid designated Dh 416. Approximately one quarter of the plants were brachytic, with shortened internodes (5 brachytic and 21 normal). One of the 5 brachytic plants was self-pollinated, and the resulting progeny were all brachytic, whilst the progeny of a normal plant also self-pollinated were all of normal stature.

The following table shows measurements of plants giving an idea of the existing differences between normal and abnormal (brachytic) progenies :—

	Brachytic	Normal
Height of plant in decimetres	8.66 ± 0.10	14.40 ± 0.24
Number of leaves above the ear	3.20 ± 0.8	3.37 ± 0 09
Total number of leaves	22.90 ± 0.19	20.80 ± 0.27
Husk leaves	0.06 ± 0.02	0.58 ± 0.13
Number of branches in the tassel	15.30 ± 0.64	25.90 ± 1.01
Length of the upper ear in cm.	14.20 ± 0.27	16.40 ± 0.23
Total ear length in cm.	27.60 ± 0.98	28.10 ± 0.71
Number of rows on upper ear.	16.30 ± 0.26	21.20 ± 0.30
Diameter of culm in 16th inches	20.50 ± 0.35	12.40 ± 0.21
Length of 4th leaf	62.60 ± 6.20	64.40 ± 8.90
Width of 4th leaf	9.20 ± 1.40	12.30 ± 1.50

It will be seen from this table that the brachytic strain exceeds the normal in the diameter of the culm and the total number of nodes, while the size of the leaves is about the same.

The upper ear is somewhat shorter, but the total ear length is approximately the same in the two strains.

Eleven ears from brachytic plants were artificially pollinated and the progenies produced exclusively brachytic plants, their mean height being 8.8 dm. When crossed with plants of normal stature, the F_1 was as tall or taller than the normal parent, and in F_2 both normal and brachytic plants were secured in the familiar 3 : 1 Mendelian proportion.

959 – **On the Genetics of "Rogues" Among Culinary Peas (*Pisum sativum*).** — BATESON, W., and PELLEW, C., in *Proceedings of the Royal Society, Series* B., Vol. 91, No. B. 638, p. 186-195. London, May 12, 1920.

In 1915, the authors described abnormal specimens of *Pisum sativum* distinguished by the following characteristics:—

1) Rogues arise sporadically from self-fertilised seeds of various races of typical high-class peas.

2) These rogues are characterised by pointed leaflets and upward curving pods. The leaves, stipules, leaflets, sepals, petals, and carpels are much more elongated in shape than those of the normal type, and the seeds are on an average slightly smaller. Taken as a whole, as regards habit and appearance generally, such plants contrast greatly with the rest of the plants in the plantations.

3) Rogues self-fertilised produce rogues exclusively.

4) Rogues crossed with normal types give F_1 plants which as seedlings appear normal, but at an early stage change to rogues, producing stipules, leaves, and eventually pods, like those of rogues.

5) The offspring produced by the self-fertilisation of these F_1 plants are exclusively rogues.

In the variety chiefly studied — "Suttons Early Giant", — plants intermediate between types and rogues are not uncommon. In them a change in the foliar parts occurs like that described in the F_1 plants: but the complete transformation from the normal to the rogue may be deferred to a much higher level than at the usual first flowering node point. On such plants the shape of the pods also often changes progressively, lower pods being straighter and upper pods curved like those of rogues.

In recording breeding results, the authors have identified two groups:

1) those in which none of the leaflets have points; these give on self-fertilisation what is called A families consisting predominantly of normal plants;

2) those in which pointed leaflets sooner or later appear; in this case self-fertilisation gives B families containing predominantly rogues.

The present study has been devoted chiefly to genetic peculiarities connected with the gradual and regular assumption of the rogue characters by the intermediate plants which sooner or later acquire pointed leaflets.

Having established the fact that in the B families, the non-pointed plants come chiefly from the bottom pods, the following experiments were made:

1) Choosing a number of intermediate plants, thought likely to throw B families, each flower was emasculated in turn, as far as possible pollinating them from rogue-free types. The seeds from each pod were sown separately.

It was expected to find that the non-pointed types would come almost exclusively from the lowest pods. This expectation, however, was not borne out by the result, for the proportion of non-pointed among the egg-cells did not diminish noticeably up to the tenth flower.

With the same plants, self-fertilised (intermediate types), it was distinctly difficult to obtain a non-pointed plant from flowers higher than the fourth flower.

How can this be explained ?

2) Tests were accordingly instituted, using pollen of the successive flowers of the intermediate plants and trying it on the ovules of types. Here again the seeds from each pod were sown separately. Compared with the preceding case it may be noted that the proportion of non-pointed decreases rapidly from about the third flower.

The results are set out in the adjoining Table where the proportion of gametes possessing the normal type characters varies with the male and female sides.

According to the data, the authors admit that up to about the 10th flowering node, rather more than 50 % carry the type characters, or at least the non-pointed character, above which the proportion declines. Of the pollen in the two lowest flowers, only about 20 % is type-bearing, and the proportion diminishes rapidly in each successive flower above this level.

960 – **Selection of Sugar Cane, in Mauritius, Java and in Cochin-China.** — See No. 983 of this *Review*. (*Ed.*)

961 – **Studies on the Suckering Habit of Reciprocal Tobacco Crosses: — Little Dutch × Cuban.** — Johnson J., in *Genetics*, Vol. IV, No. 4, pp. 307-340, figs. 2, pl. 8. Princeton, New Jersey, July, 1919.

The two varieties Little Dutch and Cuban were employed as a base for a series of reciprocal crosses. The former has leaves relatively narrow and is distinctly errect ; the number of branches ranges from 4 to 6 and these are small in comparison with most varieties of tobacco ; the number of suckers is also very limited ; the mean being 4.55 ± 0.7 with a mean weight of 22.2 ± 1.08 decigrams. The branches are thicker in the Cuban type ; the mean being 18.32 ± 0.16, and weight 49.63 ± 1.14 dgm.

There appears then to to be a difference of about 13.7 suckers in the two types, and 22.43 dgm. weight in favour of the Cuban type.

Inheritance of number of suckers. — The average number of suckers of the two parents for 1917 is 11.4 agreeing very closely with the mean found for the F_1 generation which is 11.28 ± 0.22 in one case, and 11.6 ± 0.24 in the reciprocal. The standard deviation and coefficient of variability show, however, that the F_1 is somewhat more variable than the parents, and F_2 is even more so. The standard deviation for the Little Dutch is only 0.75 ± 0.05 and of Cuban 1.64 + 0.11, while that of the F_1 is 2.26 + 0.15 as compared with 4.07 ± 0.14 for F_2.

The F_3 and succeeding generations show in a more striking manner the marked segregation which has occurred. Families have been produced which range in means from 4.11 ± .09 suckers (42 J11) to a family with a mean of 15.40 ± .33 suckers (42 V). Furthermore the standard deviations show that families like 42 J11 and 42 A11, have deviations of only 0.98 ± .065 and 1.22 ± 0.08 respectively, and other families however, as 42 G 21 and 42 M show a standard deviation of 4.03 ± 0.27 and 4.81 ± 0.23 respectively.

Inheritance of weight of suckers. — According to the results obtained in 1917, the data indicate that the mean weight of the Little Dutch suckers is 9.4 ± 0.62 as compared with 46.4 ± 1.41 for the Cuban.

The mean weight of F_1 and its reciprocal are very close and compare quite favourably with the average of the two parents, showing however, some heterosis ; Little Dutch ♀ × Cuban ♂ 30.5 ± 1.69 and Cuban ♀ × Little Dutch ♂ 30.1 ± 1.25. The F_2 and its reciprocal is on the average midway between the two parents, and in the F_3 and succeeding generations, the segregation in regard to suckering habit is definitely shown.

In F_3, strain 42 A11 possessed a mean weight of 14.3 ± 0.82, and strain 42 G21, a mean of 48.8 ± 1.61.

F_1 is apparently only slightly more variable than the average of the parents, and F_3 shows some increase in variability, but not as much as expected.

Correlation. — The preceding data indicate a marked correlation between the number and weight of suckers per plant.

Table I shows the distribution and correlation of these characters n 374 plants of the F_2 generation of Little Dutch × Cuban (1917).

TABLE I. — *Correlation between number of suckers and weight of suckers in Little Dutch Cuban F_2.*

Weight of suckers (gm.) \ Class centres of No. of suckers	3	6	9	12	15	18	21	Total
50	13	26	16	7	3	—	—	65
150	3	18	31	20	16	7	—	95
250	—	15	16	20	15	10	—	76
350	—	10	11	18	16	12	1	68
450	—	6	6	16	10	6	1	45
550	—	—	1	4	6	1	—	12
650	—	—	1	3	4	2	—	10
750	—	—	—	—	—	1	—	1
850	—	—	1	1	—	—	—	2
Total	16	75	83	89	70	39	2	374

The coefficient of correlation is distinctly high: $.423 \pm .028$.

A considerable number of random observations and some systematically recorded data tend to show that no particular correlation exists between number, size or shape of leaves, and the number or size of suckers in the second generation of a cross between the large and small suckering types. The coefficient obtained, for example, concerning the correlation existing between the number of leaves and the number of suckers per plant being merely $-012 \pm .05$. It is evident, according to Table II, that no correlation between these two characters can be said to exist.

CONCLUSIONS. — The cross between Little Dutch and Cuban Tobacco offers a striking example of combination of parental characteristics and uniformity of type in the F_1 generation, and of segregation in F_2, into a great variety of forms as regards various morphological characters. Furthermore, some of these F_2 types may breed true from the start with respect to certain characters; others, however, become fixed in the 4th or suceeding generations; still others apparently continue in a heterozygous condition until F_6.

TABLE II. — *Correlation between number of leaves and number of suckers per plant of Little Dutch × Cuban F_2.*

Amongst ratios in these various forms and characters, nothing satisfactory has yet been obtained which could in any way be made to conform to typical Mendelian ratios. This does not however prove that the characters are not conforming to Mendelian principles. The assumption of multiple factors and continuous variation as propounded by NILSSOHN-EHLE (1908-1909) and EAST (1910) can be made to explain the facts as they occur.

From the available data, little can yet be ascertained by entering into a discussion as to the number of probable genes involved ; there are undoubtely a large number of factors concerned.

963 - **Apple Tree Crossing (*Malus*).** — See No. 988 of this *Review*. (*Ed.*)

964 - **Bud Variations of Grape Fruit.** — SHAMEL, A. D., in *The Journal of Heredity*, Vol XI. No. 4, pp. 157-150, figs. 4 Washington, D. C., April, 1920.

Description of a bud variation of grapefruit studied by the author since 1919 discovered, in an orchard containiug the " Marsh " variety. Apart from the pink flesh colour of the skin and rind, the fruit appeared identical in size and shape to the normal fruits. Buds have been taken for propagation purposes from this branch, but no trees grown from such buds, have yet fructified. The case is an interesting one for the purpose of completing the existing evidence as to the origin of other varieties of the citrus bearing pink-flesh, red, ruby etc. coloured fruit different from that of established varieties bearing fruit possessing the normal colour.

CEREALS AND PULSE CROPS

965 - **Indo-Chinese Rices: — Selection, Cultivation and Hulling of Rice in Indo-China.** — I. CAPUS (President of the Rice Section of the 1918 Congress of Colonial Agriculture), in *Annales de Géographie*, Vol. XXVII, No. 145, pp. 26-42. Paris, January, 15, 1918. — II. CARLE, E. (Inspecteur des Services agricoles attaché au Laboratoire de Génétique de l'Institut Scientifique de l'Indochine), in *Bulletin agricole de l'Institut Scientifique de Saïgon*, Year II, No. 8, pp. 245-247. Saïgon, August, 1920.

For a long time, there has been an annual decrease, to the value of some millions of francs, in the amount of rice exported from Indo-China. This is due to the fact that the varieties of rice grown in that country have proved inferior to the best commercial products of Burma, the United States, Italy, Japan, and even the Dutch Indies and British India. Indo-China now ranks second among the rice-exporting countries (1).

(1) According to the *Annuaire International de Statistique agricole*, 1917-1918, of the International Institute of Agriculture, Rome, 1920, the worlds' average annual production of paddy for the 10-year period 1909-1918 (1909-1910 to 1918-1919) was 729 298 470 quintals. Indo-China takes the fifth place among the rice-growing countries (coming after China, British India, Japan, and the Dutch Indies), with 52 224 813 quintals ; the annual average rose to 54 069 649 quintals from 1914 to 1918 (inclusive). It ranks second as a rice exporting country (after British India) with an average annual export of 9 966 269 quintals of hulled rice and of 289 765 quintals of unhulled rice during the period 1909-1918.

With regard to the exportation of Cochin-Chinese rice, M. NGUYÊN-XUAN GIAC, in

The causes of the inferiority of Indo-Chinese rice have been known for some time, but as yet it has been impossible to remedy them, in spite of a series of measures which the author describes.

The initial mistake is made at the actual centres of rice-growing, where varieties differing in shape, volume, weight, consistency, etc., are all commercially shown by the same name, which is that of the district. The mixture of these heterogeneous varieties is afterwards increased and made worse by the means of buying the paddy and transporting it to the collecting works at Cholon. The Chinese are the middlemen between the Annamite rice-grower and the Cholon mills, and as long as their influence on the factories and the trade continues, no improvement by means of seed selection is possible. The conduct of the Chinaman, with the view of supplying his compatriots with food, militates against this selection. There are in the interior of the country, countless agents, who buy rice in small quantities *mix*, it in their junks, and pay the same price for average quality grain. If a rice-grower had selected his seed, the Chinese agent would not pay him sufficient to encourage his efforts, for this rice would only be mixed with other varieties, and sold at the average price. The rice cultivator has therefore no reason to worry about the quality of rice he sells but only its quantity.

At the Cholon rice-factories the grain, when bought, is again *mixed* before being milled.

The author agrees with M. PARIS, the former President of the Cochin-China Chamber of Agriculture, that the only possible way of improving

---

his work, *Le Régime économique de la Cochinchine* (Ernest Sagot and Co., 19, Rue Cujas, Paris, 1920) pp. 96, writes as follows : —

Until 1878, the only kinds of rice reserved for exportation were cargo rices, mixtures of broken grains and paddy which formed as much as 50 %.

Exported in this manner, Cochin-Chinese rices underwent a noticeable depreciation on foreign markets, especially those of Japan and the Indies. The Government, in consequence of the energetic campaign initiated by the Saïgon Chamber of Commerce, passed a resolution in 1878 fixing at 15 % the maximum amount of paddy that might be mixed with cargo-rice.

China is the best customer of Cochin-China. Formerly, the Chinese exported from that country an enormous amount of paddy which they themselves hulled. On account of the numerous complaints of French merchants and traders, a first export super-tax of 0.03 cents per 100 kg. was levied in 1882 on paddy and on cargo-rices containing over 38 % of paddy, and in 1896, this was raised to 0.125 piastre per 100 kg. The result of these measures was a considerable decrease in the amount of paddy exported to China ; from 163 000 metric tons in 1895, it fell to 72 000 tons the following year. In 1915, the total export from China was 350 099 tons. After China, France is one of the chief markets for Cochin-Chinese rice. Since 1891, in order to favour the rice of the Colony, foreign paddy, broken rice, and foreign rices has to pay a tax of 5, 6, and 8 francs respectively on their entrance into France. The amount of Cochin-Chinese rices exported into France rose from 8547 metric tons in 1890 to 23 228 tons the following year, and was 212 610 tons in 1915. The total figures for the rice exported to France include very little paddy, or cargo-rice ; out of 212 616 tons in 1915, there were only 32 134 tons of paddy, 1517 tons cargo rice, 91 700 tons of hulled rice, and 87 265 of broken rice, and rice flours. (*Ed.*)

the quality of the exported rice, is by building one or more large European factories, where the grain can be sorted before being sent to Europe Naturally, however, the factory owner will continue to be reluctant to set up a supplementary plant consisting of a series of sorters and sifters for enormous quantities of paddy, so long as, owing to the low price of Cholon rice, it is readily bought for export to China and the countries of the Far East, where most of it is sent.

This price will not induce the creation for Europe of standard varieties, selling less easily on account of their cost. We have here a vicious circle, from which, according to M. PARIS and the author, there is no escape, except by establishing regional rice-factories with French capital, which will work for the Paris market. At the same time, in the rice fields themselves, seed selection must be practised.

It must not be thought that all the Indo-Chinese varieties of rice are universally of inferior quality ; some of them are considered equal to the best trade varieties, and in the rice-factories of Havre (France) Tonkin rice may be found that surpasses the best kinds from Java.

The writer concludes that :—

(1) The commercial varieties of Indo-Chinese rice can and ought to be improved by changes to be made in the present system, with a view to *improving cultivation methods*, in order (*a*) to standardise and fix the best known sorts, (*b*) to alter the defective arrangements for selling rice and transporting it from the fields to the store-houses, and (*c*) to complete the factory equipment and thüs ensure the sorting of industrial varieties

(2) These improvements are inter-connected, and interdependent ; they must be carried out simultaneously.

(3) The profit that rice-cultivators could obtain from these improvements can be gauged by comparing the different prices of the competing varieties. In normal times, the loss on Indo-Chinese rices (paddy, cargo and hulled rice), imported into France alone, is not less than 13 million francs.

The author then considers in detail the improvement by the choice of seed, *individual selection* of the seed, and the manner in which it should be carried out. He then studies the improvement of the crops, systematic rotation, and fertilisers, etc. The Annamite scarcely ever manures his rice, but depends upon the rich alluvium deposited by the irrigation water, and upon the fertilising substances contained in the rain (1).

The author believes that by selection and by improving the cultivation methods, the rice production of Indo-China might be increased at least 20 %. Since Cochin-China alone produces annually more than 2 million metric tons of paddy on 1 ½ million hectares, the annual gain would be 400.000 tons in quantity, and 4 million francs in value. The present production of the whole Indo-Chinese Union, which now amounts to about 5 million metric tons, would be increased by 1 million

(1) See " The Economic Value of Tropical Rains " by the same author summarised in *R.*, May, 1914, No. 408. (*Ed.*)

tons, worth at the normal price of paddy in the field, 10 million francs. This sum can rightly be regarded as lost at present and if it is added to the 13 million francs mentioned above, a total of 23 million francs annually is obtained. These figures show the great importanoe of the question.

II. M. CARLE, like the preceding author, asserts that Cochin-China possesses varieties of rice rivalling in quality the best kinds produced in Burma, Java, and Japan; the latter are, however, always sold on the European markets at a higher price than the so-called "Saïgon rice," which is the term used on those markets for all the Cochin-Chinese rice exported before the war as cargo-rice.

Cochin-China varieties of rice are regarded, as a whole, as of inferior quality, and a large amount of the stock exported is used in the manufacture of alcohol.

The factors to which this depreciation is to be attributed are of various kinds:—

(1) The variation in quality of the same variety from one season to another, due to too little, or too much water.

(2) The small amount of care taken by the natives at harvest-time, which renders it impossible to obtain pure varieties with homogenous grain.

(3) As the stubble is not dug up at once after the harvest, but only when the rains begin, the seeds that have fallen during the harvest germinate, and the seedlings grow up with those of the freshly-sown variety.

(4) Another more serious mixing of the rice takes place when it comes into the hands of the first buyer, who is usually a Chinese.

The author expatiates on this fourth point, which has already been dealt with above. He comes to the same conclusions as M. CAPUS, and mentions M. GRESSIER'S modern French factory which has already obtained excellent results, but its success should be assured by the previous solution of the provisioning question.

M. GRESSIER, who ow s large rice-fields in the Province of Soctrang, first worked for many years at their progressive and systematic management; having greatly improved the cultural conditions, he succeeded in obtaining more regular crops of better qualities of rice. The suppression of the Chinese middle-man ensured the success of his hulling factory. The factory installed in 1912, is working under excellent conditions. It first treated the paddy grown on the several thousand hectares belonging to M. GRESSIER, but gradually its work was extended, thanks to the purchases effected in the surrounding districts, and to the fact that a higher price was paid for good varieties than for inferior types. M. GRESSIER sells selected seed to growers with an undertaking to buy the crop raised from it. His example has excited a certain amount of emulation in native circles.

It is much to be wished that M. GRESSIER'S initiative should be followed in all the western region. As soon as there are some twenty small

factories scattered throughout this district, the paddy trade will no longer be in the hands of Chinese, and it will then be possible to supply the Paris market with the finest types of table rice.

In the meanwhile, the Direction of the Agricultural Services through the medium of the Indo-Chinese Economie Agency at Paris, with which this Service is in constant connection, has already made known some varieties of rice. If they were introduced into France under their true name, they would very soon be classified on the markets, though hitherto, Paris merchants have simply assimilated and mixed them with foreign varieties.

Two or three consignments of rice of the Huêky variety, grown from seed supplied by the Cantho Agricultural Station, and prepared at the Gressier factory, have been most favourably received at Marseilles. These consignments should be repeated on a larger scale, but, unfortunately, on account of the difficulties of transport during the War, this has hitherto been impossible.

The Director of the Indo-Chinese Economic Agency in Paris has set himself the task of making the choice varieties of Cochin-China rice better known, and obtaining a proper price for them.

The French rice factories of Cholon (which have been purchased by Messrs RAUZY and VILIE and their associates), and the GRESSIER factory at Soctrang, are now better provided than in the past with the means of dealing with consignments of pure paddy, and on their side, intend to use every effort to supply the Paris market with a constant sypply of the best rice.

966 – **Darso.** — BEESON, M. A., and DAANE, A. (Department of Agronomy), in *Bulletin* No. 127 *Agricultural Experiment Station, Stillwater Oklahoma*, Sept. 1919.

Darso is a new sorghum developed and named at the Oklahoma Ex-Experiment Station. Owing to the possibility of its becoming a valuable addition to the grain sorghums, because of its earliness, and dwarfness, selection work has been carried on at this Station for high grain yielding quality and improvement of other characteristics.

Darso is of unknown origin but probably a cross between a non-saccharine sorghum and a saccharine sorghum. It is leafy, stocky, red seeded, drought resistant, early maturing, and very uniform in height.

Comparison Tables show that the forage darso, contains a higher percentage of sugars in the juice than the Black hulled White Kafir or feterita, namely, 5.79 % compared with 2.49, and 4.73 % respectively (as sampled) and 17.85 % compared with 7.78 and 8.85 % (moisture free).

A preliminary report of a feeding experiment indicates that darso does not seem to be quite so useful a feed as kafir for hogs. The animal Husbandry Department of the Experiment Station is continuing the investigations.

The six year's average yield (bushels per acre) is shown as follows: Darso 19.4 — Black Hulled White Kafir, 16.4 — Feterita, 13.91 — Dwarf Hegari Kafir 12.7, (4 years average) — Shrock Kafir 12.1 (2 years average

— White Milo, 5.2 (4 years average). These plants took 103 — 115 — 99 — 108 — 116 — 104 days to mature, respectively.

Comparison between compositions of Darso and Kafir.

Variety	Water	Ash	Protein	Fibre	Ether Extract	Fat.
			Stalks (Green)			
Darso	70.99	2.11	1.28	7.29	17.70	0.63
Kafir	71.80	2.82	1.30	7.32	10.08	0.68
			Etain			
Darso	11.75	1.60	10.94	3.44	65.53	3.74
Kafir	10.08	1.56	10.19	2.39	72.66	3.20

Darso is able to withstand relatively long periods of drought better than kafir. The cultural methods are practically the same as for the other grain sorghums but as it matures in about 100 days, it can be planted later than most of the grain sorghums, and still give relatively good yields. The grain usually keeps better when stored in the head than when threshed Long narrow cribs are to be preferred for this purpose rather than storing threshed grain in bins.

Reports from farmers who have cultivated darso in a limited way during the past few years, indicate that this crop may be of value to the south-west.

967 — **Potato Production** — STEWART. G., in *Utah Agricultural Experiment Station, Circular* N°. 40, pp. 1-54. tables 6, figs. 20. Logan, Utah, July 1919. FIBRE CROPS

The author give details of distribution, description of the plant, place in cropping system, general cultivation grading, storage, marketing and utilisation. It is noted that too hot a climate is adverse to successful cultivation and it is therefore confined to the northernmost States of America. A cool moist climate is largely responsible for Europe's high acre yields combined with intensive farming, seed selection, and thorough rotation, and the careful use of fertilisers.

A diagram is given which shows the average acre yield and average farm price of potatoes in the United States 1866 to 1917. The annual production is 350 to 400 million bushels.

It is advised to leave at least five or six years between potato crops on the same land. After alfalfa, after maize planted on alfalfa stubble, after sugar beets, and after beans, are good places to plant potatoes according to the particular districts under inspection by the author. The application of farmyard manure should supplement rotation.

The fact that potatoes thrive best on sandy loam soils is adequately supported by the authors experiences.

968 – **Notes on Manioc in Indo-China.** — I. Balencie, H., Notes on the cultivation of Manioc made at Agricultural Experiment Station at Bêu-cat of the Economic Service of Cochin-Chine, in the *Bulletin économique de l'Indochine*, Yr. XXIII, New Series, No. 141, pp. 272-275. Hanoi-Haïphong, March-April, 1920. — II. Prudhomme, E., Note on the Composition of Six varieties of Cambodian Manioc in the *Bulletin agricole de l'Institut Scientifique de Saigon*. Vol. II. No. 7, pp. 196-199. Saïgon, July, 1920.

I. — Experimental crops of manioc were grown at the Bêu-cat Agricultural Station, firstly in soil which was light and poor, secondly without manure, after two ploughings and harrowings, then planting in ridges 1.60 metres apart, (1 metre at the base and 30 cm. high) 20 cm. cuttings at the beginning of the rainy season, so that (growth lasting from 18 to 20 months), the crop could be harvested during the dry season. The cuttings were planted, in the centre of the ridges and 1 metre apart. The only work then necessary was earthing up and weeding.

The results obtained are shown in the following table.

Variety	Weight of tubers 1917	Weight of tubers 1918	Starch	
			per cent.	weight

These results were obtained without the application of fertilisers and it is obvious that the addition of fertilisers would increase the yield.

It was found by analysis that the amount of prussic acid in the tubers of the different varieties tested is not sufficient to be injurious, so that they can be used for human or animal consumption without danger.

II. — Results of the analysis made at the " Jardin Colonial " at Nogent-sur-Marne, France, of 6 varieties of dried manioc seeds sent from Cambodia by M. De Flacourt, Chief of the Agricultural and Commercial Services of Cambodia.

These 6 specimens came from varieties created recently by selection from a seed bed of one of the three local varieties usually cultivated. Of these six types, two, No. 158A and No. 156A, are particularly interesting because of their high nitrogen content and their low fibre content.

M. De Flacourt states that they are very early and give excellent yields.

FORAGE CROPS MEADOWS AND PASTURES

970 - ***Pithecolobium Saman*, a Tropical Tree Producing Fruit that Can be Used as Cattle Food in the Dry Season.** — Salomon, X., Vernet, G. and Nguyen-Duc-Long, in *Bulletin agricole de l'Institut Scientifique de Saïgon*, Year II, No. 7, pp. 193-196. Saïgon, July, 1920.

Stock-feeding during the dry season is a most important problem in Indo-China. MM. Vieillard and Tran-Van-Huu have lately published a paper on this subject, in which they have shown how necessary it is to grow specially cultivated crops during the dry season in that country.

The authors have contributed to the solution of the question by studying the fruit of *Pithecolobium Saman* Benth., a leguminous plant belonging to the Sub-Order *Mimoseae*. This tree is especially valuable in Cochin-China, because its fruiting-season begins in December and lasts till the end of March, that is to say, during the very months when there is a scarcity of grass in the Colony.

The fruits are shaped like a large bean, and have an average length of 17 cm. ; they are very dark brown when dry and much resemble those of the carob-tree, though they are narrower. The pods contain 18 seeds forming 19.82 % of the total weight; the integuments weigh 80.18 %.

The average composition of the entire fruit (integuments and seeds) is as follows :—

Moisture	30.52 %
Nitrogenous matter	13.08 »
Fats	1.45 »
Sugar and Starch	36.14 »
Fibre	15.90 »
Ash	2.66 »
Undetermined	0.25 »
	100.00 %

The feeding value of the fruit of *P. Saman* is thus high.

The seeds are very hard, but experiment has shown that they are digested, and that those present in the dung had all been disintegrated during their passage through the alimentary canal.

These fruits are readily eaten by herbivorous animals (horses and cattle). No toxic symptoms were ever observed in the case of the ani-

mals in the Saïgon Botanic Garden, even after the ingestion of large rations of the fruits.

P. Saman seems to do well in many soils, and would be of great use to planters as a stock-feed during the dry season. It grows into a large tree; those in the Saïgon Botanic Garden, are 45 years of age, their trunks have an average girth of 2.70 m., at 1 m., from the ground; the average diameter of the crown is 30 m., and the fruit yield is large.

Planted 20 m., apart in all directions (i. e., 25 trees per hectare), these trees could also act as a shade to other crops.

971 – **The Prairies of Madagascar.** — PERRIER DE LA BATHIE, H., in the *Bulletin économique de Madagascar*, Vol. XVII, Nos. 1 and 2 1st and 2nd quarters, 1920, pp. 1-16. Tananarive, 1920.

The prairies of Madagascar are composed of gramineae which have replaced the trees formerly destroyed by brush-fires. In fact, nearly all the forests on the island have thus been destroyed. The natives, in course of time, have destroyed the virgin forest, there they cut and burned clearings and started a temporary cultivation on the ashes; then by repeated brush-fires burning the vegetation, immense spaces have finally been left completely bare, the end of the process being the exposure of the hard rock, laterite in particular, by unimpeded erosion. The prairie has taken the place of trees and shrubs, and each phase in the denudation of the soil corresponds to a particular type of prairie, characterised by special types of grasses. By ancestral custom the natives still continue to burn the prairie stubble when it is dry. This annual custom of burning finally destroyed all annuals or plants having superficial rhizomes, leaving only species that can live under such conditions (i. e., grasses with deep, perennial roots, and hard and tough culms.) In consequence, in the central regions, where the prairies can hardly be utilised for feeding cattle, the grasses constitute but poor pastures on which the cattle often remain thin and sometimes die of starvation.

Cattle breeding, however, is one of the principal resources of Madagascar (1). The prairies cover, in consequence of the aforementioned methods of the natives, $^3/_4$ of the area of the Island. It is then of great interest to study the types of flora on these prairies and to find means of improving them and making them of more use as pasturage. This the author has done, and gives his observations in the present note.

Although the usual plants of the prairies are either cosmopolitan or common to tropical countries and thus not very sensitive to changes of climate or altitude, there are certain differences in the botanical composition of the prairies in different parts of the island, and the species which are common to these parts behave differently according to place and vegetation.

The author has also studied separetely the prairies of the eastern slopes, the central plateau, and the western slopes, and has made a list of the species which constitute, in the fire areas, the prairies of each of

(1) See *B.* Jan. 1919, pp. 1-11. (*Ed.*)

these regions and he has tabulated also those species which are good for fodder, messicoles, ruderals and authochtones, and grow around the prairies, but are prevented by the fires from entering them.

After having studied in detail the three regions of Madagascar, from these points of view, the author draws the following conclusions :—

In all this area, which comprises $^3/_4$ of the whole area of the island, there are only about 20 species. The reason for this is that only those species able to withstand fire have become dominant and can thus be found everywhere in the island wher. burning is practised.

It is fortunate three of these species make good fodder, viz., " vero " (*Andropogon rufus*) " rambonalika " (*Pennisetum setosum*) and " ahitrombilahy " (*Chrysopogon* sp.), as well as two mediocre species " danga ' (*Heteropogon contortus*) and " mafiloha " (*Andropogon intermedius*).

In addition, no species is actually harmful to cattle, but the seeds of the ' danga " and one or two others give rise to a skin disease and loss of wool, and for this reason there is very little sheep breeding.

The great fault of these prairies is that they rarely have the characteristics of meadows, even in the best regions of the island, and they are not able to nourish more than a limited number of cattle. In the west as much as 5 to 6 hectares are necessary per head of cattle.

All the bad parts of the prairie can easily be modified by simply applying manure to the most sterile soils, then ploughing, followed by the sowing of a good type of fodder chosen from those which have been a long time in the island. Afterwards it will only be necessary, in order to maintain these species indefinitely, to cultivate it by the usual methods and stop the practice of burning.

The good forage species which the fires have prevented from spreading over the prairies, abound in the other parts of the island. It will thus be sufficient to choose those which best suit the soils in order to produce this or that kind of fodder and so to create the various kinds of pasturage In this way the pastures would nourish 20 times more cattle than the present prairie .

Apart from the forests destroyed by fire, and those that will be destroyed, if care is not taken, the fires are harmful in many respects. They are ruining the pastures, stopping all shrub and tree plantation and preventing all the moral and social progress which comes from permanent cultivation and the increase in the value of the soil. Nevertheless, it is impossible and even dangerous to try to stop them at present. The suppression of the fires is none the less an aim that should be kept in view. The establishment of native ownership, which is the only way to make the natives take an interest in increasing the value of the soil, the abandonment of extensive methods of cultivation and cattle-breeding and the consequent improvement in methods of cultivation and breeding, will quickly compel them to stop the fires, by leading to a complete utilisation of all prairie products. Besides, an integral part of the progress remaining to be accomplished should be to turn the island into a great and beautiful country of cultivation and cattle-breeding.

FIBRE CROPS

972 - **Cotton Growing in Mesopotamia.** — *Bulletin of the Imperial Institute*, Vol. XVIII, No. 1, pp. 73-82, London, Jan.-March, 1920.

The soil in Mesopotamia is sandy, but fertile. The climate varies from extreme heat (ranging between 78° and 115°F with a mean of about 90°—100°F in July and August to a degree of cold in winter comparatively rare in corresponding latitudes (ranging between 37° and 62° F with a mean of about 47° to 55° F in December and January).

The rainfall is not sufficient for the requirements of agriculture, and irrigation must therefore be practised. The mean annual precipitation amounts to only about 10 inches, but considerable variation occurs from year to year, the rainfall in 1894 for example being as much as 22 inches, whereas in 1901 it was only 1.6 inches. The typical soil of Mesopotamia is a light calcareous loam which contains about the same amount of nitrogen as the average soils of Egypt, and sufficient potash and phosphoric acid to maintain the growth of cotton without the application of manures.

The region between the Tigris and Euphrates is liable to inundation over a wide area covered by the tributaries. From Bagdad to the sea coast, the Tigris has a slope of 1/130 000, and has deposited its coarser mud within the first 150 miles. This has rendered the upper reaches of the river exceptionally fertile. At about 50 miles below Bagdad, the deposits begin to become finer and salted, and this continues to the sea. The latter soils are sometimes too salt for agriculture, and are much inferior to the friable deposits of the north and south of Bagdad, which are eminently adapted for cultivation under irrigation. The salt lands should, however, be easily reclaimable, provided that a sufficient supply of water is available.

Cotton has been grown in Mesopotamia to some extent from very ancient times, and is now cultivated by the Arabs in small quantities along the banks of both the rivers for local use. The plants are usually grown in conjunction with food crops. The native cotton which is apparently derived from *Gossypium herbaceum* is of variable quality, but on the average approaches the "middling" American grade. Attempts have been made from time to time to grow Egyptian varieties, and small quantities of these cottons are now cultivated at Amara, Bassra and other places. On the banks of the Diala, another variety is grown which resembles the Indian types of *G. herbaceum*.

Mesopotamia possesses a soil and climate favourable to the production of large yields of excellent cotton.

The development of the industry is at present restricted, however, by the smallness of the population, and the need for irrigation and drainage. It is also necessary that transport facilities should be improved, agricultural machinery introduced, and instruction given to the natives in the methods of cultivating and harvesting the crop.

In 1917, Captain R. THOMAS was appointed as Cotton Expert for Mesopotamia, and experiments were forthwith conducted at Karradab on the outskirts of Bagdad with divers varieties of cotton; further

experiments are still in progress. The British Cotton Growing Association proposes to establish a number of model plantations as large scale demonstration and seed farms.

It is estimated that there are at present about 300 000 acres on the banks of the Tigris and Euphrates which could be irrigated from the rivers themselves by means of mechanical appliances ; about 80 000 acres are capable of canal irrigation for summer crops on the banks of the Diala river above Bagdad, and about 120 000 acres on the Euphrates commanded by the Hindia barrage. Assuming that cotton will be grown in rotation with other crops, and that it would occupy only one-third of the total area, in any one year, there is a total of 150 000 to 200 000 acres which would be cultivated annually.

973 – ***Malachra capitata* and its Fibre.** — CAYLA, V., in *L'Agronomie Coloniale*, Year V, No. 32, pp. 33-35. Paris, August, 1920.

The author had the opportunity of seeing, in Guiana, some cultural experiments with two species of *Malachra* (fam. *Malvaceae*, tribe *Ureneae*), viz. *M. capitata* L. and *M. radiata*, which grow wild in the Savannahs. They were first tested at the Landbouw proefstation at Paramaribo, but it is only since the end of 1918 that a cultural experiment on several acres has been carried out at the Kleinhorp Station on the banks of the Cottica near its junction with the Commewijne.

Like all the plantations of the low, alluvial land of Dutch Guiana, the cultivated land at Kleinhoop is banked up into polders ; part of it is planted with commercial cacao trees. Although the riverwater is brakish, the polders and their dykes are kept in such good condition that the cultivated soil is entirely free from salt. On this sandy loam soil, M. DROST, the Director of the Cultural section of the Agricultural Services, obtained the first results which, although still incomplete, are now reported by the author.

Of the two species, *M. capitata* is the more important ; it attains the height of from 2.50 to 5 m., while *M. radiata* is not more than 1.5 to 2 m. high. Hence, the fibres of the latter are shorter than those of *M. radiata*.

When these plants are cultivated they are only sown once, as they re-sow themselves afterwards. In order for them to grow well, it is, however, necessary to keep the ground very clean, and to thin out the crop in the third year.

From 5 to 6 months after sowing, *Malachra* is large enough to produce saleable fibre. It is then cut, and 2 crops can be obtained a year.

The plant appears to grow well in any soil, provided it is not too clayey, and that it is free from salt ; but it has to be carefully hoed, without however exposing the base of the stem.

The average fibre yield obtained in the experiments was from 25 to 40 gm. of tow per plant (a maximum of 65 gm. has been obtained). M. DROST does not think that more than 10 to 15 gm. of fibres 2 m. long could be expected from ordinary crops ; he counts on getting 1250 kg., of tow per hectare. The fibre is prepared by merely retting it for 12 hours.

Thanks to the Director of the Nogent-sur-Marne Colonial Garden, a sample of the fibre brought back by the author was examined by M. DANTZER, professor at the Conservatoire des Arts et Métiers.

He found *Malachra* fibre to be very similar to jute, but its tensile strength is only about $^3/_4$ that of the latter, and it is less flexible; the length of the tow is only $^3/_5$ of that of jute. *Malachra* fibre resembles the fibre of Dâ (*Hibiscus cannabinus*) and of Paka (*Urena lobata*); it could be used for the same purposes as jute of inferior quality.

Malachra capitata could be cultivated with advantage in the French Colonies.

974 - ***Carludovica palmata* and the Manufacture of Panama Hats.** — CAYLA, V., in *L'Agronomie Coloniale, Bulletin mensuel du Jardin Colonial*, New Series, Year V, 1920-1921, No. 31, pp. 21-23. Paris, July, 1920.

Carludovica palmata R. and P. (fam. *Cyclanthaceae*, intermediate between the palms and the *Pandaneae*), is a tree of Equatorial America that occurs from the North-West of Brazil to Central America. As is well-known, its leaves, when specially treated, are used for making the so-called "Panama", or "Guayaquil", hats.

Until lately, this industry was entirely confined to Central America, but recently, according to a report by the French Vice-Consul at Port-of-Spain (Trinidad), *C. palmata* has been introduced into the British Lesser Antilles, and British Guiana. The tree is said to grow well in Grenada, and hats are already being made in Jamaica.

C. palmata is also cultivated in the two Dutch Colonies of Curação and Surinam. The production of the latter colony is of little importance, being limited to the Station of Paramaribo, which supplies leaves to a school of girls, who make them into hats. The author has visited the plantations, and gives information as regards the cultivation of the tree and the preparation of the leaves.

Carludovica is grown either from seeds or cuttings; it prefers the soil of ancient forests, requires shade when planted, and is not much affected by the excessive moisture of the soil. The leaves can be used in 5 years if the trees have been grown from seeds, or in 2 if cuttings were planted. In order for the plant to flourish, half the leaves only must be taken each year, which gives a total varying from 14-20. Dr. G. STAHEL, of Paramaribo, reckon an average of 14 leaves.

Before the leaf is expanded, it is cut at the base of the petiole; it then has the form of a much elongated spindle. The sheath is cut longitudinally in such a way that the knife slightly pares the hinges of the folds of the palmate lamina, which in the inside is folded in accordion-pleating. In this way, a series of parallel strips 2 to 2 cm. wide, and 55 to 60 cm. long are obtained; these remain attached to the petiole. The strips are subjected to a combing process, that reduces their width to about $^1/_{10}$ of the original width; they are then bleached chemically and finally dried. All this work is done by women and children.

It is calculated that 1000 *Carludovica* trees can be planted on 1 hec-

tare. When adult, they can furnish 7 to 10 leaves annually, so that the return per hectare is very small.

The author thinks that the cultivation of *C. palmata* should be left to private families ; it can only form a subsidiary industry to be undertaken by the owners of small plantations. It is particularly suited to the natives and their families. In this way, however, excellent hats of fine quality could be made in those regions of the French Colonies where *C. palmata* grows.

PLANTS YIELDING OILS

RUBBER GUM AND RESIN PLANTS

976 - **The Future of Rubber Plantations.** — *Bulletin de l'Association des Planteurs de Caoutchouc*, Vol. VII, No. 7, pp. 251-253. Antwerp, July, 1920.

Rubber plantations, as well as the rubber industry and trade, are at present passing through a crisis which arouses feelings of anxiety and even apprehension in all concerned. However, according to the author, there is no cause for anxiety, for all that is needed is a judicious change in the methods of working the hevea plantations. The owners must acquaint themselves with this change, which is inevitable, but will bring about a new state of affairs more in harmony with present conditions.

The existing crisis is due to the fact that plantations were suddenly made on a large scale, without previous and conclusive experiments, and hence without any systematic method. At the beginning of the plantation period in the Far East, the sole idea of the promotors was to plant with the greatest speed the largest areas possible, without paying sufficient heed to practical, economic questions of which the following are some of the most important :—

(1) Labour available.

(2) Cost of labour, and the hygienic measures to be adopted with regard to the agricultural workers (1).

(3) The character and drainage of the ground, and the choice of suitable soils for plantations.

(4) The upkeep of this land.

(5) How far apart the trees should be planted in order to ensure normal development and encourage growth.

(6) The most economical methods of tapping, so as to obtain the highest yield without injury to the trees.

(7) The coagulation methods most likely to produce rubber of the best quality.

(8) Pruning the trees.

(1) In the same number of the *Bulletin de l'Assoc. des Planteurs de Caoutchouc*, on page 263, the following observation on Malaria in the Straits Settlements is made :— " Active measures are being taken in these Settlements to strengthen the hands of the Medical Officers and to coordinate their efforts in controlling the mosquito. In Negri Sembilan, over 11 790 persons died of malaria in six years, and there are more than 98 000 cases of malaria in the State annually. As it is calculated that each case represents at least five days illness, this disease costs the planters every year 496 165 days of work. It should be noted that the labour question practically resolves itself into a medical one. " (*Ed.*)

(9) The establishment of nurseries, and the choice of the best seed for sowing.

(10) The selection and clearing of the land ; the removal of all old stumps which would afterwards cause much trouble as the centres of fungoid diseases.

Apart from these questions, which are still being studied, no definite data exist as to the rate of growth of the trees. Large areas have been planted without any attention having been paid to these matters, and it is calculated that there are now 2 450 000 acres under hevea in the Far East, the annual yield of rubber amounting to 350 000 tons.

Rubber is the only raw material of which the price has not risen on account of the war, owing to the fact that hevea exploitation has suffered relatively little from the war itself, which can be readily understood, seeing that the countries where it is grown are so far from the war zones. Owing to the freightage crisis, and the impossibility of selling rubber to central Europe or Russia, large stocks accumulated in Asia, and subsequently found their way by degrees to the European markets. In spite of the extraordinary development of the motor car industry in both America and Europe, these stocks decreased but slowly, and there are in London at the present time 20 000 tons of rubber as against 13 000 in 1919. It must not, however, be supposed that the production exceeds the demand. It should be remembered, that only the United States and certain European countries are now making up the arrears of some years. As soon as Central Europe and Russia again begin to buy rubber, not only will equilibrium be quickly established, but it is to be feared that even taking into account wild rubber, the supplies will soon be far below requirements.

Although the great hopes entertained ten years ago of the future of rubber plantations in the East will not be wholly realised, owing to the circumstance that important factors have since revealed themselves which were then not taken into account, there is, however, no reason for pessimism. It is true that the production of the plantations is now decreasing on account of too early and intensive tapping which has exhausted those heveas that are 20 years old, the density of the plantations, and want of care and method. Indeed, the total export of rubber from the Straits Settlements from January until the end of May, 1920, was only 67 772 tons, as against 77 666 for the same period in 1919 ; yet it is clear that the demand will continue to increase (at least 15 to 20 % annually), so that the inevitable high prices will make up for the smaller quantity sold. It is easy to foresee that the price of the raw material will soon begin to soar. If the demand increases, and continues to do so, it is on account of the extraordinary number of purposes to which rubber can be applied (1) and especially of the requirements of mechanical traction.

(1) The progress in technique encourages the industrial use of rubber. We should here mention in this connection, a new process of vulcanising rubber, described in the *Bulletin de l'Association des Planteurs de Caoutchouc*, Vol. VII, No. 7, p. 263. Antwerp, July, 1920. Hitherto, rubber has been vulcanised by melting it with sulphur at a temperature

It may be roughly estimated, that $^2/_3$ of the rubber produced is absorbed by motor traction. It is calculated that the United States alone turned out 1 600 000 motor-cars and 400 000 motor-lorries in 1920; the number of motor vehicles at present in use in the United States is estimated at 7 000 000, and the annual increase at 1 000 000. In order to equip all the existing vehicles and those in course of construction, the consumption of rubber in the United States will increase 25 % annually.

What technical changes should the owners introduce into their plantation? In principle, all the experts are agreed that it is necessary to give up tapping 4 year-old trees and to wait until the heveas have attained a reasonable girth, in order not to check their growth by a too early removal of their young bark and latex, which at that time contains an insufficient amount of rubber (1).

The trees must not be so thickly planted as to deprive them of the air and sunshine necessary to their growth (2). The injury already done cannot be remedied by late thinning out; further, the useless trees which are subsequently removed have impoverished the soil to the detriment of those remaining (3). As a matter of fact, 1 acre of plantation ought not to contain more than 30 to 35 well-grown trees (4).

During the winter (when the leaves fall), tapping should be entirely suspended to rest the trees, which produce very little latex at this season.

In order to get plantations into good condition that have been badly managed, and where the bark has been destroyed by intensive tapping, the trees should only be tapped every other day (5) and all plants suffer-

---

of 138° C., which has prevented the addition of any substances liable to be destroyed by this high temperature. A new process has been invented by PEACHEY, of the Manchester Technical School (England), in which vulcanisation is effected in the cold, by means of sulphuretted hydrogen and sulphur dioxide, which react and produce water and free sulphur. The raw rubber whether solid or in solution, is treated simultaneously by the two gases, and the sulphur liberated by the reaction vulcanises the rubber. If sawdust, scraps of paper, or leather are added, the mixture is vulcanised. This new discovery seems likely to open a new and very large field for the use of rubber. Rubber could be used for making linoleum, wall-hangings, etc., and for various articles of artificial leather, not to mention rubber boots (which could be made seamless, in one piece), and felt. This new process could also be used in the manufacture of pneumatic tyres. (*Ed.*)

(1) M. E. GIRARD considers that tapping should be deferred, if possible, until the heveas are from 7 to 8 years of age, and have attained a minimum circumference of 60 cm. (an average of 70-75 cm. at 1 metre from the ground. See *R.*, Jan., 1920, No. 50. (*Ed.*)

(2) and (3) Since 1913, M. GIRARD has reduced the density of the Susamah plantation to 100 trees per hectare (before that date, there were 200 per hectare), and in 1915 he made new plantations with very large spaces between the trees, i. e., 18 m. in all directions (30 heveas per hectare) with a catch-crop of coffee-plants. See *R.*, Feb., 1919, No. 205, and Jan., 1920, No. 50. (*Ed.*)

(4) See M. CRAMER'S article on experiments in thinning a hevea plantation in Java, in *R.*, June, 1920, No. 644. (*Ed.*)

(5) As regards tapping methods, see M. GIRARD'S article in *R.*, Jan., 1920, No. 50. (*Ed.*)

ing from " brown bast " (1) should be scraped and cleaned ; dense plantations ought to be thinned, old stumps removed, and floods prevented by adequate drainage, for excessive damp encourages the development of moss, fungoid diseases, and various pests.

It is well to consider that the life of well-tended heveas is from 30 to 35 years, and every year new plantations should be made according to the latest approved methods.

977 – **The Growth of *Hevea brasiliensis* in the Philippine Islands.** — YATES, H.S. (Botanical Section of the Biological Laboratory, Bureau of Science, Manila), in *The Philippine Journal of Science*, Vol. XIV, No. 5, pp. 501-503, tables 16. Manila, May 1919.

The author states that it has been demonstrated that rubber will grow and yield satisfactory returns in the Philippine Islands. The results of a number of girth measurements of trees of various sizes are given with data regarding climatic and soil conditions in the southern part of the Philippine Archipelago compared with that recorded in other countries, especially the Orient, where Para rubber is now being successfully cultivated. The suitability of the former region is indicated for *Hevea* culture.

The rate of growth of *Hevea brasiliensis* is also compared between these countries. It certainly finds its optimum habitat in regions at comparatively low elevations, possessing a climate with a rainfall not much below 2000 mm., evenly distributed throughout the year, and with a temperature rarely, if ever, falling much below 19 or 20°C, at least for any extended period. The humidity should also be fairly high.

It is probable that the retardive effect of altitude upon rubber is related to the lower temperatures prevailing at higher elevations. According to the Table giving the results of an Experiment in Malaya to show the effect of altitude upon the growth of *Hevea*, a considerable reduction in the rate of growth as elevation is increased, should be noted. Generally speaking Para rubber may be said to do well on any soil that will support a heavy forest growth, provided drainage is good, but heavy clay soil is not so suitable as loam or sand.

Measurements of trees at present growing in the Philippines show a rate of growth comparing favourably with records in Ceylon and Malaya. The average yearly increment of all trees measured appears to be about 2.4 inches.

The yield obtained from trees now being tapped is very satisfactory and compares well with the above mentioned countries.

978 – **Experiments on *Hevea brasiliensis* on Grey Soil (2) in Cochin-China.** — DEVRAIGNE, G. (Chief of the Economic Service of Cochin-China), in *Bulletin économique de l'Indochine*, New Series, Year XXIII, No. 142, pp. 275-405 plan, 1 + diagr., tables 3, numerous figures, graphs, and photos. Hanoï Haïphong, May-June, 1920.

The results of experiments extending over the 3 years, 1917-1919, at the Bêncat Agricultural Experiment Station, Cochin-China.

(1) " Brown bast " is a very common hevea disease in all the hevea plantations of the Far-East. Experts are not agreed as to the causes of the malady, as they have not yet been thoroughly determined. (*Ed.*)

(2) For the nature and distribution of the " red soils " and " grey soils " of Indo-China See *R.*, Feb., 1919, No. 205. (*Ed.*)

The following is the analysis of an average soil sample taken from the diagonals of the 16 hectares under heveas at the Station :—

Composition per 1000 *parts of crude soil dried at* 100°C.

Physical analysis		Observations
Coarse sand per 1000 parts of dry soil	38.79	—
Fine sand	774.89	Sandy soil poor in fertilising substances
Organic remains	7.89	
Clay	172.50

Lime as CaO	traces
Magnesia as MgO	0.200

The experiments are to be continued for several years in order to know whether the differences now observed will continue. Until this is decided, it is impossible to arrive at any exact conclusions, but, for the moment, the author simply gives the results obtained.

Spacing. — Two lots of hevea, A and B :— lot A contains only trees planted 6 m. × 6 m., and lot B trees planted more closely at 4.50 × 4.50 m. In close spacing, the yield per tree is less than where the trees are farther apart, but the total quantity of rubber per hectare is greater (1).

The extra yields obtained by planting closely were :—

in 1917	138.192 kg. more per hectare
» 1918	296.278 kg. » » »
» 1919	206.949 kg. » » »

Tapping methods. — Comparative experiments with the various systems of tapping usually employed in the case of trees of the same age in widely-spaced, and closely-spaced plantations.

The following tapping methods have been tried :—

(1) The ¼ spiral, ½ spiral, half-herring bone over ½ the circumference in the case of trees planted in 1907 ; (1) $^1/_5$ spiral, with 2 notches one above the other, $^1/_5$ spiral with 1 cut, half herring-bone-cut over half the circumference of the trees planted in 1910. It was found that the longest cuts produced the most latex, while in the case of incisions

(1) The author points out that definite conclusions should not be drawn from these results obtained in 3 years; further, the question of the future of the plantation must be taken into consideration, as well as the yield at any given time ; see, as regards spacing of heveas, *R.*, Feb., 1919, No. 205, and *R.*, June, 1920, No. 644. (*Ed.*)

of equal length, the half herring-bone-cut over ½ the spiral gave the best results.

Inclination of incisions. — The experiments were made on trees planted in 1900 in avenues 6 m. apart, those on one side being tapped from right to left, the others from left to right. The direction of the incisions was altered twice, and it was always found that the best results as regards yield were obtained with incisions from left to right.

Alternation of tapping. — Experiments made on trees planted in 1912, and tapped for the first time in 1920. The best results have hitherto been obtained (both as regards yield per tree and per hectare) by tapping every day. A decrease of 50 % in the yield of dry rubber occurred in the series of trees tapped alternately.

In the case of daily tapping, the bark destroyed amounts to 40 cm. per annum ; with alternate tapping, only 20 cm. should theoretically be destroyed, as the tree is tapped half as many times. As a matter of fact, however, 30 cm. is destroyed, owing to the greater desiccation of the surface of the incision, which obliges the tapper to remove a thicker layer (1).

The author has drawn up a complementary programme for the study of alternation which was to be put into execution n 1920 in the plantation belonging to the Ongiem Prison (Maison Correctionelle), adjoining the Agricultural Station. He intends to publish the results obtained at the end of each year.

Tapping rotations. — The tapping methods now on trial at Bêncat are the following :—

(1) $^1/_5$ spiral with one cut (complete rotation in 10 years with $^1/_5$ of the circumference in 2 years, or in 5 years with $^1/_5$ of the circumference of the tree every year) ;

(2) $^1/_5$ spiral with 2 superimposed cuts (rotation in 5 years with $^1/_5$ of the circumference every year) ;

(3) ¼ spiral with 1 cut (rotation in 8 years, with ¼ of the circumference of the tree every year) ;

(4) ½ spiral with 1 cut (rotation in 6 years, with ½ the circumference of the tree in 3 years) ;

(5) Half herring-bone incision on half the tree (rotation in 6 years with ½ circumference of tree in 3 years).

The coolies should never destroy more than 40 cm., of bark per cut per year ; good tappers, tapping every day, only remove from 30 to 35 cm., annually.

(1) The same observation as that made in the previous note : M. E. Girard and many other experts advise wide-spacing, later working, and the substitution of moderate and alternate tappings for intensive methods. This advice takes into account the future success of the plantation, the time for which it can be worked, and the total rubber yield throughout a long series of years. See especially, *R.*, Feb., 1919, No. 205, and *R.*, Jan., 1920, No. 50. (*Ed.*)

The appearance and growth of the trees. — So far, the different tapping methods tested at the Station have not exhausted the trees, and their yield in dry rubber increases every year.

in 1917 the average yield per tree was													0.058 kg.
» 1918	»		»	»	»	»							1.634 »
» 1919	»		»	»	»	»							2.376 »

Trees with heavy yield. — As some trees planted in 1900 were remarkable for the very large amount of rubber they produced, they were each numbered, their rubber collected, prepared, and weighed separately, in order to study the regularity and continuity of these exceptional yields. The seeds of these trees are carefully collected, and sown in a separate nursery. The following Table gives the production in 1918.

Exceptionally High Yields of Certain Heveas.

No. of trees	*Year 1918* — 344 days tapping at 40 cm. above the ground — Weight of rubber obtained in kg.	*Year 1919* — The field has slightly decreased owing to the tapping being done at 80 cm. above the ground — Weight of rubber obtained in kg.
103	8.403 (latex rubber)	3,633 (latex rubber)
119	7.122 » »	3,288 » »

Total	90.520 » »	67,944 » »
	If to this total is added the amount represented by the secondary rubber 12.573 kg., it will the seen that these heveas have yielded on an average 10 kg., per tree, or about 30 gm., per day of tapping.	If to this total is added the amount represented by the secondary rubber 12.410 kg., it with be seen that the heveas have produced on an average 8.055 kg., per tree, or about 25 gm., per day of tapping.

The author subsequently describes the collection and preparation of the latex at the Bêncat Station.

The Quality of the Bêncat Station Rubber. — Tests applied to this product have shown it to be of excellent quality.

979 – **Some Preliminary Experiments on Alternate Tapping of Heveas in Cochin-China.** — VERNET, G., in the *Bulletin de l'Institut Scientifique de Saïgon*, Year II, No. 8, pp. 227-236. Saïgon, Aug., 1920.

The author has started work on the " grey earths " (1) following on the studies of M. GIRARD (*Note sur la culture de l'hévéa en Cochinchine*) (2), which dealt with red earths.

The author used trees in the plantation of MM. GUERY and PÂRIS at Tân-thanh-Dông.

M. GUERY experimented on the tapping of sectors of varying importance where exploitation had begun at various intervals of time. The author found in December, 1919, that it was not wise suddenly to change the sectors tapped as the trees had been worked for several years and the tappings had reached the basal portion of the tree ; tapping thus should not be deferred until the moment when yield is small. Moreover, by alternate tapping during the dry season the bark remaining on the low part of the trunk, the best results are obtained. In fact, this enables the trees to be prepared for alternate tapping, and makes it possible to see the influence of interrupting tapping on sectors of equal importance.

The general plan followed was :—

(*A*) In December, 1919, a comparative study of the growth and yield of the trees under unchanged conditions.

(*B*) From January to April, 1920, a study of the influence of alternate tapping on trees in sections worked in a similar way.

(*C*) From April onwards a study of the influence of alternate following tapping on sectors of varying importance.

During these experiments comparison was always made with trees tapped daily, with incisions covering ¼ of the circumference.

The author gives the results of the two first periods of the series of investigations.

A) STUDY OF THE GROWTH AND YIELD OF THE TREES INTENDED FOR THE EXPERIMENTS. — The author made use of strips in his studies and doubles his experiments so as to permit of establishing comparable averages.

Rows 1-6, used as controls, gave at the end of December an average daily yield per tree of 3.84 gm. of dry rubber. The heveas were from 40.9 cm. to 1.5 m., in girth just above the ground.

Rows 2 and 5 tapped every day in December, but destined for alternate tapping (1 month in 2) gave 3.88 gm., per day per tree in December, the average girth being from 42 cm., to 1.5 m.

Rows 3 and 4, tapped each day in December, but destined to be tapped 1 month in 3, yielded 3.62 gm. per tree per day. Girth 41.2 cm., to 1.5 m. When the experiments were begin the average yield was from 3.62 to 3.88 gm., per tree per day, and the average increase in girth was from 40.9 to 42 cm., which was sufficiently close to permit of a comparative study.

(1) For information on the red and grey earths of Cochin-China see *R.*, Feb., 1920, No. 205. (*Ed.*).

(2) See *R.*, Feb., 1919, No. 205, and *R.*, Jan. 1920, No. 50. (*Ed.*).

(*B*) Influence of alternate tapping on the yield of sections of similar importance. — The following table gives the influence of alternation on the rubber yield per day of tapping as compared with controls tapped continuously :—

	Yield per tree per day. Average of 2 rows.		
	Controls	Tapping 1 month in 2	Tapping 1 month in 3
January 1920	4.02 gm.	not tapped	not tapped
February »	3.27 »	4.31 gm.	» »
March »	3.48 »	not tapped	4.89 gm.
April »	2.93 »	4.39 gm.	—

Tapping 1 month in 2 gave in February, 1920, an increase of 1.049 gm., or 31.8 % over the controls, and in April, 1.460 gm., or 49.8 % more

Tapping 1 month in 3 gave in March, 1920, 1.41 gm., or 40.5 % increase, a still higher gain.

Influence of alternation on total yield. — From January 1 to April 30, 1920, the control row of 283 heveas gave 119.483 kg., of dry rubber, or an average of 0.422 kg., per tree.

The two rows tapped 1 month in 2 gave, in the same time, 72.523 kg., for 281 heveas, or 0.258 kg., per tree, a loss of 46.084 kg., for the 281 trees.

From January to March, the control trees yielded 93.388 kg., an average of 0.329 per tree, and those tapped 1 month in 3 gave 41.044 kg., or 0.151 kg., per tree. The difference per tree is 0.178 kg., and tapping 1 month in 3 has left in the bark, compared with the controls, 48.238 kg., for 271 trees.

This loss of latex is compensated to a certain extent by the following factors :—

(*a*) An increase in the power of production.

(*b*) A strip of bark 1 cm., wide (corresponding to 2 month's rest) is left at the base of heveas, tapped alternately, and the most productive zone of the bark is still workable.

These results cannot be used for judging the value of the method proposed by M. Girard. From figures given in tabular form by the author, other facts can be deduced. The time necessary for the trees to return to their normal yield after a long interruption has been much disputed. However, the author's figures show that, on the average the test trees equalled and even exceeded the yield of the controls in 4-5 days after tapping was recommenced.

The maximum daily yields of rubber of trees tapped 1 month in 2 are given on the 8th, 9th, 14th, and 17th days ; for tapping 1 month in 3 the 10th and 12th days after the recommencement these maxima are obtained.

980 – **Alternate Tapping** (1). — *Bulletin de l'Association des Planteurs de Caoutchouc*, Vol. VII, No. 8, pp. 285. Antwerp, August, 1920.

A circular published by the Rubber Growers' Association and dealing with two most important questions, the scarcity of labour in the plantations of the Far East, and the alternate tapping of heveas.

The labour crisis is serious in all the rubber-producing regions of Malaya, and throughout the East, with the exception of Ceylon ; it is rendered more acute by the dearth of food materials, for the different Governments insist upon the production of these, which still further reduces the number of labourers required for the hevea plantations. The demand for coolies exceeds the supply, and wages are rising in an alarming manner.

Giving the existing state of affairs, no opposition can be aroused by the suggestion of tapping the trees only every two days, but this method is further justified by the fact that there is not too much healthy bark on the accessible parts af the trees in the plantations. In Ceylon, on the other hand, where the condition of the bark is better than elsewhere, alternate tapping is practised on most of the estates.

If the bark is used up more rapidly than it can be replaced by nature, the plantations are living on their capital.

A certain number of trees have disappeared and some of the bark that had been spared has already been lost, owing to various diseases of which the most important is " brown bast ". The exact cause of this malady is unknown, and no control measures have yet been devised. Trees tapped every two days would be less exposed to " brown bast ", than those tapped every day ; this is a fact which should be taken into consideration.

The Council of the Rubber Grower's Association, after carefully considering the matter, advise all companies and owners of hevea plantations to consider whether it would not be possible to remedy the scarcity of labour by reducing the destruction of the bark either by tapping every two days (without lengthening the cut), or by giving complete rest to sections of the plantations where the bark-reserves are perceptibly diminishing.

As regards the price of rubber, if a smaller amount arrived on the market, prices would be bound to rise.

981 – **" Change-over Tapping „ Method Adopted for Rubber in Ceylon.** — Petch, T., in *Department of Agriculture, Ceylon, Bulletin No. 47.* Colombo, March, 1920.

In " change over " systems, tapping is periodically transferred from one side of the tree to the other, resting each side at intervals. This system began to be adopted in Ceylon in 1913. Tapping was made on the half and quarter method.

(1) For methods of tapping; relation between the production of rubber and the destruction of the bark ; influence of tapping in the duration of hevea trees ; choice of tapping methods, see *R.*, Jan., 1920, No. 50. (*Ed.*)

The following results relate to the comparative experiment conducted at the Experiment Station, Peradeniya from 1914 to 1918 relative to the change-over tapping at an interval of 3 months on alternate days on the quarter and on the half (the control experiments made it possible to ascertain the effect thereby obtained compared with tapping continuously).

1) A slightly increased yield was obtained by change-over tapping when tapping on quarters, but no increase when tapping on halves.

2) Six months after tapping, bark renewal was better in change-over than in continuous tapping on quarters, but there was no difference in the case of tapping on halves.

3) The weight of rubber obtained from a given volume of latex is, on the average, the same, whether the tapping is continuous or change-over.

982 – **The Camphor Tree in Algeria and on the Mediterranean Coast.** — TRABUT, in *Revue Horticole de l'Algéric*, Year XXIV, Nos. 3, 4, 5, pp. 61-63. Algiers, March-April-May, 1920.

Since 1892, the author has been making great efforts to plant camphor trees in Algeria, with a view to extracting camphor, not from the wood, but from the leaves. He has introduced camphor trees from Formosa (Japan) which are flourishing, and whose leaves contain an average of 1.5 % of camphor during winter.

Certain persons who deny the truth of the author's statements have-however, prevented him from succeeding in getting large camphor plantations established to take the place of those of cork-oak in the very damp localities on the coast of East Algeria, where the cork, owing to the climate, is " fat " and of no commercial value.

There is now no doubt as to the camphor content of the trees grown in Algeria and on the Côte d'Azur. In 1919, several hectares of the Doumia Forest were planted with camphor trees from the Algiers Experiment Garden, by the Forestry service, with the cooperation of the " Comité des Matiéres premiéres".

The tree grows quite well on the forest soils of the coast, and very fine specimens are to be seen in many places, such as Algiers, Blida, Bougie, El-Milia and El-Hanser.

The author estimates that a plantation 25 years old would easily yield 30 tons of twigs per hectare. As the analyses always show over 1 % of camphor, even taking this minimum, 300 kg., of camphor would be obtained per hectare, and nearly the same amount of camphor oil. The return per hectare. would therefore be very large, seeing the high prices camphor now fetches, and probably will continue to command for some years to come (1).

It is therefore well worth while to develop the cultivation of camphor trees in Algeria and along the entire Mediterranean coast, all the more so

(1) See for the increase in the price of camphor, M. CAYLA's article on *L'état actuel de la production du camphre, essais de culture du camphrier* (" The present condition of the production of camphor, experiments in cultivating the camphor tree "), *R.*, May 1920, No. 528. (*Ed.*)

since the Japanese industry continues to absorb increasingly large quantities of the camphor produced in Japan, and artificial camphor, which is also used by the trade, will continue to fetch a high price, since more than 2 litres of spirits of turpentine are needed to make 1 kg., of artificial camphor, and the preparation of the latter is a very troublesome operation.

SUGAR CROP

983 – **The Improvement of the Sugar-Cane.** — 1. BONAME (former Director of the Mauritius Agricultural Station), Methods of obtaining new varieties of Cugar-Cane, an article published by M. G. WÉRY in his work entitled " L'Organisation scientifique de l'agriculture aux colonies ", in *Annales de l'Institut National Agronomique* (*Ecole supérieure de l'Agriculture*) Series 2, Vol. XIV, pp. 75-84. Paris, 1919. — II. WÉRY, G. (from an article communicated by M. VIEILLARD, Directeur du Laboratoire de Génétique de l'Institut Scientifique de l'Indochine) *Ibid.*, pp. 78-71. — III. EKELENS, F. A., Improvement of the Sugar-Cane in Java and Cochin-China, in *Bulletin agricole de l'Institut Scientifique de Saïgon*, Year II No. 6, pp. 167-180. Saïgon, June, 1920.

I. *Methods of obtaining new varieties of sugar-cane.* — It has been found in all the colonies that the old varieties of sugar-cane, after having yielded a longer or shorter series of large, profitable crops, become gradually less productive, until in spite of every effort and the use of suitable fertilisers, the yield hardly covers the cultural expenses.

Whether this is due to actual degeneration, or to decreased vitality which renders the plant more susceptible to the attacks of various diseases that increase in virulence, the fact remains, and one of the chief aims of the planter is to obtain new varieties to replace the sugar-canes he sees gradually perishing.

Formerly, only one variety of sugar-cane was grown in the principal sugar-producing colonies (the white Otaïti or Bourbon variety). Its yield, however, became so irregular, that others were introduced, which frequently have given rise to periods of prosperity for the sugar industry. This fortunate turn of affairs was often only temporary, for the new canes introduced proved exacting as regards the soil, and degenerated in their turn, sometimes very rapidly.

A. *Seed-bed canes and selection.* — When SOLTWEDET, in Java in 1887 demonstrated the possibility of obtaining new varieties of sugar-cane from seed, this problem was considered solved, and it was supposed that it was only necessary to sow cane seeds in order to obtain an inexhaustible supply of good varieties that could be used as occasion arose. Though the first results have not entirely confirmed this belief, they have nevertheless proved that it is possible thus to raise new varieties, some of which hove already been substituted with advantage for the old kinds hitherto cultivated.

Sugar-canes obtained from direct sowing are always different from the parent plants, and are usually inferior to them. Variation, however, occurs, and this is reckoned as a means of procuring occasionally a variety possessing the cultural and industrial qualities required in sugar-cane grown on a large scale. From the beginning, many thousands of

plants have been procured, but those remaining after strict selection are but few in number.

The flowers of the sugar-cane do not all produce fertile seeds, the fertility of which depends on the variety and the season, whereas varieties obtained from direct sowing show an increasing tendency to bear good seed.

The author gives a detailed description of the method of collecting and sowing the seed, the cultivation and care of the young plants, and the selection of the sugar-cane.

As only a very small number of high quality plants are obtained by direct sowing, it was thought that hybridisation, or rather the crossing of different varieties, would give better results. The probabilities of self-fertilisation, or of crossing, vary to a certain extent according to the method adopted for the pollination of the seeds.

Self-fertilisation can always be ensured by covering the panicle before it is ripe with a muslin bag. Crossing can be carried out under the same conditions by opening the bag and shaking foreign pollen over the pistils when they are fully developed. It can also be secured in the field by mixing varieties that flower at the same time, or by planting (as is done in Java) alternate rows of different varieties of sugar-cane that flower at the same date. In both these last cases, no muslin bags are required.

It would be very useful to be able to detect the dominant character of the male or female plant of a known variety, and to transmit it by means of artificial pollination. If, however, it were possible to discover the dominant character, its transmission would remain most problematical, for the characters of varieties of sugar-cane are not transmitted to the seed by direct descent. No definite results in this direction have been attained in the crossing experiments.

In Barbadoes, in 1904, however, LEWTON BRAIN suceeded for the first time in effecting certain cross-fertilisation. This was done by dissecting the flower under a lens, removing the stamens before they reached maturity, and dusting the stigmas at the right moment with foreign pollen. This is an exceedingly delicate operation in the case of the sugar-cane for the reasons set forth by the author. It thus appears that practically the best means of obtaining sugar-canes from seed is by the usual methods requiring no special technique, and giving large number of plants that can be systematically selected. The quantity of plants thus obtained compensates for the possibly low percentage of individuals of superior quality.

The directly-sown canes are distinguished by a number preceded by the initial of the country from which they came : L, for Louisiana, J. for Java, M. for Mauritius, H for Haurïu, D for Demerara, T for Trinidad, B for Barbadoes, etc.

It should be observed that a cane which is very ordinary in its own country, may develop new qualities when imported, but that the reverse has also occurred. Hence, while it is necessary to try and get the best

varieties, new kinds of sugar-cane must always be experimentally cultivated, before being distributed and grown on a large scale.

In short, the results of the experiments are important, and have been confirmed by the success of crops of sugar-canes that have grown from seed, and have largely taken the place of the old varieties in some colonies.

Compared with the latter, they have a more marked tendency to flower and set fertile seed, which is an advantage as far as sowing is concerned but not from the cultural point of view. Further, there is sometimes a difficulty in finding a sufficient number of shoots or tops; flowering arrests the growth of the stem; and the new varieties are often more susceptible to the climate, etc. Cultural experiments should be carried out in all plantations of fair size, in order to obtain good new varieties that can replace the old ones as soon as they begin to deteriorate.

B. *Mutations.* — Sometimes one stem in a tuft of sugar-canes is found to be different from the others. This shoot variation or mutation is generally quite easily reproduced by taking a cutting. A wise choice of shoots, as well as selection, will often make it possible to take advantage of a mutation.

C. *Selection with a view to increasing sugar content.* — The author quotes the experiments made in Barbadoes, Java, and Mauritius, and describes the technique employed. These experiments did not, however, give any very important results.

II. Pasoeroean Station for Sugar-Cane Cultivation. — This is certainly the most complete scientific Institution in the world for the study of the sugar-cane or perhaps of any other crop. It has published several important books and pamphlets the last of which consists of 6 octavo volumes forming an Encyclopaedia of the Javanese sugar-cane.

The Station, founded in 1887, is wholly independent of the Government. Like the Pakalonga Machinery and Technology Stations, it belongs to the Sugar-Cane Planters' Syndicate, which represents 157 plantations of an average of 1000 *bouw* (709 hectares, 1 *bouw* = 0.7096 hectares). The author describes the administrative and financial organisation of the Station.

In addition to the offices, archives, and libraries, the Station includes:— (1) A laboratory for physical soil-analysis; (2) a laboratory for chemical soil-analysis; (3) a botanical laboratory; (4) a lecture theatre for courses of lectures to planters; (5) a laboratory for the study of certain questions relating to sugar-cane cultivation and the industry; (6) a laboratory of sugar-cane bacteriology; (7) a laboratory of soil bacteriology; (8) an entomological laboratory; (9) a laboratory for testing sugar-cane juice; (10) an electrocultural plant (so far no results); (11) a shed where methods of rat destruction are studied; (12) a set of vats for making sugar according to native methods (for using sugar-canes grown at the Station but not reserved for selection).

III. The Improvement of Sugar-Canes in Java (and in Cochin-China. — A. *Java.* — At present there are over 200 varieties at the Pasoeroean Experiment Station.

Many hybrids have been tested, especially those obtained in the first instance from the very strong, wild sugar-canes known in the West Indies under the name of " Glabah " (*Saccharum spontaneum* L.). Of the countless individuals tested, many have been rejected, and there are only a few which can be said to be really of great value. The series of experiments which are always going on, is moreover endless.

Amongst the best and most highly prized varieties, the author mentions the following (according to J. van Harreveld) : E. K. 28 ; 247 B ; D. J. 52 ; 100 POJ ; E. K. 2 ; F 90 ; S W 3 ; Chéribon noir ; Fjep 24. These varieties covered 91 % of the total area under sugar-cane in Java in 1919-1920.

The first hybrid of any value was 100 POJ, which is the result of a cross made in 1893 between the dark-red Borneo sugar-cane and the Luzier variety ; 247 B is a cross Chéribon × Canne morte. Four other hybrids should be mentioned : DI 52 and S W 3. (= Batjan × Chéribon), 36 POJ and 139 POJ (crosses between " Cunnee " from British India and improved varieties).

A graph constructed by M. Ph. van Harreveld shows that the sugar production has been more than quintupled in the 77 years from 1840 to 1917, as it has increased from 23 *piculs* to 130 *piculs* per *bouw* (1).

As the varieties are increasing, it is necessary to find characters which allow them to be distinguished from one another as exactly as possible. At present, the following order has been adopted in the description of the varieties :—

1) Stalk : — Colour, shape, wax-coating, hairs.
2) Internodes : — Size, shape, appearance.
3) Nodes : — Shape, " verules ", hairs, number of rows of buds.
4) Leaves and sheath :— Shape, appearance, colour, hairs, etc.
5) Tuft : — Shape and character.
6) Juice :— Composition.
7) Stem :— Number and appearance of shoots.

As soon as new varieties have been obtained, their value must be ascertained by truly comparative methods. The first experiments are undertaken in order to eliminate the unfit, each variety being tested in a separate plot ; then follow the orientation tests. These preliminary trials being completed, the value of the best varieties is tested " by division experiments ". In these, the compartments reserved for the variety A under study alternate with those planted with the variety B, with which it is to be compared : the so-called " touchstone ". In this way a kind of chess-board with alternate squares, usually 24 in number, is obtained :—

A	B	A	B
B	A	B	A
A	B	A	B
B	A	B	A
A	B	A	B
B	A	B	A

(1) 7 *bouw* = 5 hectares ; 1 *picul* = 100 katties = 61.761 kg. = 136 lb. (*Authors' Note*).

As many as 3 varieties, A, B, and C can be compared, but this is the maximum ; then there are 36 divisions for the new varieties and 12 for " the touchstone variety ".

A	B	C	A	B	C
B	C	A	B	C	A
A	B	C	A	B	C
C	A	B	C	A	B
B	C	A	B	C	A
C	A	B	C	A	B

The author describes this method in detail, as well as the system of harvesting and of examining the results. As regards the latter, the probable error must be determined (for all the divisions planted with the same variety at the same time do not give identical results) ; for this, Dr. Ph. van Harreveld's formula is used :— $E = \sqrt{\frac{\text{sum } d^2}{n\,(n-1)}}$, where d is the difference between the production of each division and the average production, and n is the number of divisions used at the same time in each experiment A, B, or C. The results are entered on the following Table : —

Sugar factor . . . . *Date of harvest . . . .* *Experiment Field No. . . .*

Yield in cane						Field in sugar that can in extracted first from the juice extraction					
No. of division	Yield		d	d^2	Probable error	No. of divisions	Yield		d	d^2	Probable error
	Per division	Per hectare					Per division	Per hectare			
1						1					
3						3					
5						5					
etc.						etc.					
Total					E =	Total					E =

The data obtained are marked on the map of the experiment field. The cane production is noted in the top left-hand corner of each division, the saccharose content of the juice in the centre, and the sugar yield in the bottom right-hand corner. All divisions of which the cane yield is at least three times greater than the probable error are marked with one red circle, and a second red circle is added if there is the same excess of sugar. Low yields are indicated in the same manner, but the circles are blue, instead of red. As all the divisions included in the same experiment have been coloured, shaded or cross-hatched, in the end a chess-board is obtained showing the relative value of the different lines according to the orientation (east-west, or south north), and the varying richness of the soil. Any comparative difference in yield below 3 times

the probable error is not regarded as of importance ; before arriving at a definite conclusion, it is, however, necessary to refer to the Experiment Garden memorandum-book in which all the data of the experiments will have been carefully entered.

The method described is not only employed in the selection of varieties, but also for resting fertilisers, the effects of irrigation, cultural systems, etc. The author gives instances of its use in the case of fertilisers, and also deals with the methods of soil analysis in Java, giving an instance of its application to Cochin-Chinese soils which he sent to the Pasoeroean Station for analysis.

B. *Cochin-China* (1). — The author sent to Java samples of the varieties of sugar-cane most cultivated in Cochin-China. The information given to him by M. Ph. VAN HARREVELD was as follows :— " Chinese " Cane No. 1 : — Slender Japanese Variety which, on account of its vigour, resists cold climates better than thick varieties ; resembles the Hong-Kong " Tek-cha " cane, which the Pasoeroean Station has already in its collection.

" Yellow cane No. 2 " :— this is the Lahaina variety, largely grown in Hawaii and used in Java in the Panorogo districts under the name of " Mata-été " (2).

" Red Cane No. 3 " : — this is probably the variety known in Tengger as " Teboe Baloeng ". It was gathered in November at Poespo, near Tosari.

" White Cane No. 4 " :— Probably the White Djapara.

" Red Cane No' 4 " : — Closely allied to a variety received at the Station in 1904, and sent from the Ketegan sugar-factory under the wrong name of Ardjoeno ; this cane had the typical double nodes.

Of this collection, Nos. 2, 3, and 4 were sent to the mountains to remove them from any danger of contracting the " sereh " disease.

The author concludes that Cochin-China possesses valuable species of sugar-cane which, however, have to be found, selected, improved, and studied from the cultural point of view, in order to obtain the highest possible sugar yield, from them.

984 - **Sugar Maize.** — See No. 1028 of this *Review*.

985 - **The Cultivation of Different Varieties of Coffee Plant in Tonkin.** — BOREL M., in *Les Cahiers Coloniaux, Institut Colonial de Marseille, " L'expansion coloniale "*, New Series, No. 23, pp. 27-28. Marseilles, August, 1920.

STIMULANT, AROMATIC, NARCOTIC AND MEDICINAL PLANTS

Contrary to what is maintained by some authors, the author states that coffee-growing is a paying industry in Indo-China, except at an unusual time like the present, when the value of the *piastre* is extremely high. He, however, considers that *Coffea robusta* is not suited to Tonkin. In

(1) For Sugar-growing in Cochin-China, see M. QUESNELS' report to the Colonial Agricultural Congress in Paris, 1918, of which an abstract is given in *R.*, Nov., 1918, No. 1190. (*Ed.*)

(2) A Javanese name denoting that the diseased sugar-cane resembles a plant of citronella or of sweet vernal grass (*Anthoxanthum odoratum*) (*Authors' note*) — See *R.* Oct. 1917, No. 963. (*Ed.*)

fact. from its not being able to stand occasional cold winters, it is useless to grow it there, although it may do well in Cochin-China and South Annam. The author has been trying for 12 years to cultivate it in Tonkin but has finally resolved to up-root the 6000 plants he had at Da-Han, although they are in excellent condition, and only to keep a few individuals to serve as a control, like those in his plantation at Bavi.

Coffea liberia, like *Coffea robusta*, is not a variety for Tonkin. While the average yield of *C. arabica* at Da-Han, and Bavi, was 500 gm., per plant, that of *C. robusta* never exceeded 150 gm. At the last picking, 2 kg., were obtained from *C. excelsa* (Chari) ; 900 gm., from *C. arabica*, and 150 gm., from *C. robusta*. All the varieties had, however, received the same care.

It must not be supposed from these figures that *Excelsa* is an ideal variety ; its berries are most susceptible to the cold January fogs, for as they are not ripe before July, they are not fully developed so early in the winter. The 1919 crop was good, thanks to the mild winter, but other years, the yield was only 600 gm., to 1 kg., in the Da-Han plantation, where the plants received the same attention as the *Arabica* variety. It should be mentioned that there are only 500 *Excelsa* plants per hectare, as against 1000 *Arabicas*.

986 – **Cinchona Bark from East Africa and the Cameroons.**— *Bulletin of the Imperial, Institute*, Vol. XVIII, No. 1, pp. 22-25. London, Jan.-March, 1920.

In addition to Java, India and Ceylon whence cinchona bark is now chiefly obtained, *Cinchona* trees have been introduced into other parts of the tropics. Samples of bark from the former German Colony in East Africa and from the Cameroons have been received and examined at the Imperial Institute, and these are described in the present article.

Cinchona chips from East Africa. — The manufacturers to whom the first samples of East African bark were submitted for evaluation in 1918 expressed a desire to purchase a shipment of the bark, and in 1919 a consignment was forwarded to the Imperial Institute by the Acting Administrator of the former German East Africa. The consignment consisted of 52 bags of cinchona chips which were apparently derived from *Cinchona succirubra* and 1 bag of quills (net weight 60 lb.), which more resembled the *C. Ledgeriana* type of bark.

A chemical examination of these samples gave the following results: —

	Chips	Quills
	%	%
Moisture	8.8	10.9
Total alkaloids	5.86	4.46
Quinine (1)	1.81	3.39

(1) *Equivalent to crystalline quinine sulphate.*

It will be seen that the yield per cent. of quinine was higher in the sample from *C. Ledgeriana* than in the chips from *C. succirubra*.

In 1918, the samples of chip bark from the latter material yielded. 3.39 % of crystalline quinine sulphate compared with 2.45 % from the

present consignment, whilst the yield was comparatively the same for both years from the quills resembling the *C. Ledgeriana* bark.

The results of the investigation confirm the view that cinchona bark of good quality can be grown in East Africa, although the samples of *C. succirubra* have shown variation in the amounts of total alkaloid and quinine present. It would therefore appear desirable to take steps to extend the plantations of cinchona trees, particularly of the *C. Ledgeriana* type, with a view to the production of the bark for British manufactures.

CAMEROONS. — Cinchona has been produced from experimental plantations established by the Germans at Buea in the Cameroons, and 4 samples of bark from these plantations were received from the Government of Nigeria for examination at the Imperial Institute in 1918.

The bark had been stripped from the trees and dried in the sun.

Sample No. 1 was collected from trees growing at an elevation of about 3000 ft.; samples Nos. 2 and 3 were from a plantation about 200 ft. higher up the Cameroon mountain, and No. 4 was from a plantation at a still higher altitude. The 4 samples were similar in appearance, and consisted of quilled pieces of natural bark; the outer surface was in many cases covered with lichen; the inner surface was dark reddish brown and the fracture was light brown.

The barks were analysed at the Imperial Institute with the following results: —

	No. 2	No. 2	No. 3	No. 4
Total alkaloids	7.5	6.3	7.0	8.3
Moisture	9.9	10.2	10.3	10.1

The value of the cinchona barks depends chiefly on the amount of quinine obtainable by the process used by the manufacturer; the samples were submitted to a British firm of manufacturers for further examination, and the following results were obtained: —

	No. 1	No. 2	No. 3	No. 4
	%	%	%	%
Quinine alkaloid	6.14	5.05	5.27	5.28
Cinchonidine	0.55	0.24	0.23	1.17
Yield of crystalline quinine sulphate	8.19	6.73	7.02	7.04

These results show that all samples are of good quality, furnishing from 6.7 to 8.2 % of quinine sulphate.

It appears probable that samples 1,2 and 3 were derived from the *C. Ledgeriana* type, and sample 4 was probably derived from a hybrid.

The results show that these cinchona barks from the Cameroons furnish more quinine sulphate than the average cinchone bark from Java. It is possible, however, that when the trees are regularly stripped, the percentage of quinine may be diminished.

Investigations have proved, nevertheless that only small quantities of cinchona trees exist in the Cameroons, and that all the trees are of the *C. Ledgeriana* variety.

VARIOUS CROPS

987 - **Broom as a Paper-Making Material.** — BLIN, E., in *Journal d'agriculture pratique*, Year, 84, Vol. 33, New Series, No. 8, pp. 150-151, and No. 9, pp. 173-174. Paris, Feb., 1920.

M. ARDOUIN-DUMAZET has recently drawn attention to the possibility of utilising broom (*Sarothamnus scoparius*) as a paper-making material (1). N. ROGER took up this question in 1903, and the investigations made also by the author in 1912, 1913 and 1914, and the communication which he received from Prince BORGHESE with respect to the trials conducted in Italy, have led him to the conclusion that the attention of farmers and manufacturers should be directed towards this use of broom.

The author first deals with methods of cultivation, a matter which should be considered, as the production from wild plants would be insufficient.

As regards sowing, the seed should be collected before it is ripe and left to dry in a well ventilated place. In the spring the seed should be sown very thinly in a field of oats, and in small holes 1 m. apart, putting 2 or 4 seeds in each hole. Later the seedlings are thinned out to 1 plant per hole. In the spring of the third year, the plants are cut back to a height of 30 cm., to encourage sucker growth ; the numerous branches which thus develop are cut each year and utilised for industrial purposes.

It is possible to obtain 10 000 plants per hectare in this way and to cut as many as 3 times from the second year onwards with a constant yield for 20 years. According to the data recorded in Italy, the average yield per annum is from 200 to 230 quintals per hectare. It is estimated that 12 000 quintals of green broom yield 6000 quintals after drying, and that this quantity will provide 4200 quintals of paper pulp.

After drying and dressing, the dried broom is passed into a cold, alkaline bath containing either a mixture of sodium carbonate and milk of lime, potash, or some other alkaline substance in suitable proportions to give the same results as the caustic soda. After 3 or 4 days, the disaggregated branches are taken out of the bath, carefully washed and put into another bath containing 1 to 2 % chloride of lime. The stems remain in this bath for 2 or 3 days until they become very soft ; they are then taken out and plunged into a cleansing bath containing a small quantity of sulphuric acid or sodium hyposulphite.

After this treatment, the broom is crushed in order to obtain the required fineness of pulp.

The liquid from the baths containing either alkaline soda, potash or other alkalis, retain the chlorophyll, and dissolve the gums and resins, a part of which is saponified and a part set free. By adding fats or oil to this liquid, a good-quality soap may be obtained. In short, the manufacture of paper according to this method includes the following operations : — Cutting ; beating ; soaking for 6 to 7 days ; further grinding ; expression in a hydraulic press (to eliminate water, chlorophyll and other by-products) ; separation and washing in the so-called " hollandaise No. 2 " machine ; and finally grinding.

(1) *Journal d'Agricultura pratique*, No. 45, Dec. 11 1919.

To treat 16 to 20 quintals of dried broom in one day, and obtain a yield calculated at 12 to 14 quintals of paper pulp, the following plant is necessary :— 2 cutters, 3 cylinder crushers, 2 hydraulic presses, 4 " hollandaise " machines, and 2 grinding machines.

Apart from the residue formed in the alkaline liquid, the infusion leaves a definite residue composed of chlorophyll and gum which will yield 38 kg. of good-quality soap per quintal of pulp.

Considering that with maceration and steeping, a yield of as much as 75 % is obtained from fibrous vegetable materials (straw, bamboo, etc.), it is evident that the utilisation of broom as a source of pulp supply constitutes a valuable supplement to forest trees whose exploitation will only be possible after a considerable time (1).

FRUIT GROWING

988 – **The Origin of the Cider Apples Cultivated in Normandy and Brittany.** — CHEVALIER, A. in the *Comptes rendus de l'Academie des Sciences*, Vol. CLXXI, No. 11, pp. 521-523. Paris, Sept. 13, 1920.

There used to exist, according to certain authors, several thousand varieties of cider apples in France, but their origin is little known. Up to the end of the last century the existence of only one species was known, viz, *Malus communis* Lamk., which combined the qualities of the wild and the cultivated apple, but not including those from the Eastern Asiatic and North American *Malus*, which are very different species. Under the present state of scientific knowledge it appears necessary to split *Malus communis* into four elementary types which can be crossed and produce numerous fertile races from which the different cultivated species originate. These are *M. acerba* Mérat. the *M. dasyphylla* Borkh. and *M. praecox* Borkh. (the last two being often combined under the name *M. pumila* Mill.), and *M. prunifolia.*

The species *M. acerba* was created in 1815 by MERAT for the apple trees which grow wild in nearly all the European forests. It had already been classified as *M. sylvestris* Miller (1759) and *M. spinosa* Roussel (1806). The latter, being the oldest name, should be retained.

It is generally supposed that French cider apples have been derived from *M. acerba* and the eating apples from *M. dasyphylla.* However, the author, after examining numerous specimens of cider apples in the west of France concluded that they have all sprung from *M. dasyphylla.*

M. acerba has grown wild in the forest of Europe since very ancient times. Apparently it was the only species used for making cider up to the IX century; it was not cultivated but the apples were gathered in the woods. The good Normandy cider apples sprung from grafts brought from the north of Spain (Biscay and Asturia), and persisted a long time. It was between the XIVth and XVIIth centuries that the cultivation of the cider apple extended to a large part of Normandy and Britany. The species introduced from Spain was *M. dasyphylla*, which originated in Armenia and Turkestan, where G. CAPUS found it in 1881, growing wild in the fo-

(1) Another species of broom (*Spartium junceum*) has been used as a paper-making material. See *R.*, Feb., 1920, No. 204. (*Ed.*).

rests ; its cultivation has spread around the Mediterranean basin from the earliest times.

M. praecox is the " Pommier Paradis " or " Pommier Saint Jean," which is used by horticulturists as a stock to obtain the dwarf garden varieties. It originally came from Southern Russia and from Asia Minor, and appears to have been introduced into Europe at the time of the Crusades.

M. prunifolia is a native of Central Asia and its cultivation has spread, on the one hand towards Russia and Siberia, and on the other towards China and Japan (1).

The four species cited and their various descendants, about which little is known as yet, transformed by cultivation and inter-hybridisation, have furnished many varieties of cultivated apples.

Occasionally the nurseries show recessives presenting almost pure parental characters. *M. baccata* Borkh. and other microcarpous Asiatic species, when crossed with the modern cultivated varieties have yielded new ones able to withstand cold and which are increasingly cultivated in Canada. But these have not yet been tried in the mountains or the North-West of France, although they offer good prospects for these regions.

989 - **Wild Apples at Tran-Nihn, Laos** (2). — MIEVILLE, R., in the *Bulletin agricole de l'Institut Scientifique de Saïgon*, Vol. II, No. 7, pp. 204-211. Saïgon, July, 1920.

There are many species of wild apple at Tran-Ninh and complete specimens have been sent to M. A. CHEVALIER (Director of the Institut Scientifique de Saïgon) with a view to their botanical determination.

The author gives the main characteristics of four species :—

SPECIES I (*Sample N°. 7*). — First branches commence 2 m., above the ground when grown in the open air, and in the forest 8 m., above the ground. Wood hard and yellow amber in colour, grain fine and close.

In 1920, flowering commenced on March 1, and lasted 8 days. The fruit was ripe at the beginning of October, and picking lasted one month.

The apples are round, bell-shaped near the stalk, yellow, and possess a pleasant odour ; the fish is too bitter for use at the table, but when sugared and roasted it is quite good. These apples make excellent cider. The trees are very productive, mature specimens giving 500 kg., of fruit at the rate of 15 apples per kg. (66 gm., per apple).

SPECIES II (*Sample Nos. 10 and 11*). — Trees as much as 12 m., high, in 1919, commence flowering on March 20 ; ripening begins at the

(1) See *R.*, July-Aug., 1920, Nos. 760 and 761. (*Ed.*)

(2) The question of the cultivation of European fruit trees in Indo-China is being followed up by MM. CHEVALIER and MIÉVILLE. Already these authors have published several articles on this subject :— Fruit cultivation in Indo-China. *R.*, July Sept., 1919, No. 908. The cider apple of the high plateaux of Indo-China. *Ibid.*, No. 909. Research on the Amygdalaceae and hardy apples of Indo-China and south China, *R.* July-Aug. 1920, No. 760. See also the note by M. RETIF on Fruit trees of, Tonkin, *R.*, Jan., 1920, No. 58. (*Ed.*)

end of October and lasts one month. Fruit round, larger than the preceeding ones, and giving 12 apples per kg. (83 gm. per apple).

Species III (*Sample No.* 13) — Fruit like a quince in form. Flowered in 1920 between March 20 and 27. but no fruit was set on the old trees.

Species IV (*Sample No.* 14). — Fruit elongated, yellow, and perfumed. Ripening from the end of October to the end of November.

As regards fertilisation, the late varieties of fruit whose flowers are subject to rainstorms, give very irregular yields.

The wild apple exists at Chapa, in the province of Lao-Kay, and thus grows at an altitude of 1400 metres ; at Tran-Ninh it grows at 1200-1300 metres. It grows very scattered ; its natural habitat seems to be in the forests but it is also found around the Pagodas, probably planted there by the Bonzes. At the Agricultural Station of Xiêng-Khouang, an orchard was started from seedlings. The best time for this is February, when there is no fear of frost. The seeds, covered with fine earth to a depth of 1 to 2 cm., take roughly one month to spring up in the open, provided they are watered lightly and regularly. When the seedlings reached 30 cm., in height, they are transplanted to the nurseries 50-70 cm., apart. As they fear the sun they must be shaded while young or sprayed with lime-wash ; the suckers should be cut off.

Final planting can take place in the second year, in December or January after a preliminary lime-wash to protect the thin bark from the sun. They are pruned at a height of 2 m., in order to help the fruiting branches to develop. The trees begin to yield fruit about their 10th or 12th year.

The author has not succeeded in grafting the wild apple with French varieties.

He has made excellent ciders, both dry and foaming, from the wild apples of Tran-Ninh, and describes the method of preparation. The apples can also be dried according to the author's method (1), a hundred kg., of fresh fruit giving 20 kg., of dry slices. Dried apples may also be used for cider-making, but the result is not as successful as when fresh fruit is used.

The author suggests that the planting of wild apple trees along the roads of the higher regions of Indo-China should be given a trial by the Administration, in a way similar to that employed in Normandy and in several departments of France.

990 – **Parthenocarpy in the Apple-Tree.** — Manaresi, A. and Romagnoli, G., in *Il Coltivatore*, Year 66, No. 22, pp. 521-525, figs. 3, Casale Monferrato, August 10, 1920.

It is well known that the fruit of the apple-tree, like that of the pear and some other trees, can develop without fertilisation having taken place. Such fruit not only differs from the normal product in being seedless, but in its shape, which is frequently characteristic, thus enabling it to be distinguished during the early stages of growth.

(1) See *R.*, Jan., 1920, No. 121. (*Ed.*)

Parthenocarpy is of direct practical interest, for seedless varieties are the best to cultivate, being less subject to those external factors that may hinder or prevent regular fertilisation.

Seedless fruit cannot, however, be obtained from all varieties of fruit-trees. R. EWERT (Blütenbiologie und Tragbarkeit unserer Obstabäume, in *Landwirtschaftliche Jahrbucher*, Vol. XXXV, Parts 1-2, pp. 259-257, 1906 ; Die Parthenokarpie oder Jungfernfruchtigkeit der Obstbäume, Berlin, 1907 ; Neuere Untersuchungen über Parthenokarpie bei Obstbäumen und einigen anderen fruchttragenden Gewächsen, in *Landwirtschaftliche Jahrbücher*, Vol. XXXVIII, Parts 5-6, pp. 767-839, 1919) recognised the parthenocarpy of the Cellini and Charlamowski varieties (Borowitski × Duchesse d'Oldenbourg) ; Mr. LESLIE (Gordon Corrie, in *The Journal of Heredity*, Vol. VII, pp. 365-369, Washington, 1916) adds the Lord Derby variety, and Sig. MANARESI (Contributo allo studio della partenocarpia nel pero e nel melo, in *Bollettino dell'Associazione orticola professionale italiana*, No. 6, San Remo, June, 1915) adds yellow Belfiore. Amongst varieties with incomplete parthenocarpy, M. EWERT classes Golden Winter Pearmain and Summer Calville de Fraas, but Sig. MANARESI has shown that, in all probability, the former should be omitted from the list. According to Mr. EWART, no parthenocarpy exists in the following varieties: — Cox's Orange, White Astrakan, Bismarck, White Winter Calville, Hawthornden, Langton Incomparable, Emperor Alexander, Lord Suffield, Cox Pomone, Downton Poppina, London Poppina, Baumann Reinette, R Burchardt, R. de Landsberg, Skiliankowoi; and according to Sig. MANAREESI's investigations, Antonowka and Reinette of Champagne.

The authors have continued the search for parthenocarpic varieties of apple-trees, and carried out experiments in 1915 and 1916, partly in the Garden of the Royal Agricultural College at Bologna, and partly in an orchard belonging to the Bologna Horticultural Establishment of BONFIGLIOLI and Son. These experiments were made in the manner advised by M. EWERT : the fertilisation of the ovules was prevented by covering the stigmata of the flowers some days before they opened, with a solution of sodium silicate or some other substance which by its mechanical and chemical action completely hinders the germination of the pollen. It is sufficient to carry out this operation on a small number of the flowers, choosing the finest and earliest, and removing the others, as well as all later formed blossoms. Near the tree thus treated, there will be one or more specimens with intact flowers, which can thus serve as controls.

The results of these experiments were as follows : — The varieties Francescona and Graham's Royal Jubilee are parthenocarpic; Starr and Stump are partially parthenocarpic ; there is no parthenocarpy in Calville, Fauquet, Honey, Noire de David, Red Pearmain, Préfet Goully, Quetier, Rambour de Winnitza, Reinette, and Zolotoi Kourski.

In order for these results to be of general application, they will have to be confirmed by experiments carried out in other years and different places, as they are not everywhere the same.

991 – **Observation on the Apricot and Some Other Trees of Eastern Morocco.** — DUCELLIER, L. (Prof. at the Maison-Carrée School of Agriculture, Algiers), in *Revue Horticole d'Algérie*, Year XXIV, Nos. 3-4-5, pp. 45-51, figs. 38 Algiers, March-April-May, 1920

In some parts of East Morocco, apricot trees attain an unusual size, some of them measuring over 3 m., in girth ; the author himself saw one with a diameter of 1 metre.

The author suggests the formation of orchards and the planting of row of different trees on either side of the roads in damp or irrigated districts. Amongst the local species most adapted to this purpose are the " betaum," nettle tree, carob, white poplar, olive, tamarisk, and date palm.

The orchards would not only produce a large quantity of apricots that could be used fresh, but would support a canning industry. Apricot paste, fruit preserves (such as are made at Orléansville and Relizane), and dried apricots could all be made, thanks to the dryness and heat that prevail in Eastern Morocco at the end of May and in June, which is the time when the fruit ripens.

The author also gives the results of his observations on apricots in 1916-17, with the object of drawing the attention of fruit-growers to the present condition of the different varieties.

As grafting is never practised by the natives, the number of varieties is considerable, and some of the fruit is remarkably beautiful and fine. In the markets (esepcially at Taourirt, for instance), there are fruits of every shape (spherical, oval, flattened) and of variable size, from the " mech mech " which are not much larger than billiard-balls, to apricots that would be in no wise inferior to the best improved French varieties, if more attention were given to the trees. The bright colouring of certain fruits is most striking ; the colour and flavour of the pulp is also very variable.

The existence of these differently shaped fruits greatly increases the interest of the study of the apricot in Eastern Morocco, where the systematic choice of native varieties, without in any ways interfering with the experiments in improving existing varieties which are habitually carried out in new countries, would no doubt lead to the production of more uniform fruits, and at the same time, improve their quality, as the soils of certain valleys, amongst others of Oued Za, are very suited to the cultivation of the apricot-tree, and also to that of the fig.

The fig is still more commonly grown than the apricot. In the Oued Za valley, magnificent and very distinct varieties are to be seen. The fruit is delicious and is of all possible colours and shapes :— Ribbed, green or violet, plum, yellowish-green, glaucous ; elongated, pear-shaped, spherical, conical, flattened, etc. The fig-tree is worth careful study, in order to make known its best varieties. Its fruit begins to ripen at a time when the apricot crop is partly over, therefore the two kinds of trees could be worked in together, and would be a source of considerable revenue to the districts.

Other fruit-trees, such as olives, vines, pears, etc., are also worthy of interest.

The author gives a botanical description of the varieties of apricots based chiefly on the characters of the stone. He mentions the observations of numerous writers which form an extensive bibliography.

The cultivation of fruit-trees, especially of the apricot, ought to be greatly extended in Eastern Morocco. Apricot-growing is necessarily limited by the water-supply, although the tree is not dependent on irrigation, in fact being often cultivated without it in the mountains of Algeria ; in the plains, one or two waterings suffice. The climatic condition must, however, be taken into consideration, for early flowering makes the apricot very susceptible to frost.

The cultivation of the apricot is very remunerative, and it is not more difficult to grow than other fruit-trees, such as the orange, or the Japanese medlar. Further, there will always be a ready sale for the delicious preserves, etc. made from the fruit.

992 - ***Pithecolobium Saman*, Forage Tree for Tropical Countries.**— See No 970 of this *Review*. (*Ed.*)

VINE GROWING

993 - **First List of Vines with Female Flowers.** — SANNINO, F. A., in *Rivista di Ampelografia*, Year I, No. 13, pp. 189-191. Alba-Ivorno, July 1, 1920.

Most of the vines cultivated for their grapes are hermaphrodite, and those with female flowers are in the minority.

The two kinds of flowers are distinguished by their stamens, which are long and almost straight in hermaphrodite flowers, and short and folded over the ovary in female flowers. Further, the anthers of the former contain much fertile pollen ; those of the latter contain little pollen and that is sterile.

Amongst vines growing from seed, like wild vines, plants with male flowers are also found. They are without a central ovary but their stamens resemble those of hermaphrodite flowers. It is known that such vines bear clusters but no grapes, as fruit-dropping is the sure and inevitable rule.

Vines with hermaphrodite flowers are little if at all subject to non-setting, for if their flowers are not fertilised by fertile pollen from other vines (which is the most common form of cross-pollination), they are fertilised by their own (direct fertilisation).

The non-setting of vines with hermaphrodite flowers is due to sterile pollen, in spite of the conformation of the flowers, as the author observed at Catania, in the case of sterile stocks of " Catarratto ".

Vines with female flowers are subject to non-setting in rainy years, because they are not fertilised by the pollen of other varieties, and their own pollen is sterile. Non-setting may also take place in fine weather, should the female flowers open much later than other flowers with fertile pollen. Such is the case with a nameless variety that the author found in flower in 1893, at Mercato S. Severino (Salerno), early in July, when the grapes of the other vines were already of considerable size.

A list of vines with female flowers is not without practical utility, for in the greater number of cases, such vines are subject to non-setting to a greater or less extent, and thus their yield is variable. Therefore,

the author considers it worth while to publish this first list, compiled from the ROVASENDA collection and from the other vines at the Alba Vine-growing School. The list is not complete ; the *Vitis Labrusca* direct bearers are still wanting as well as many recent direct bearers obtained by artificial crossing in the experiments of M. COUDERC and other French and Italian investigators.

This list becomes of additional importance, when the structure of the flowers is correlated with setting and non-setting, and with the extent of the latter.

Cases of non-setting are not very common in hermaphrodite flowers, but it occurs not only in " Catarratto " in Sicily, but also in " Cabaret," especially when this variety is grown on its own roots.

In the study of vines, the characters of the flowers are some of the most constant characters of the plant ; for this reason, a vine with female flowers, when propagated by cuttings, layering, or grafting, will always bear female flowers. This fact will be very useful in distinguishing a vine with female flowers, which cannot be mistaken for others bearing hermaphrodite blossoms.

The list in question is given below : —

The " uva molle " is a white table-grape that keeps a long time and is grown at Montaldo Roero (Alba district) and in two or three adjoining communes. It is not mentioned either in ROVASENDA'S *Saggio di un'ampelografia universale*, nor in the French edition of the work, although it figures in a short list compiled by ROVASENDA on the occasion of a Meeting of the provincial Ampelographical Committee held at Alba in 1875, where it is entered under the name of " uva molle."

The so-called " uva molle " variety is interesting, because it has female flowers with sterile pollen that will not germinate in a 10 % sugar-solution, as the author observed in the spring of 1920. The vine gives a certain crop, if it flowers in fine weather, as the vine-growers of Montaldo Roero know. This year, it flowered early during beautiful weather, and on June 4, the clusters had already formed, there being no sign of fruit-dropping.

994 – **Italian Riesling and Rhenish Riesling.** — SANNINO, F. A., in the *Rivista di Ampelografia*, Year I, No. 12, pp. 173-174. Alba-Livorno, June 15, 1920.

After 1893, many vineyards in Venetia, especially in the Province of Treviso, were planted with low, specialised vines. Those growing on the plain have now disappeared; some were pulled up, and others thinned out, or grown higher.

French and German vines were planted nearly everywhere, amongst those most grown, being the Italian Riesling or Wälschriesling of the Germans and Austrians. This is a rather weak vine, but produces a heavy crop of sweet grapes ripening at the third early period of PULLIAT, and in Venetia, at the beginning of October. In rainy years, its ripening is delayed, but its sugar content never falls below 18 %.

The Italian Riesling wine, is straw-coloured or light yellow, according as to whether it is made from must alone, or from must with the addi-

tion of the grape-skins; it has a good vinous smell, and a dry, slightly bitter taste. It is rich in extract, and has the right amount of acidity. Mixed with Verdiso wine, it increases the alcohol content of the latter and perceptibly improves it. A fine wine, aging when bottled, is also made from Italian Riesling grapes, but owing to its deficiency in the characteristic bouquet and necessary flavour, it does not rank high amongst other white wines of good quality. These defects may perhaps be due to the soil, which in the "Trevigiano," contains little or no calcium carbonate.

The Rhenish Riesling produces better wine on the same soil. As its name denotes, it comes from the banks of the Rhine, and some of the finest white wines are made from its grapes. In the Venetian vineyards of Italian Riesling vines, there are always some stocks of the Rhenish Riesling variety. These are distinguished by their great vigour the colour of the woody shoots, which are brownish-red, whereas they are yellow in the Italian vines. The greatest differences occur in the buds, leaves, and berries. In the Rhenish Riesling, the small leaves of the tip of the herbaceous shoot are violet-red, and in the Italian Riesling they are greenish-yellow. The leaves of the Rhenish variety are dark-green, thick, vesicular, entire or trilobate, rounded, with a red centre to the veins and thick down on the upper surface. The leaves of the Italian vine are pale-green, thin, smooth, with five lobes, sharp teeth and have a thin down on the lower surface.

Putting aside the differences in the bunches, there are two points about the berries that prevent the vines being confused. The grape of the Rhenish Riesling has a greenish skin turning golden-yellow where most opposed to the sun, and it is covered all over with numerous dark dots. The skin of the Italian Riesling is only yellow at one spot, the pistil, exactly opposite to the point of the insertionof the peduncle. The pulp of the Rhenish grape is fleshy, and it has a slight, very pleasant odour; the flesh of the Italian grape is soft and devoid of aroma.

These differences are clearly pointed out by MOLON (*Ampelografia*, Vol. 2, pp. 1036-1039), and are shown by the two fine, accurate plates in R. and F. GOETHE's *Atlas* (Pl. V and Pl. XIX) the dots on the berry in the one case and not in the other, prevent pickers, who know nothing of the leaf-characters, from making any mistake between the two varieties at the vintage-time.

The Rhenish Riesling has not been as popular in Italy as the Italian Riesling, though it produces a better wine. In "Trevigiano", and other Northern provinces, it is little or not at all grown. It should, however, be preferred to the Italian variety in districts, like the hills of Broni (Pavia), where the soil is calcareous.

The Rhenish vine is equally productive when grown with spurs, therefore an attempt should be made to prune it in the form of horizontal cordons with spurs, which are much more satisfactory than the tree-like forms, or long canes.

Both varieties of vine are subject to grey mould in the grapes caused by *Botrytis cinerea ;* they should therefore be grown in exposed, well-ventilated, and dry places.

Root-rot, due to *Dematophora,* was very prevalent at Conegliano, in a vineyard of Italian and Rhenish Riesling vines situated on the plain. It, however, only attacked the former variety, the Rhenish vines remaining perfectly healthy and growing vigorously. This strong growth of the Rhenish Riesling, which ripens some days earlier than the Italian Riesling, has been observed wherever the former is cultivated.

995 – **The Tokay Vines Cultivated in Italy.** — Sannino, F. A., in *Rivista di Ampelografia* Year I, No. 11, pp. 157-158. Alba-Livorno, June, 1, 1920.

The importation of foreign vines into Italy has contributed greatly to the confusion of the nomenclature.

A white vine, found by the author in many localities between the Piave and the Tagliamento, is very widely grown in Venetia under the name of Tokay.

One of the first Tokay vines notified is at Portogruaro where, on the estate of the Duke della Grazia, an excellent wine is made from the grapes. It is white, and contains over 11 % alcohol, but it soon becomes ropy. The wine is obtained by fermenting the must alone, therefore the author advises the addition of tannin, and subsequently of gelatine ; by these means, satisfactory results are obtained, even in consecutive years.

On visiting the estate in September, the author found that the vines are planted in radiating lines, in vineyards situated on the banks of the canals uniting the Portogruaro district with the Venetian lagoon. The vines are the same variaties as those cultivated in the Conegliano district, where they go by the name of " Tokay." The author was informed that they had been brought by Hungarian horse-dealers who, even after 1866, visited the markets of Venetia.

Having been taken to Alba, in 1911, this vine, under the name of Sauvignon, was cultivated in the Rovasenda collection, and was found by the author to be identical with the Venetian variety known as " Tokay." In order to prevent mistakes, it should, however, be called by the name it received at Alba.

In Venetia, the Sauvignon variety is both strong and hardy, producing a large crop of excellent grapes. If it be remembered that, at Portogruaro on the edge of the marshes, this vine when grown high and well pruned like vines on radiating cordons, yields an excellent wine, it will readily be understood how profitable it would be to extend its cultivation, not only to the plain where the Verdiso grapes grow badly and are very subject to mildew, but also to the hill-sides. It is always best to grow it in radiating lines.

Another Tokay grown in Venetia and other provinces of Italy is Furmint, which really comes from Hungary, where it produces the Tokay wines. There is a good coloured plate of Furmint (No. 13 in H. and R.

GOETHES' *Atlas*) which gives the most striking characters of its hairy leaf with its involute edges, folded over on the upper surface, thus revealing the soft velvet of the lower side without the necessity of turning over the lamina. Furmint ought to be grown in Venetia, if only for the preparation of " vini santi," which are very similar to Tohay.

The great defect of Furmint is that its has close-set bunches of small acid berries. It would therefore be well to choose cuttings from the shoots with the best bunches and, if possible, those free from this drawback. It is necessary to use plenty of superphosphates in the fertilisers.

In Venetia, the grey Pinot variety is also cultivated under the name of Tokay, and this name is used in Switzerland, Savoy, and Piedmont ; it is also found in the *Luxembourg Catalogue*, and in the Catalogue of Marquis INCISA. It is better, however, to keep the old name of grey Pinot for this vine.

In Venetia, it produces heavy crops of grapes with a large sugar content. When grown in radiating lines on the plain near Sacile, it bears a large quantity of grapes with over 20 % of sugar.

LIVESTOCK AND BREEDING

996 – **The Loco-Weed Disease.** — MARSH, C. D. (Physiologist, Pathological Division Bureau of Animal Industry), in *U. S. Department of Agriculture, Farmer's Bulletin* No. 1054, pp. 1-19, figs. 11. Washington, D. C. July, 1919. HYGIENE

The loco-weeds are leguminous plants growing in the arid and semi-arid regions of the west of the United States. They cause heavy losses amongst horses, cattle and sheep. The characteristic symptoms of loco poisoning are ; stupefication, irregularities in gait and mastication, paralysis, emaciation and eventually abstinence from all food, and then death. These symptoms are more marked with horses and cattle than with sheep. Loco is generally supposed to predispose to abortion.

Three distinct species of locoweeds are known :— " white loco " (*Oxytropis Lamberti*), " purple loco " (*Astragalus mollissimus*), and " blue loco " (*A. diphysus*). The second affects horses ; the third affects chiefly horses, but also cattle and sheep ; the first causes heavy losses of all 3 classes of animals.

While it is reasonably certain that other plants give rise to loco weed disease, the 3 already mentioned are responsible for most of the losses.

Locoed animals may be cured by careful feeding (as for example with alfalfa and grain), but the cure is hastened by the use of FOWLER'S solution (daily doses of 4 to 6 drams or 20 c. c. for not less than one month) ; and strychnin given in hypodermic doses to cattle (9 to 12 mg. daily for one month or more).

Locoweeds may be destroyed by digging, to accomplish which it is necessary to cut the root 2 or 3 inches below ground level. It is advisable to keep the stock away from badly infested areas until the grass is started.

997 – **"Coffee Bean" (*Daubentonia longifolia*) and *Astragalus tetrapterus*, Sheep Poisoning Leguminosae.** — *The Producer*, Vol. II, No. 1, pp. 31-32, figs. 2. Denver, June, 1920.

The discovery of a new sheep poisoning plant from the southern States of North America identified as *Daubentonia longifolia* "coffee bean" has been notified.

The second species noticed, namely, *Astragalus tetrapterus*, related to the locoes, has so far been observed only in the foothills of southern Utah and western Nevada, where it occurs in scattered patches, and never in large quantities. The animal staggers as it walks, and the plant is injurious to cattle, sheep and probably also to horses.

The symptoms caused by eating this poisonous weed are not especially characteristic.

When other forage is lacking, the best preventive is to remove the animals to pasture where they can get abundant feed.

998 – **"Horse Sickness" in the Belgian Congo.** — VAN SACEGHEN, R. (Directeur du Laboratoire de médicine vétérinaire de Zambi, Lower Congo), in *Bulletin agricole du Congo belge*, Vol. X, Nos. 1-4, pp. 162-172. Brussels, March-December, 1919.

"Horse sickness" has been known for over a century in South Africa, especially in Cape Colony, as well as in German West Africa, and in Rhodesia, where it has destroyed as many as 90 % of the equine population. In 1917, this disease made its appearance in the Horsebreeding Section of the Agricultural College at Zambi (Lower Congo).

The horse is the animal most attacked, mules and hinnies being less susceptible, whilst the donkey enjoys a still greater degree of immunity. The malady produces fever in goats and sheep; it does not, however, affect man. The pathenogenetic agent is ultramicroscopic, and is found not only in the blood, but also in the exudates and bronchial secretions. Blood from the heart of a foetus borne by a mother suffering from "horse sickness" can induce the disease.

The virus is one of the polyvalent type. According to THEILER and KOCH, the disease is inoculated by *Anopheles* and *Stegomia*; REINECKE believes that it is spread by means of ticks. WILLIAM found epizootic "horse-sickness" in a district where the only hematophagous insect was *Lyperiosa minuta*; SCHUBERG and KUHN have produced the disease in horses by means of *Stomoxis*.

Some days before death, the temperature of the infected animal rises to from 40 to 40.9° C. The animal is depressed; the mucous membranes are much congested, there is great difficulty in breathing, and in some cases a frothy mucus like beaten-up white of egg issues from the nostrils. The oedemata of the head and lips are very irregular. The animal does not lose its appetite, but death is occasioned by suffocation.

Post-mortem examination reveals that the blood is black and asphyxic, and infiltrations of an amber-coloured, gelatinous liquid are found in the interstices of the muscles; very often a large quantity, sometimes several litres, of amber liquid is found in the pleural cavity. The pericardium, which is greatly distended, is surrounded at the base with a gelatinous

amber substance, which is also found in the coronal veins, and on the valves of the heart. The most constant lesion is that affecting the mucous membrane of the right *cul-de-sac* of the stomach and the pylorus; this membrane is very hemorrhagic, and covered with large discoloured patches or ecchymoses. The mucous membranes of the colon and caecum are likewise very hemorrhagic.

The author is of opinion that the malady was spread in the Belgian Congo by sheep infected with "heart-water" and introduced from Angola in 1917. This is rendered probable by the fact that previous to the importation of these animals, "horse-sickness" was unknown. Further, if 20 cc. of pericardial fluid taken from a sheep showing symptoms of "heart-water" are injected into a horse, the latter dies with all the symptoms and lesions that characterise "horse-sickness." EDINGTON and MORTON COUTTS believe the diseases to be identical, but THEILER and STOCKMANN do not think that the same virus is the etiological cause. The author, however, is convinced, and his experiments confirm his belief, that "horse-sickness" and "heart-water" are two varieties of the same virus, of which there are distinct races and varieties. Equidae entirely hyperimmunised to one form, can fall victims to another. The horse would be as susceptible to "heart-water" as to "horse-sickness", but in its passage through *Equidae*, the heart-water virus would lose much of its virulence for ruminants.

According to COUTBURG, the tick transmitting the disease is *Amblyomma hebraeum*, which does not exist in Zambi.

The author believes that the disease is spread not only by *Anopheles*, *Stegomia Lyperosia*, and *Stomaxis*, but also by other blood-sucking parasites, and amongst them, a Nemocera of the genus *Culicoides*, which is only seen in the early morning, and *Tabanus*.

The horse is the animal most susceptible to the malady. Senegal horses are more resistant than others.

Mules bred from a Belgian mare are less resistant than those with a Senegal mare for a mother.

Swine, rabbits, and guinea-pigs do not contract the disease.

There is only one treatment, and that is a preventive consisting of strong doses of concentrated camphorated oils; 10 to 20 gm. of camphor administered in the form of a subcutaneous injection have given good results, especially in chronic cases.

It appears that an animal can be rendered immune by progressive injections of serum taken from a horse that has succumbed to "horse-sickness." The serum must be mixed with half its own volume of glycerin, and submitted for 12 hours to the action of a quarter of its volume of ether.

999 – **Anti-Infection Power and Bacteriotropic Action of Anti-Streptococcic Serums Prepared from Living or Dead Bacteria.** — CARPANO, M. (Director of the Military Bacteriological Laboratory of Rome), in *Annali d'Igiene*, Year XXX, Nos. 3-4, pp. 164-168. Rome, March-April, 1920.

The preparation of the anti-streptococcic serum used for the immunisation of horses presents many difficulties when living cultures of virulent

forms are employed. This is due to the fact that sometimes, for reasons at present not wholly understood (fall of external temperature, fatigue, contusions, etc.), the animals become seriously ill after inoculation, and may actually die of true septcaemia, even when they are " serum-producers " that have attained a high degree of immunity.

Seeing that cultures of streptococci killed by heat are, on the contrary, well tolerated by horses, the author proposed do discover whether they could not be used instead of living cultures in making anti-streptococcic serum. They therefore made two serums with cultures of living and of dead bacteria respectively, and studied their anti-infection effect on rabbits.

The results clearly showed that the serum prepared from living cultures had a *stronger immunising effect* than that made from dead streptococci. On the other hand, the *bacteriotropic power* of the two serums was nearly equal. The *opsonic index* of the serum prepared with dead bacteria was 3.72, as against 4.86 in the case of that made from living bacteria.

From his experiments taken as a whole, the author draws the following conclusions : —

(1) The bacteriotropic action of anti-streptococcic serum prepared from dead bacteria is almost the same as that of serum obtained from living streptococci.

(2) The *anti-infection* action of antistreptococcic serum obtained by immunising the serum-producing animal with living bacteria is much stronger than that of serum prepared from dead streptococci ; for this reason, although the former method is attended with the great difficulties inseparable from the use of living cultures, it is much to be preferred to the latter, on account of the greater efficacy of the product.

(3) Between the *bacteriotropic action* and the *anti-infection power* of the anti-streptococcic serum, no complete parallelism therefore exists, hence a bad opinion of the protective power of the serum itself would be formed if its bacteriotropic properties alone were taken into account.

1000 - **Warble Flies: *Hypoderma lineatum* and *H. bovis*** (1). — HADWEN, S. (Chief Animal Pathologist Ottawa, Ontario) in the *Department of Agriculture, Canada, Health of Animals Branch, Scientific Series*, No. 27, pp. 1-24, pl. 4-figs. 29. Ottawa. July, 1919.

The object of the experiments was to discover expedients to reduce the number of Warble Flies, and, consequently, the damage they occasion.

Investigations were started in 1911 at Agassiz, British Columbia, and a summary is here given of the subject matter of a series of papers published by the author. The magnitude of the still unsolved problem is indicated. A description is given of both *Hypoderma lineatum* and *H. bovis* including seasonal prevalence, oviposition and its psychic effect on animals, and methods of penetration.

(1) See *R*, Feb. 1913, No. 144 ; *R*. June 1914, No. 534 ; *R*. Sept. 1914, No. 830.

Experiments made with the larvae of *H. lineatum* showed that they choose the easiest and most non-vascular tissues in their migrations (1) and it would seem probable that even when they are newly hatched, they would have the same habits that they adopt in later migrations. If this is correct, probably they gain entrance to the œsophagus in the region of the throat. The greatest number were found in the gullets during December, and they gradually diminished until March, and then disappeared from this region. In tracing their subsequent migration, direct evidence has been secured that the larvae make use of the posterior foramen to gain entrance to the neural canal, and are found in the soft areolar tissue which surrounds the dura mater. The larva evidently makes use of the canal as an easy means of access to the lumbar region. No larvae have been discovered in muscular tissue; they follow connective tissue exclusively. The mature larvae leave the animals backs from the early part of the year up to the first days of July.

The periods for the 2 species have not been fully worked ont, but judging from records of the pupal period and the time of year the flies are on wing, *H. lineatum* begins to emerge in February and finishes about May 1st. (eggs are laid during May). *H. bovis* begins about May 1st. and ends approximately on July 1st. The average pupal period is 32.5 days and for *H. lineatum*, a little less.

In other countries no doubt variations in life history will be noticed, but the period spent by the larvae within the host must be of the same duration ,owing to the uniform animal's temperatures.

Advice is given to house animals during the heat of the day to prevent flies laying upon them. Warble grubs should be squeezed out as early as possible during the year to lessen the damage to animals and their hides.

Co-operative measures are essential if the total eradication of the pest is attempted.

1001 – **The Prevention and Treatment of Aphthic Fever by the Serum or Blood of Animals Having Recovered from the Disease.** — LEBAILLY, C., in *Comptes rendus de l'Académie des Sciences*, Vol. CLXXI, No. 12, pp. 555-556. Paris, September 20, 1920.

It has long been experimentally known that anti-aphthic serum is efficacious in the treatment of aphthic fever (LOEFFLER, ROUX, NOCARD, and VALLÉE) ; the method is, however, not generally adopted, on account of the difficulty of preparing a sufficient amount of very active serum. Serums obtained with difficulty by dint of hyper-immunising animals by means of apthic virus or blood, have to be used in large doses, and are not much more active than the serum of animals that have been cured of the diseases. The latter serum has been used by the author M. BERTIN, and several other verterinary surgeons.

The serum was obtained by bleeding 5 animals that had recovered some ten days before from a serious attack of the disease. From 3 to 6 litres of

(1) See *R.*, March 1914, No. 251 ; *R.*, May 1914, No. 445. (*Ed.*)

blood were taken from each animal. The serums were mixed and put into graduated bottles (each division marking 100 cc.) 1 gm., of carbolic acid being added to every 800 cc. of serum.

For convenience sake, blood was generally used in place of serum; in the above-mentioned bottles was put a solution consisting of 50 cc. water 5 gm. sodium chloride + 5 gm. sodium citrate + 1 gm. carbolic acid, and blood to make up 800 cc.; this solution was carefully mixed. The blood thus prepared had to be injected within 48 hours.

More than 500 animals, nearly all cattle, were treated, some with blood and others with serum.

The results obtained were exceedingly good, both from the preventive and curative standpoints. No case of death occurred, but the immunity was of short duration. The amount of the mixture varies from 10 to 200 cc. according to the age of the animals, the strongest dose being for adults. After 8 days, the sub-cutaneous injection should be repeated.

Slow intra-veinous injection of the serum is most efficacious.

1002 – **Virulence of the Milk of Animals Suffering from Aphthic Fever.** — LEBAILLY C., in *Comptes rendus de l'Académie des Sciences*, Vol. CLXX, No. 6, pp. 372-375. Paris, August 9, 1920.

It has long been known that the milk of animals suffering from apthic fever is contaminated with the virus of the disease. This was attributed to the presence of vesicles on the teats, which frequently occurs, and to their rupture during the operation of milking. TERNI has observed that the aphthic virus is carried off by the milk.

The authors' experiments have shown that the virulence of the milk is a very early symptom of aphthic fever; before any other sign of the disease manifests itself, and while the health of the animal appears in no wise affected, its milk is already virulent.

The passage of the virus into the milk is the chief cause of the spread of the disease and of the mortality among young animals; it explains occurrences that would otherwise be most mysterious. On visiting the centre of the epidemic, the observer cannot fail to be struck by the fact (which seems paradoxical at first sight) that the first cases of aphthic fever are those of young calves, shut up in the shed and never going out. These animals are attacked by a rapidly progressive malady, and die suddenly although aphthic fever has only just made its appearance on the milch cows, or is not even recognised till the next day, when the vesicles break out. As a matter of fact, this eruption, though generally regarded as an initial symptom, really indicates an advanced stage of the disease, and is the forerunner of complications due to secondary infection. The same remark applies to the disease in the case of pigs. The large amount of virus introduced into the digestive system by the ingestion of the milk explains the acute nature of the attack on young animals and their sudden death even before the appearance of the vesicles. The virulence of the milk develops at a very early stage, and is parallel to that of the blood during the time when the temperature of the animal is rising.

These facts explain the discouraging results obtained by breeders who have taken the trouble of boiling the milk given to calves and pigs ; this precaution was excellent but it was deferred until too late.

On certain farms, disastrous results ensue from the practice of using the unboiled milk of cows supposed to be healthy. When aphthic fever breaks out among stock, there are always some individuals which, though apparently uninfected, are yet in the fever stage of the disease. Their milk contains the virus (at that moment at the height of its activity), and the animals fed with this milk at once contract the disease.

The great mortality among calves during the prevalence of epidemics of aphthic fever can only be prevented by using a thermometer, in order to detect the first symptoms of the disease, and by boiling the milk and sterilising all vessels with boiling water.

1003 – **Uterine Disease in Cows. The Extent to which They are Due to the Bang-Stribolt Bacillus.** — Rivabella S. (Royal Veterinary College of Modena), in *La Clinica veterinaria*, Year XLIII, Nos. 13-14, pp. 329-349, Bibliography of 29 publications. Milan, July 15-30, 1920.

Inflammation of the uterus is one of the most common causes of sterility and abortion in domestic animals. In order to diagnose the symptoms with certainty and accuracy the author proposes (*La Clinica veterinaria*, 1917, Nos. 12 and 13) a cytological examination of the uterine secretion collected *in vivo* from the animal with special precaution and according to a new method.

In the present article, the author describes a series of experiments made for the purpose of comparing the results of his method of diagnosis with those of methods based exclusively upon bacteriology and serology, in order to determine whether the lesions of the uterus are always accompanied by the Bang-Stribolt bacillus.

Out of more than 100 cows examined, 76 were proved by cytological examination of the uterine secretion to be suffering from disease of the uterus. This diagnosis was confirmed in the case of some cows by means of microscopic examination, and in that of others by careful observation of the symptoms. Of these 76 cows, only 10 gave a positive result to the agglutinaton test for the Bang-Stribolt bacillus. Thus, it would appear that this micro-organism is only the cause of uterine disease in a very limited number of cases.

This supposition agrees with the observations of Prof. Stazzi upon the distribution and gravity of cases of abortion and vaginitis in the various regions of Italy. He noticed that epizootic abortion due to the Bang-Stribot bacillus is a disease peculiar to large farms, where cattle breeding is intensive, and the animals are kept in the sheds and stall-fed throughout the year.

1004 – **Treatment of Surra in Camels by Intravenous Injections of Tartar Emetic.** — Cross H. E. (Camel Specialist, Sohawa, Punjab, in *Agricultural Research Institute, Pusa, Bulletin* No. 95, pl. 4. Calcutta, 1920.

In 1917, the author treated and cured 6 camels attacked by surra by means of intravenous injections of a 1 % solution of tartar emetic.

Taking into account the fact that only a small number of animals were treated, it may however be concluded that tartar emetic gives promise of success. The method of treatment is described and stress is laid on the following points: 1) that the solution should not be injected subcutaneously but into the vein to prevent sloughing; 1) that injections should be given during the intervals between the paroxysms; 3) that a 60 cc. of a 1 % solution can be safely given to fully grown camels if the amount is given in 4 injections with a 2 or 3 hours interval between each; a single dose results in death.

1005 – **Study on Avian Plague.** — JOUAN, C. and STAUB, A., in the *Annales de l'Institut Pasteur*, Vol. XXXIV, No. 5, pp. 343-357, Bibliography of 24 publications. Paris, 1920.

Avian plague which was recognised in 1880 by RIVOLTA and DELPRATO, began to be studied in 1901 by CENTANNI, and then by MAGGIORE and VALENTI, LODE and GRUBER, DUBOIS and other investigators.

In 1916, the results obtained from these researches were that fowls pheasants, parrots, and goslings less than 6 months old were all found to be susceptible to the disease. Adult geese contracted it only if inoculated with virus under the dura mater. An epidemic was observed among wild ducks (*Anitra germana*). The virus passes through BERKEFELD and CHAMBERLAND filters and BECHHOLDS ultra-filter. According to these experiments, the size of the pathenogenetic agent is 2.4 million parts of a millimetre; a subcutaneous inoculation of 1/10 000 000 c. c. or even less is often sufficient to produce death. In the case of the fowl, the blood and all the organs, as well as the contents of the intestine, contain the virus; in that of the gosling, the blood and brain contain it for the 3 first days after inoculation; in the adult goose only the brain.

It is generally acknowledged that the blood corpuscles contain more virus than the serum; in fact if fresh globules are added to virulent serum, the latter yield up some of its virus to them.

In its resistance when in glycerin this virus resembles the pathogenetic agents of rabies, small pox and syphilis, though from the effect of saponin, which does not act upon bacteria, but destroys trypanosomes, etc., it would seem to be a protozoon.

With regard to resistance to heat, the virus is killed after 5 minutes heating at 60°C, according to some observers; but others state that it can withstand 70°C, and is destroyed by 80°C. When in the brain, the virus is said to resist 4 hours' heating at 65-80°C.

Hitherto, all attempts at vaccination with heated virus have failed. Fowls however, have been inoculated with the brain of an infected gosling, dried in a vessel full of caustic potash.

Serum from a fowl that has recovered from the disease destroys the virus *in vitro*, and protects fowls from infection. Sheep inoculated with the virus provide a serum of little activity.

The authors have found that blood retains its virulence for a long time in closed flasks: viz. from 12 to 18 months in the refrigerator, for 25 days at a temperature of 37°C. Entire bood is very rich in virus; 1/11 000 000 cc. of

it kills an animal quickly ; the brain contains the same amount of virus, but there is a little less in the pericardiac fluid.

Twenty-four hours after inoculation, fowls show signs of depression, they ruffle up their feathers, close their eyes, and their temperature rises to 43.5° or 44°C. Than the temperature falls, somnolence increases, and the birds die (37-38°C) without any symptoms of nervous disturbance.

The authors have succeeded in transmitting the pest from pigeon to pigeon after transmitting it consecutively 4 times, beginning with a young bird 3 to 4 weeks old and finishing with an adult pigeon. The fifth pigeon was very seriously ill, but the sixth pigeon, and a fowl inoculated with portions of its brain and some of its blood taken on the 12th day when it appeared to have recovered, were not killed.

Towards the fourth day after intramuscular or intracerebral inoculation, the pigeon shows signs of nervous derangement ; it cannot keep its balance, which is a sign that the virus is chiefly lodged in the encephalus. In spite of this, however, all the subjects of the experiment did not succumb.

According to the authors, infection can be produced by merely introducing the virulent blood into the oesophagus, or even sprinkling it over some grains of food ; experiments proving these facts are cited. It is probable that the excrement on the ground where the fowls range is a source of contagion.

The following data indicate the heat resistance of the virus :—

At 44°C., after 24 hours, the virus is not killed, but is less active.
At 46°C., after 2 days, the virus is not killed.
At 47°C., after 3 days, the virus is killed.
At 55° C., after 3/4 hour, the virus is not killed.
At 55°C., after 1 hour, th virus is killed
At 60°C., 10 minutes suffice to destroy the virus.

When virus killed by heat was used for inoculation, it was found that virulent blood kept for 3 days at 46°-47°C., and introduced in sufficient quantity (10 cc.) into the mucsles was able to confer immunity.

Considerable resistance, if not complete immunity, was obtained by the inoculation of heated virus, or by sero-vaccination.

Experiments are described which prove that inoculated and hyper-immunised fowls furnish an active and antibacterial serum, which is best obtained by means of intravenous inoculation.

If a mixture of serum and virulent blood is used, the inoculated animals are not ill, but after 10 days they succumb to a virulent test. In order to prevent this destructive action of the serum upon the virus, the authors thought of impregnating the latter with the anti-bodies of the serum. The serum,on being heated at 56°C., for half an hour still destroyed the virus. They then removed the alexine present in the virulent blood, and which had the power of re-acting on the serum. In order to effect this, rabbit blood-corpuscules were used that had been washed and restored to the original volume of the blood. In order to remove the alexine in 8 cc. of fowl serum, 3 cc. of blood must be taken from a rabbit, and the corpuscles washed 3 times, the last water being replaced by the 5 cc. of fowl serum,

with which the corpuscles are emulsified. After contact for 30 minutes at 33°C all the alexine will have disappeared from the serum.

If it is a case of the entire blood of avian plague (not only the serum, for each 8 cc. of virulent blood freed from fibrin, the corpuscles in 2 cc. of rabbit blood should be taken. In order to be more certain the author used 3 cc. and thus obtained a virus free from alexine, which after being mixed with blood taken from a hyper-immunised fowl and heated to 56°C., can be employed for inoculation after contact for 24 hours at 33°C.

After experimenting with different proportions of serum and virus, it was found that it was possible to inoculate fowls with this mixture, but the authors do not deny that the process should be improved still further.

All their attempts at cultivating the virus by the usual methods proving vain, they experimented with yolk of egg, and found that the virus developed in an incubated egg when the incubation had continued for at least 3 days ; this may perhaps be due to some change in the egg which is favourable to the growth of the virus.

FEEDS AND FEEDING

1006 – **Comparative Return of Albumen and Carbohydrates.** — GOUIN, A. and ANDOUARD, P., in *Bulletin de la Société scientifique d'Hygiène alimentaire*, vol. VIII, No, 6,pp. 376-378. Paris, 1920.

Physiologists are still engaged in discussing the question whether albumen on account of its complicated structure does not require a much larger expenditure of energy in its digestion than starch and sugars. If this be the case, as is maintained by CHAUVEAU, its nutritive return would be considerably diminished. Although the authors' experiments were not undertaken for the special purpose of deciding the matter they yet afford some useful data.

In the many years during which they have drawn up the nutritive balance for calves fed on maximum rations, the composition of the latter was very varied. The nutritive ratio of the feed in some cases varied from 1 to 3.5, and in others as much as 1 to 8.

The amount of the nutritive principles ingested remained, however, always the same, which would seem to show that the digestion of albumen is no slower than that of carbohydrates. The animals grew as rapidly on the one diet as on the other. The sum of the nutritive principles absorbed in growing and for the maintenance of the body never changed, however much the rations varied.

Numerous experiments with pigs, which, however, were not carried out with the same accuracy, confirmed the results of the experiments on cattle.

In their experimental piggery, they carried out as intensive a system of breeding as possible, the animals from the beginning being given as much as they could eat. The rations consisted entirely of concentrated feeds, often diluted with a little skim milk. The pigs were weighed every week.

For a long time, the authors thought it best only to give the pigs the full amount of nitrogen required for flesh-formation and the reconstruction of waste tissue. The nutritive balances for 5 consecutive months showed that the animals had never received less than was needed for these purposes.

For the rest of their vital expenses, these being by far the most important, they drew with equal success upon the starch or sugars.

In the case of very young animals, the nutritive ratio was as 1 : 5; later, it rapidly widened and ended by being 1 : 10 or even more.

As starchy substances and sugars were not available for stock-feeding during the war the authors were obliged to have recourse to 2 cakes viz. groundnut cake which contains excess nitrogen and has a nutritive ratio of 1 : 1 at most, and palm-nut cake of which the ratio is 1 : 4,5.

As a rule, the pigs did not eat palm-nut cake very readily; in order to induce them to consume the enormous rations required by intensive breeding, it was necessary to mix the cakes, giving half of each. Then the nutritive ratio fell to 1 : 3, when the average with starchy food had previously been 1 : 8. The average daily gain in weight of the 26 pigs raised from 1910 to 1916 with this wide ration was as follows :

Pigs weighing.	18 to 30 kg..	605 gm
Pigs weighing	30 to 100 »	720 »

or a daily gain, for each pig weighing 18 to 100 kg,, of 700 gm. The daily increase in weight of the 11 animals which had to be fed on a very narrow nutritive ratio from 1917 to the beginning of 1920 was as follows :

Pigs weighing	18 to 30 kg.	536 gm.
Pigs weighing	30 to 100 »	718 »

or an average gain of 684 gm.

Although when the pigs were very young, lower results where obtained with nitrogen than with starch, the authors are of opinion that no decisive conclusion can be drawn from this fact.

On the other hand, it seems certain that, in spite of the difficulties entailed in the digestion of nitrogenous substances, omnivorous and herbivorous animals alike are able to make use of the same amount of nutritive principles, whether the food contains excess nitrogen, or only the necessary amount, and that the nutritive return is the same in both cases.

These experiments on young animals and these nutritive balances, clearly prove that for the maintenance of the body and provision for growth, the value of albumen is not below that of starch and sugars.

1007 – **Some Feeding Experiments with Dried Blood in Great Britain.** — Newman, L. F., in *The Journal of the Minister of Agriculture*, Vol. XXVII, No. 3, pp. 266-271. London, June 1920.

In recent years, several firms have placed dried blood on the market as animal food, and considerable claims have been made as to the value of this preparation when used as part of a fattening animals rations. It was therefore considered desirable by the Food Investigation Board to institute a series of trials in which blood was the main source of nitrogen.

Dried blood, when properly prepared, is a dry powder with a little smell, a pleasant meaty taste, and a salt flavour.

A number of trials have been carried out by different investigators on dried blood, and the results have indicated that it possesses considerable food value whe added to a mixed diet, but it was decided to restrict the

experiment to the effect of blood as an addition to a carbohydrate diet. For this purpose two series of experiments were arranged : 1) blood as an addition to maize meal ; 2) blood as an addition to wheat offals.

Twenty-eight pigs were selected and divided into 4 lots of 7 pigs each, each lot being arranged to average, as nearly as possible, the same live weight.

Experiment I. — The 4 lots were fed as follows : — I wheat offals only ; II maize meal only ; III, wheat offals and dried blood ; IV maize meal and dried blood. In addition, each pig received ½ oz. bone meal daily. The amount of blood fed to each pig in Lots III and IV was 2 oz., per day to begin with, rising gradually to 6 oz., per pig per day, an average of 4 oz., per day ; an extra 5 lb., per pen was allowed so as to bring the total to 1.25 cwt., in all for both lots of blood-fed pigs. Each lot received altogether 1.25 cwt., of blood during the 11 weeks of the experiment.

In both diets, the blood-fed pigs were much livelier and more hungry than the controls. The pigs were weighed at weekly intervals and after 11 weeks feeding gave the following results : —

Lot	Weight at start	Weight at finish	Gain in Loss
	lb.	lb.	lb.
I	381 3/4	600	218 1/4
II	409 1/4	406	—3 1/4
III	402 1/4	686	283 3/4
IV	415 1/4	623	207 3/4

The pigs in Lot II showed very little appetite, and after a week or two took their ration of plain maize meal only with reluctance and when pressed by hunger ; this explains their decrease in weight.

Experiment II. — To ascertain if the addition of a small amount of fresh vegetable food, might possibly affect the general metabolism of the animals.

The pigs in Lot II were divided into 2 pens, and one pen received a single kohl-rabi plant per pig per day, in addition to the diet, for another period of 4 weeks. With the exception of Lot III, when there was no marked difference in weight between the 2 pens, the other 3 lots gave evidence of a distinct difference in weight between the pens which received vegetable food compared with the control.

Conclusions. — The results obtained indicate that the addition of blood to an ordinary farm ration of wheat offals may cause a very considerable gain in weight compared with the results obtained from a farm diet of offals only, while the addition of blood to plain maize meal gives an increase equal to results obtained from feeding offals only. (These results with maize meal alone compare exactly with those obtained by American observers who undertook experimental work of feeding maize to pigs as a comparison with maize + casein).

The addition of a small quantity of fresh vegetables to the diet showed a very considerable gain against an ordinary ration, but their use appeared to be unnecessary when a full diet of wheat offal plus blood was fed.

The author adds that this part of the experiment is tentative only, and requires further trial with a larger number of pigs before any definite conclusions can be drawn.

1008 – **Sunflower Silage.** — NEIDIG, R. E., and VANCE, L. E. in *Journal of Agricultural Research*, Vol. XVIII, No. 6, pp. 325-327. Washington, D. C., Dec. 15, 1919.

In many parts of the Pacific Northwest, the selection of a suitable crop for silage purposes is a matter of some difficulty because of the variable climatic conditions. New crops that are more or less resistant to drought and that will yield a heavy crop of green material are greatly desired for this purpose. The results obtained by ARNETT and TRETSVEN in 1917 on sunflower silage were so encouraging that the Idaho Experiment Station started to grow for silage. During the early part of September, 1918, the sunflowers were cut and made into silage, and it was with the said silage that the authors undertook chemical experiments with special attention paid to the acid formation. As the crop of sunflowers was not sufficient to entirely fill the silo, maize was added in adequate quantities. The samples of silage were taken in January: Sample 1 was taken at a depth of 2 ft: the silage was dark in colour and had a strong, disagreeable odour; Sample 2 was taken at a depth of 6 ft., was lighter in colour with only a slight disagreeable odour; Sample 3 was taken at a depth of 9 ft., and possessed all the appearances of having undergone normal silage fermentation.

The authors determined the kind and amount of acids found in each sample, with a view to establishing the type of fermentation in each case.

The acid fermentation of No. 1 does not appear to be normal, for butyric acid is present in a large quantity, while only a trace of lactic acid is found. Sample 2 also contains butyric acid and therefore can not be classed as first grade silage. Sample 3, however, showed an acid fermentation similar to that found in good maize silage. The abnormal fermentation of Samples 1 and 2 is no doubt due to the fact that 10 days elapsed between the filling of the silo with sunflowers, which allowed air to penetrate the silage. The results with Sample 3, show that under proper conditions, sunflowers will produce an excellent silage: The chemical analyses of the 3 Samples are given as follows (see Table p. 1164):

The composition of sunflower silage compares very favourably with that of maize silage. No data are at present available on the digestion coefficients of the sunflower silage. Practical feeding, however, indicates that it is equal to maize silage for many purposes, and may quite well be used as a good substitute in districts where maize can not be grown.

Composition of Sunflower and Maize Silage.

Kind of Silage	Water	Ash	Protein	Crude fibre	Nitrogen free extract	Ether extract
	%	%	%	%	%	%
Sunflower, Sample number						
1	76.6	2.4	2.3	7.1	10.5	1.1
2	78.0	2.7	2.6	5.6	10.1	1.1
3	81.0	2.2	2.4	4.6	8.9	1.1
Average	78.5	2.4	9.8	5.8	1.1	2.4
Maize (average of 121 analyses)	73.7	1.7	2.1	6.3	15.4	0.8

1009 – **Food Value of Fruits of *Pithecolobium Saman*.** — See No. 970 of this *Review*.

HORSES

1010 – **Metrical Studies on the Mule in France.** — PORCHEREL, A., in *Revue vétérinaire* Vol. LXXII, No. 6, pp. 338-345, No 7, pp. 415-429. Toulouse, June and July, 1920.

The aim of the author was to test, by means of a series of measurements of the mule, the truth of the hypothesis that in hybrids, there are both juxtaposition and fusion of the parental characters, and that in the case of crosses between 2 domestic species, the offspring most resembles the parent which has been least altered by domesticity.

The author himself took the measurements of the mules and asses that he uses as a basis for his conclusions, and sets forth in a series of tables. The data respecting the measurements and proportions of the horse he took from well-known sources and especially from M. F. X. LESBRE's treatise entitled "*Précis de l'extérieur du cheval*". From the data, the following facts have been collected :

LENGTH OF EARS. — This varies in the mule,

from 40 to 47.1 % of the head length in 44 % of the animals examined
from 35.7 to 40 % » » » » 32 % » » »
from 30.8 to 35.7 % » » » » 24 % » » »

In the ass, the ears are nearly always more than half as long as the head.

HEIGHT AT WITHERS. — In the horse this is usually 2 ½ heads, in the mule, with few exceptions, it is nearly always below 2 ½ heads, though it only varies by 1 to 4.5 cm ; in the ass, the height is less in proportion to the length of the head than in the mule.

PROPORTION BETWEEN THE CHEST AND THE HEIGHT OF THE GIRTH. — The height at the withers depends upon two elements of which the proportions are very variable, i. e. the chest and the girth. On an average, in the case of the horse, the first is $^1/_{10}$ head more than the second, that is, the total height at the withers which is 2 ½ heads, is made up of chest 1 $^2/_{10}$ head, chest and girth height, 1 $^3/_{10}$ heads.

In the mule, the girth height is always from 3 to 19 cm. more than the chest height. As a rule, mules stand higher, the chest being sunk but little between the fore-limbs. This difference is less striking in the case of the donkey. According to the writer's measurements, the proportion between

chest and height varied from 2.05 to 2.1 in the mule, and from 2 to 2.17 in the ass.

RADII OF THE FORE LEG: *Length of shoulder.* — In the horse, the length of the shoulder measured from the extremity of the withers to the point of the fore-leg is about 1 head, varying between 5 cm. more and 5 cm. less. The shoulder length of the mule is a little less than the head length, but is longer than in the ass, thus approaching more nearly that of the horse.

Slope of shoulders. — A shoulder is oblique when it forms an angle of about 55° with the horizontal. In 11 out of 21 mules measured by the author, the slope of the shoulder was from 50 to 59°; in 9, it was from 64 to 69°, and in 1, it was 70°. The proportion of mules with sloping shoulders was in this case 52.3 %, i. e., more than half.

Length of fore-limb. — In the horse, the distance from the point of the shoulder to the point of the elbow is about $^2/_3$ of the head length.

In the mule, the author found a length of arm varying from $^2/_5$ to $^3/_5$ of the head, and in the ass an arm length equal to $^3/_5$ of the head. The length of the arm of the mule approaches that of the arm of the ass, one of the upper radii being shortened.

The inclination of the arm. — According to the author, this varies in the mule from 30 to 46°. the scapula-humeral angle varies from 92 to 111°. As a rule, the slope of the arm is inversely proportional to that of the shoulder, but great variability is met with.

The length of the two upper radii of the fore-limb (the shoulder measurements resembling those of the horse, and the arm measurements those of the ass), together with variable slope of the arm, indicate a juxtaposition of characters.

Length of fore-arm and cannon-bone. — In a horse of average proportions, the distance from the point of the elbow to the knee-joint is equivalent to the distance of the knee-joint from the ground, and these two measurements added together are $^3/_4$ of the head.

In horses that stand high, especially race-horses, the second measurement is generally 3 to 5 cm., more than the first, whereas in other horses, especially work-horses, the reverse is the case. The measurements taken by M. LESBRE show that the pre-brachial length, although not absolutely invariable, remains nearly $^3/_4$ of the head, and that it is the metacarpo-digital measurement that is especially changeable.

The author found that the pre-brachial measurement of the mule is always less (variation from 2 to 5 cm ; equality in 2 cases out of 21) than that of the metacarpo-digital ; in most cases, it is $^2/_3$ of the head, and only in very few cases does it attain $^3/_4$.

In the mule, in most cases, the cannon-bone region is $^1/_2$ the length of the head ; sometimes, however, it exceeds the half by from 6 to 10 cm. The metacarpo-digital region is generally $^3/_4$ the length of the head.

The fore-arm region in the ass is about $^3/_5$ of the head, and that of the cannon-bone is half the length of the head, as in the case of the mule. The metacarpo-digital region is $^3/_4$ of the head.

As regards its fore-arm, the mule is intermediate between the ass and the horse and, in some cases, nearer to the horse. In all three animals, the metacarpo-digital region is about $^3/_4$ of the head.

Radii of the hind-limb. — In the horse, M. LESBRE reckons at about $^5/_6$ of the head the distance: (1) From the knee-cap to the haunch; (2) from the knee-cap to the point of the croup; (3) from the knee-cap to the point of the hock.

The vertical height of the point of the hock he reckons to be, on an average, $^{19}/_{20}$ of the head, and the distance between the point of the hock and the spur to be $^3/_4$ of the head or 2 or 3 cm., less.

The measurements taken by the author show that in the mule: (1) The distance from the knee-cap to the point of the croup is usually the same as that from the knee-cap to the haunch; but in 11 cases out of 21, the latter is from 1 to 10 cm., longer; (2) the distance from the knee-cap to the point of the croup is generally $^3/_4$ of the head; (3) the distance between the knee-cap and the haunch varies between $^4/_5$ and $^3/_4$ of the head; (4) the distance between the point of the hock and the spur is about $^3/_4$ of the head; (5) the distance between the knee-cap and the point of the hock varies between $^3/_4$ and $^5/_6$ of the head; (6) the vertical height of the point of the hock above the ground is very variable; in 2 cases out of 21, it was equivalent to the length of the head, in other cases, it was $^4/_5$, $^5/_6$, $^6/_7$ or even $^{11}/_{12}$ of the length of the head; (7) the slope of the thigh is more accentuated than in the horse.

In the donkey: (1) The distance from the knee-cap to the point of the croup, and from the knee-cap to the haunch was equal in 2 cases out of 3 ($^5/_6$ of the head); (2) the distance from the knee-cap to the point of the croup was $^3/_4$ and $^5/_6$ of the head; (3) the distance from the point of the hock to the spur was $^2/_3$ and $^3/_4$ of the head; (4) the distance from the knee-cap to the point of the hock was $^3/_4$ and $^4/_5$ of the head; (5) the vertical height above the ground of the hock was equal to the length of the head, except in one case, when it was $^4/_5$ of it.

These last measurements vary very greatly in the mule, but they more nearly approach those of the donkey than of the horse for the upper radii are shorter in both mule and donkey; this also holds good for the arm.

Length of body. — In the horse, the length of the body measured from the point of the shoulder to the point of the croup should (according to BOURGELAT) equal the height of the withers (2 ½ heads) M. LESBRE has shown that most fine horses are longer than they are high (2 $^6/_{10}$ heads) and that the length from the point of the shoulder to point of the ischium varies from 2.45 heads to 2.75 heads.

The author's measurements show that, as a rule, mules are longer than they are high and that the length from the point of the shoulder to the point of the ischium varies from 2.3 heads to 2.7 heads. In small asses (those from Africa) the difference between the length of body and height is a little accentuated.

LENGTH OF NECK. — In this the mule more closely resembles the horse than the ass.

GIRTH OF CHEST. — The proportion between chest girth and height is much less in the mule than in the horse.

CROUP. DISTANCE FROM SCAPULA TO ILIUM. — In the mule, as in the ass, the croup is nearly always wider than it is long ; in the mule its length varies between $^4/_3$ and $^5/_6$ of the head ; in the ass, it is as much as $^2/_3$ of the head. The croup of the mule is usually more sloping than that of the horse, without however always being sharp. The scapula-ilial distance always exceeds the head length.

CIRCUMFERENCE OF CANNON-BONE. — This, in the mule, is about $^1/_9$ or $^1/_{10}$ of the chest circumference. In the ass, it is rather more (about $^1/_8$).

***

It would appear from an examination of these measurements that in the mule there are certain characters intermediate between those of the ass and horse (fusion of characters of parents), whereas others belong either to the horse or the ass (juxtaposition). There is great variability. To try to assign fixed morphological characters to the mule would be to show ignorance of the laws of heredity.

The mule has 2 and sometimes 3 chestnuts, which are always less developed on the hind-legs.

The fore hoofs are generally intermediate between those of the horse and ass, and are more rounded than the hoofs of the latter. The hind hoofs resemble those of the ass.

The hair is more developed in the mule than in the ass ; this is especially the case in the tail. The mane and tails of some mules differ little from those of horses.

The sharp croup known as the mule's croup (even when it occurs in horses) is found in the majority of mules, but some have rounded croups. The author found sharp croups in 53 % and rounded croups in 45 % of the mules examined ; those with rounded croups were almost all of French origin.

The back of the mule is nearly always straight, being convex only in rare cases, and the author met with 2 young animals, 4 and 6 years of age respectively that had the defect of being saddle-backed The eye is not always as covered as that of the ass, therefore it is an exaggeration to say that the mule has a gloomy, unintelligent expression.

The mule has a good memory for places ; when well-trained and properly treated it is not obstinate, and is a most useful animal. It, however, is more irritable and less good-tempered than the horse.

1011 – **Investigations on the Hair of Different Breeds of Cattle.** — CAMEK, J. (Veterinary Institute and Institute of Animal Industry of the Polytechnic High School Prague), in *The Journal of Agricultural Science*, Vol. X, Pt. 1, pp. 12-21, bibliogr. of 12 publications Cambridge, Jan. 1920. CATTLE

Investigations have recently been made under the direction of Prof. KAŠPÁREK in connection with relations existing between certain characteristics concerning the type of hair produced, and the age, quality and

breed of the cattle. As a result of his investigations, KAŠPÁREK came to the following conclusions:

The hair of bulls has usually a thicker fibrous layer than that of cows. The cross section is different according to sex.

2) There is no relationship between the colour of hair and the development of the fibrous layer and the medulla, but exception must be made with white hair, which in both sexes has a medulla of greater diameter than coloured hair.

3) The hair of prairie and valley cattle has a more strongly developed fibrous layer than that of mountain cattle.

4) The nature and form of the hair is closely connected with the breed of cattle involved.

5) The relationship between the diameter of the medulla to the cortex which is a characteristic of the original stock, remains unchanged, even when the animals are transfered to other countries, and is not influenced by insufficient feeding and selective breeding. It is supposed that the relation between the medulla and cortex in cross bred animals of two heterogeneous breeds shows the dominant or recessive characters just as much as other morphological and physiological characters.

6) There seems to be no fixed law which establishes a relation between the diameter of the hair and the breed of cattle.

The author made further investigations with a view to determining the length, width and ash content of hair in different animals according to their sex and breed.

The hair of the following breeds was investigated: Lowland animals, black chequered and red chequered Dutch cows; red chequered East Friesland cows; shorthorn brown Alpine cattle; Montafons and Swiss breeds, shortheaded dark red Pinzgauer; Frontosus breed, and roan coloured and light-coloured Simmentaler cattle from Bohemia. Other additional studies were made which refer to the crossbreed Bernese × Hanak (red chequered type from Moravia). The hair was collected in November, December and January, at which time the greater part of the covering hair had already developed, and was taken from the same parts of the body in every case. One hundred hairs were examined from each type, and the measurements and characteristics ascertained.

Measurements of the length of hair:

East Friesland Breed. The average length of hair was: (*a*) Red hair: in 4 cows, 2.58 to 3.15 cm.; in 6 head of young cattle 6 months to 2 years old., 4.16 to 5.93 cm. (*b*) white hair: with one exception, shorter than the red ones, 2.96 to 6.09 cm.

Dutch breed cattle: (*a*) black chequered (1) black hair in 5 cows: 3.05 cm., in 1 cow 7 years old; 1.84 cm., in 1 heifer 2 years old. 5.50 cm., in 1 bull 4 years old. 3.82 cm.: (2) white hair, 1 cow (7 years) cm. 1.71 cm., heifer (2 years) 4.68 cm., 1 bull (4 years) 3.30 cm., (*b*) Red chequered (1) red hair: 3 cows, 1.98 to 2.90 cm.; 1 cow (4 years) 2.91 cm.; 1 heifer (2 years) 4.65 cm.; ditto (1 year) 5.06 cm.; ditto (6 months) 2.74 cm,; 1 bull (4 years) 3.49 cm.; ditto (2 years) 5.70 cm.

(2) white hair, 1 cow (4 years) 2.61 cm,. 1 heifer (1 year) 4.21 cm., ditto (6 months) 2.58 cm.,; 1 bull (4 years) 2.10, ditto (2 years) 5.20 cm.

Bernese-Hanac chequered cattle: Average length of red hair in 15 cows was 2.12 to 3.33 cm.; for white hair 1.75 to 3.25 cm.

Simmentaler Breed: The white hairs were shorter than the red.

Montafon Breed. 10 cows average length 2.83, 11 heifers (from 3 months to 2 years old), 3.15 to 4.76, 4 steers 3.19, 2 oxen (6 years) 2.72.

Swiss Breed: Length of the hair varies between 2.26 to 3.18 cm. in 6 cows; in a steer (2 years) 3.96 cm.

Pinzgau Breed: Average length in 3 cows 1.86 to 2.93 cm.; in a heifer (3 years) 3.85 cm.

Measurements of the thickness of hair. — In the determination of the diameter, the measurements were made at a magnification × 80, and the relation of diameter to length of hair.

The results show that there is no regular relation between diameter and length. The longer hair, is as a rule, thicker and stouter, and in short hair, the diameter is proportionately greater than in long hair.

Ash content of hair. — Ninety-three analyses were made on white, black and coloured hair taken from various breeds of different age and sex. Results show: (1) that the ash content of hair is not characteristic for a given breed; (2) that the white hair, is on the whole less rich in inorganic material than coloured; (3) that the more intensely coloured hairs contain the greatest proportion of ash. Similar results were obtained as regards sex: the hair of bulls of all breeds was richer in ash than the hair of cows of the same age, and the hair of oxen had the same amount of ash as that of cows

The following conclusions have been drawn as a result of these investigations:

(1) The maximum length of hair in pure bred animals is found to be between the ages of 6 months to 2 years. Older animals have shorter hair. The hair of bulls is always longer than that of cows and oxen of the same age. In a given animal the white hairs are shorter than the coloured ones; there is a large variation in the measurements of the coloured hairs in the individual animal.

(2) Young cattle up to the age of 3 months have the thinnest hair. After this period, the thickness of the hair is the same as that of adult animals. Bulls have always thicker hair than cows and heifers of the same age. The white hair of a given animal is thinner than that of the coloured hair.

(3) The relation of thickness of hair to length is not always the same With short hairs, the diameter is relatively greater than with long ones. With bulls the ratio $\frac{\text{diameter}}{\text{length}}$ is smaller than in heifers and cows of the same age.

(4) The ash content of hair is not constant. It depends on pigmentation, age, sex, and possibly also on feeding.

1012 – **Conformation and its Relations to Milk Producing Capacity in Jersey Cattle** (1). — GOWEN, J. W. (Maine Experiment Station Orono Maine), in *The Journal of Dairy Science*, Vol. III, No. 1, pp. 1-32, tables 723, Bibliogr. of 14 publications, Baltimore. Jan. 1920.

This paper presents a biometrical analysis of the relation of conformation to the milk producing capacity of the Jersey cow. The study is based on the material collected by the American Jersey Cattle Club in its *Registry of Merit* work compiled by R. M. Gow. The mean conformation as measured by score is given for the cow as a whole and for the parts into which it is divided. In this group under investigation the score was 89.848 ± 0.073.

The variation of the different body parts is compared by means ot standard deviation and the coefficient of variation. The most variable part of the body included the eyes, horns and muzzle, and the least variable, the size of the body. Bone material was in general found to vary slightly less than the scores assigned to parts of the body depending chiefly on variations in bone length. The variation of the udder parts was found to beat the lower end of the range of variation of other soft parts of the body Correlation coefficients for milk yield with the conformation as a whole and for the various parts were determined and ranged from — 0.0697 ± 0.0165 to 0.1941 ± 0.0160. Out of the nineteen correlations the total score had the highest correlation with milk yield. The parts of the conformation having a distinctly significant relation to milk production of the cow were the milk veins, size and condition of udder, size and shape of rear udder, shape and size of barrel and the general appearance of the cow.

A 7-day test has a correlation coefficient with the year milk yield of the cow of approximately 2 ½ times that of the conformation, as a whole or in part. The short test consequently is superior to the conformation as a guide to milk production.

1013 – **Feeding Experiments with Calves in New Zealand.** — BRUCE, J. L. (Superintendent ot Experimental Farm), in *The New Zealand Journal of Agriculture*, Vol. XX, No. 5 pp. 289-298, figs 10. Wellington, May 20, 1920.

With the object of obtaining reliable data as to what extent supplementary foods (mainly home-grown) can be profitably substituted for milk and whey, a scheme of feeding tests, combined with the best practice in calf-rearing generally, was undertaken at the Ruakura and Weraroa Experimental Farms in 1919. In each case 16 calves were divided into 4 groups of 4 each and fed strictly on the respective dietary assigned to each group for 17 weeks. The results were satisfactory ; there have been no deaths, and the calves are in excellent health.

At Ruakura, the calves comprised 12 Shorthorns, 4 Shorthorn × Jersey crossbreds ; at Weraroa the calves used were crossbreds comprising Fresian × Jersey, Shorthorn × Jersey, Ayrshire × Jersey, Fresian × Shorthorn, Guernsey × Jersey and also grade Jerseys.

The substitute feeds at Ruakura were prepared as follows :

(1) See *R.*, Feb. 1917, No. 167 ; and *R.*, April 1917, No. 346.

Group I :— Whole linseed flour soaked overnight in water and boiled for 20 minutes next day ; flour mixed with a little water and added 5 minutes before boiling is completed.

Group II :— Boiling water added to linseed meal and bean meal, the whole covered up for 24 hours.

Group III :— Oat meal, and crushed linseed made into porridge and mixed hot with skim-milk.

Group IV :— Dry crushed linseed stirred into the skim-milk immediately before feeding.

TABLE I. — *Results of Feeding Tests at Ruakura.*

Group	Feeding formula per head per day	Weights and gains		Cost of food per head
			lb.	£. s. d.
I	For 2 weeks :	Total first weight	301	1 14 11
	Whole milk . . . . . 8 lb.	Total final weight	1071	
	For 15 weeks :	Total gain	770	
	Whole linseed . . . . 8 oz.	Average daily gain per calf.	1.61	
	Flour . . . . . 2 oz.			
	Skimmed milk . . . . 15 lb.			
II	For 2 weeks :	Total first weight	302	1 8 1
	Whole milk . . . . . 8 lb.	Total final weight	952	
	For 2 weeks :	Total gain	650	
	Linseed meal . . . . 7½ oz.	Average daily gain per calf.	1.36	
	Bean meal . . . . . 12 oz.			
	Skimmed milk . . . . 8 lb.			
	For 13 weeks :			
	Ditto minus skimmed milk . .			
III	For 2 weeks :	Total first weight	303	1 19 6½
	Whole milk . . . . . 8 lb.	Total final weight	1036	
	For 15 weeks :	Total gain	733	
	Oatmeal . . . . . 8 oz.	Average daily gain per calf .	1.54	
	Crushed linseed . . . 9 oz.			
	Skimmed milk . . . . 15 lb.			
IV	For 2 weeks :	Total first weight	301	1 14 7
	Whole milk . . . . . 8 lb.	Total final weight	1148	
	For 15 weeks :	Total gain	847	
	Crushed linseed . . . 9 oz.	Average daily gain per calf.	1.77	
	Skimmed milk . . . . 15 lb.			

From the foregoing Table it is evident that the dry crushed linseed added to skimmed milk gave the highest daily increase in weight. A con-

siderable amount of difficulty was experienced in getting the calves to take bean and linseed meals (Gr. II), but it was found that after 24 hours the food had a sour smell.

The substitute feed at Weraroa was prepared as follows:—

Group I. — Linseed soaked overnight in 2 ¼ pints of water, boiled next day for 20 minutes, adding flour (previously mixed to a smooth paste with cold water), 5 minutes before boiling is completed.

Group II. — Crushed oats fed dry.

Group III. — Linseed boiled to a jelly in water.

TABLE II. — *Results of Feeding Tests at Weraroa.*

Group	Feeding formula per head per day	Weights and gains	Cost of food per head
		lb.	£ s d
I	For 2 weeks: Whole milk . . . . . 8 lb. For 7 weeks: Skimmed milk . . . . 16 lb. For 18 weeks: Flour . . . . . 4 oz. Linseed meal . . . . 3 oz.	Total final weight (17 weeks). 979 Total gain . . . . . 718 Average daily gain per calf . 1.5	17 3 ½
		lb.	£ s d
II	For 2 weeks: Whole milk . . . . . 8 lb. For 2 weeks: Skimmed milk . . . 16 lb. For 13 weeks: Crushed oats . . . . 1 lb.	Total final weight . . . . . 1102 Total gain . . . . . 822 Average daily gain per calf. 1.7	19 10 ½
		lb.	£ s d
III	For 2 weeks: Whole milk. . . . . 8 lb. For 15 weeks: Skimmed milk . . . 16 lb. Linseed gruel . . . 1 qt.	Total final weight . . . . . 1032 Total gain . . . . . 770 Average daily gain per calf . 1.6	1 7 3
		lb.	£ s d
IV	For 1 week: Whole milk . . . . 8 ½ lb. For 1 week: Skimmed milk . . 16 lb. For 15 weeks: Bean meal . . . . 8 oz. Linseed meal . . . 6 oz. Warm water . . . 3 qt.	Total final weight . . . . . 1355 Total gain . . . . . 1077 Average daily gain per calf . 2.3	18 10

Group IV. — Boiling water added to linseed meal, plus bean meal, the whole mixed and covered for 24 hours.

From these results, the author concludes that the most important and essential factors in calf rearing (apart from the diet) are : a clean new grass paddock ; a good supply of fresh drinking water ; clean feeding utensils. There is no doubt that the absence of scour among the calves was largely due to the latter precaution.

1014 – **Notes on Breeding Wool-Producing Sheep in Madagascar.** — CAROUGEEN (Chef du Service vétérinaire), in *Bulletin économique de Madagascar*, Year XVII, Nos. 1 and 2 (Ist. and 2 nd, half-years of 1920), pp. 95-105 + 1 map. Tananarive 1920. SHEEP

Notes assembled by the author whilst passing in review the different experiments that have been made on the introduction of sheep wool-producing sheep into Madagascar, and during his study of the question of establishing and developing this industry in the centre of the island, and in the southern regions of the island which are adapted to it.

In the third part of his article, the author mentions a report by M. ROQUETTE, Veterinary Surgeon, which shows that the extreme south of Madagascar is an excellent region for sheep-breeding. . There exists in this zone, a fat-tailed, woolless breed that is perfectly acclimatized and capable of rapid improvement by crossing with wool-producing rams from Europe. The hybrids, after a few generations, have fine fleeces.

In the fourth part of his article, the author describes M. JAUSSAUD'S experiment on the acclimatisation of Craú merinos at Tulear (south-west of Madagascar). This experiment proves that it would be well worth while to raise sheep for the frozen-meat trade (the meat of the crosses is excellent) Sheep, however, only do really well in dry seasons ; in damp, or marshy, places, the mortality among them may be very great.

1015 – **Increase in the Weight and Quantitative and Qualitative Changes in the Wool of Lambs Having Undergone the Operation of Unilateral Thyroidectomy With or Without Castration.** — AGNOLETTI, G. (Istituto di Fisiologia sperimentale della R. Scuola Superiore di Medicina veterinaria, Milan), in *La Clinica veterinaria*, Year XLIII, Nos. 10-11, pp. 245-269, Bibliography of 9 works. Milan, May 31, and June 15, 1920.

With the intention of continuing Prof. PUGLIESE'S studies (*Biochimica e Terapia sperimentali*, Parts 3 to 6) on the correlations between the internal secretary glands and growth phenomena, the author studied the correlations between the testicle and the thyroid and between their behaviour and that of the other endocrinal glands. The author experimented on lambs so as to be able to investigate both the phenomena of growth and those of the nutrition of the wool.

The experiment lasted from June 13,1919, to January 10, 1920, and was made upon 4 lots each containing 2 lambs.

I) Male lamb of the Bergamasque breed ; the right thyroid was removed one week after weaning. Control lamb not operated upon.

II) Lamb of the Valtelin breed ; the rigbt thyroid gland was removed, with castration, 2 weeks after weaning. The control lamb was castrated at the same time.

III) Lamb of the Bergamasque breed ; castrated, with removal of thyroid gland, 5 days after weaning. Control lamb castrated at same time.

IV) Lamb of Bergamasque breed (male) ; Lamb of Bergamasque breed (female).

The results obtained are summarised in the appended Tables.

TABLE I. — *Increase in Weight and Yield of Wool.*

Lots	Treatment	Initial weight	Final weight	Increase in weight in 212 days	Increase %	Wool produced
		kg	kg	kg	%	kg
I	Bergamasque lamb (male) right thyroid gland removed	13.15	23.9	10.4	77.03	0.890
	Control	15	24.6	9.6	64.00	0.730
II	Valtelin lamb: castration and removal of right thyroid	16	28.9	12.9	80.62	1.185
	Castrated Valtelin lamb	18.6	29.7	11.1	59 67	1.000
III	Bergamasque lamb: castration and removal of right thyroid	9.8	22.3	12.5	127.44	0.685
	Castrated Valtelin lamb.	11.6	22.3	10.7	92.24	0.535
IV	Bergamasque ram lamb	19.5	31.5	12.0	61.53	1.265
	Bergamasque ewe lamb	19.5	30.5	11.0	56.41	1.185

As regards increase in live-weight, the lamb which had undergone thyroidectomy was superior to the control lamb by 13.03 % ; the difference was much greater when the animal was also castrated. It is therefore advisable to perform lateral thyroidectomy at the same time as castration, seeing that the former operation involves no risk, gives rise to no disturbances of the system, and induces a larger yield of mutton, without any deterioration in the quality of the meat, and of wool. Though the wool of such animals is not as strong, this is not a defect in the case of this rather coarse type, as it becomes finer and more elastic (which is a great advantage), softer to the touch, and almost as lustrous as silk.

The amount of lanolin was found by the author to be below the normal owing to the fact that the lambs were always kept in a shed and had no exercise, so that they produced but small quantities of this substance.

From his experiments, the author concludes that the testicular hormones have a stimulating effect upon the piliferous system, whereas the action of the thyroidal hormones is just the reverse. Thus, the manes and tails of stallions are much thicker and longer than those of geldings, and the bull has much larger horns than the ox.

Table III shows that, in the case of animals castrated when very young, there is less development of the hypophysis, and that the superrenal capsules must have a great influence upon growth.

TABLE II. — *Characters of the Wool.*

(The 3 numbers of each of the 5 columns refer respectively to the wool of the flank, side, and shoulder.)

Lots	Breed and treatment of lambs	Strength gr.	Elasticity mm.	Diameter μ	Length cm.	Curls. per strand	Lanolin %
I	Bergamasque lamb: thyroid removed	10–10–11	13–13–13	34–31–31	11 –11.5–11.3	30–32–31	5.7
	Control	11–11–11	9– 9– 9	40–37–37	9 –10 – 9.6	37–34–32	6.8
II	Valtelin: castration and removal of thyroid	20–21–20	15–15–15	43–43–43	14.5–15.3–14.5	43–42–43	6.5
	Castrated Valtelin	24–24–22	11–13–11	52–49–55	13 –13.5–13.2	32–36–35	6.8
III	Bergamasque castration and removal of thyroid	11–11–11	14–15–13	31–40–37	9.6–10.3–10	35–33–35	7.7
	Castrated Bergamasque	15–15–15	11–11–11	40–46–43	9.2– 9.3– 9.3	30–30–34	8.4
IV	Bergamasque ram lamb	20–21–18	13–12–12	46–47–49	9.7–10.3–10.3	33–34–33	—
	Bergamasque ewe lamb	20–21–20	17–17–16	49–47–47	11.5–11.4–11.5	34–33–34	—

The strength and elasticity are determined 40 tests per sample, the initial tension being 0.2 gm. The length is determined from 25 tests; the number of curls from 20 tests.

TABLE III. — *Weight in grammes of the various organs.*

Lots	Breeds of lambs and treatment	Left thyroid	Right thyroid	Hypophysis	Sur-renal body	Brain	Thymus
I	Bergamasque: thyroid removed	0.977	—	0.037	2.487	80	9.6
	Control	0.932	0.934	0.067	2.824	85	14.0

POULTRY

1016 – **Results of the VI and VII Irish Egg Laying Competitions.** — *The Journal of the Department of Agriculture and Technical Instruction for Ireland*, Vol. XIX, No. 1, pp. 25-41, Vol. XX, No. 1, pp 20-38. Dublin 1918 and 1919.

These competitions were conducted by the Department of Agriculture and Technical Instruction for Ireland and were held at the Munster Institute, Cork.

Competition VI. — 1st October 1917 to 31st August, 1918. The following foods were used for the 210 birds entered : — Bran and pollard, 21 ½ cwt — Maize meal, 17 cwt. — Dried grains, 3 cwt. — Dried yeast. 2 ¾ cwt — Palm Nut Meal, 5 ¾ cwt. — Fish Meal, 15 ¼ cwt. — Cracked maize, 10 cwt. — Small wheat, 4 ½ cwt. — Oats. 61 ¼ cwt. — Crushed Oats, 12 ¼ cwt. — Potatoes, 43 ¼ cwt. — Meat Meal, ½ cwt. — Dry Mash, 11 cwt.

The soft mash was fed as usual each afternoon, grain being given in the forenoon, and is the most economical for farm use. The total cost of food for the 4 periods of the competition amounted to £ 161.3s.6d. To this may be added £. 12, the value of grit and cultivated greens used. The average cost per bird is threfore 16s 6d.

The total number and value of eggs from the pens are grouped as follows : White Wyandottes — 1286 — 1256 — 1250 — 1213 — 1208 (6 hens per group). These took the leading place, and were followed by White Leghorns 1174. The two groups lowest on the lists show 760 and 751 for White Wyandottes (Nos. 25, 26 in order of Merit).

Competition VII. — The following foods were used for the 306 competing birds : — Bran and pollard, 2855 lb. — Maize meal, 2888 lb. — Dried grains, 567 lb. — Dried yeast, 578 lb. — Palm nut meal, 39 lb. — Wheat (damaged) 1506. — Oats, 9728 lb. — Barley meal, 1520 lb. — Rice (damaged), 262 lb. — Fish meal, 3142 lb. — Dry Mash 7863 lb. — Potatoes, 564 st. The total cost of food for the four periods amounted to £. 303,17s. including cost for grit, shell, and cultivated greens.

The general results are given and the comparison with former years in tabular form. The winning pen of Wyandottes heads the list with 1359 eggs. The pen of White Leghorns holding third place with a total, of 1347. The last place is occupied by Rhode Island Reds, 776 (No. 36. Order of Merit).

Eleven months ending Aug. 31 st	No. of Pullets	No. of Eggs laid	Average No. of eggs per bird
1913	318	38 199	120.1
1914	282	39 216	139.0
1915	264	39 764	150.6
1916	294	49 830	169.5
1917	210	36 660	174.6
1918	210	36 196	171.0
1919	306	55 124	180.0

1017 – **Effects of Feeding Silk-worms on Mulberry Leaves Exposed to the Thick Dust of Main Roads.** — FUSCHINI, C. (Chair of Silkworm-Rearing of the R. Istituto Agrario di Perugia), in *Informazioni seriche*, Year VII, No. 13, p. 198. Rome, July 5, 1920. SERICULTURE

Since 1915, private silk-worm breeders and the members of agricultural institutions have asked the author for his opinion on the subject of planting mulberry trees along main roads, and as to how far the silkworms would suffer should the dust be deposited thickly on the leaves. A first series of experiments had already convinced the author that it was necessary to direct the attention of silk-worm breeders to the bad effects that might be expected if such leaves were fed to the insects ; and now, after 3 years of experimental research on the subject, he has arrived at the following conclusions :—

(1) Mulberry leaves exposed to the thick dust of main roads are injurious, if fed to silkworms.

(2) The injury caused is proportional to the quantity of leaves given and to the amount of dust upon them. The effect of the dusty leaves is to decrease the yield of cocoons (the decrease may be as much as about ⅓ of the normal production) and to render the quality of the silk inferior, to the extent of causing loss to silkworm breeders and silk-spinners.

(3) These bad effects can, however, be prevented by carefully washing the leaves in ordinary water or by spraying them thoroughly with ordinary water, employing sprayers such as are used for the control of mildew. The leaves should be allowed to dry a little before being given to the silkworms.

(4) The slower somatic growth of larvae fed on dusty leaves appears to be traceable to the imperfect utilisation of the nutritive elements of the leaves, on account of the dust absorbing a certain amount of gastric juice, which is therefore prevented from acting with equal intensity upon the whole contents of the stomach.

(5) Whilst awaiting the results of further experiments dealing with the latter part of the question, the author thinks it well to discourage the plantation of mulberry trees along main roads, especially those frequently used by motor-cars, which owing to their rapid motion, raise great clouds of dust.

1018 – **Training Camels.** — DROANDI, I., in *Agricultura Coloniale*, year XIV, No. 5, pp. 201-218, 1 pl. Florence, May, 1920. VARIOUS ANIMAL

As a general rule, camel-breeders raise the males for work and the females for breeding purposes ; it is only under exceptional conditions that the females are used for beasts of burden, or for riding. Sterile females however, are sent to the butcher's or used for work.

Those Nigerian tribes that employ female camels as mounts are an exception to the rule ; they divide the females into 2 classes : females that have been made sterile (" seiddh "), and females in the fourth to fifth months of gestation (" naya ").

As the female camels habitually enjoy liberty and are well-fed, cases of abortion are reduced to a minimum. The young are suckled under the

most favourable conditions, and as the stallions are chosen with the greatest care, the offspring grow well and their strength is insured.

Male camels are born with the characteristic callosities of the camel, which are in fact *all* congenital, although some writers (H. Wolff, Blachère) regard the sternum callosity alone as congenital.

The young camel is weaned shortly before it is a year old, that is to say, when its mother is again about to be fertilised. From this time, it lives solely on grass. Sometimes camel-breeders collect the yearlings into herds and keep them separate from the herds of the adult camels. At 3 years of age, the young camel is ready to be trained.

There are several breeds of camels, those called " mehara ", and only used for riding (such as the animals raised by the Touaregs and Schiambas), those supplying exclusively beasts of burden, and those that can serve either as pack-camels, or saddle-camels : the best animals are used for the latter purpose, and become " running camels "

The characters distinguishing running camels are : — Very light head, carried high and horizontally; eye large and gentle; long neck; wide, sloping shoulders ; withers high, spare, horizontal, long ; haunches strong, sloping backwards ; legs thin, with prominent tendons and masses of muscle ; thigh wide, flat, long ; hocks low ; perfect balance ; coat white, skin fine ; hair short.

Training only lasts a few months, after which (in countries where it is customary) the camels are generally castrated ; this operation is always advisable, as it renders the animals more elegant and slim in shape. Camels when broken in are gradually accustomed to work.

The first part of the taming process consists in accustoming the young camel to the presence of man, which, however, begins at birth ; in fact, in order to secure part of the camel's milk, the keepers bind some of the teats, or pass a string round the udder. In districts where the attacks of wild beasts are to be expected (e. g., in Erythrea, where hyenas attack the camel, the camels are collected in the evening and to prevent their escaping, their fore-limbs are fettered, and they are forced to lie down.

The second stage of domestication commences by teaching the animal to lie down and rise at the word of command; this is done by taking advantage of the greediness of the camel and tempting him with a handful or fresh grass, barley, or durra. When this is done a long stout rope is fixed to the bar of the camel or to the halter ; the tamer holds the other end of the rope, and leads the animal to places whither it goes unwillingly or with fear, such as the most crowded and noisy parts of the town, beneath trees, on where it is more or less difficult to pass. When the camel has leant to follow his driver readily, to get up and lie down when told, to pass quietly through a crowd, to have no fear of noises, and to remain at a distance from its companions without groaning, it is said to be tamed. The taming process is the same for pack-camels and riding-camels, but the latter have to do all the manœuvres without groaning. On the other hand, the training the camel receives depends on work it has to do.

THE TRAINING OF PACK CAMELS. — When the animal has been tamed in the manner described above, its pack is put on while it is in *decubitus sternal*, and in such as way that it gets accustomed to support the load for some hours. Once this is done, on the following days the camel is made to get up, walk and eat with the pack on its back, and is walked about just in the same mannr as during the first taming-stage. Then, when the caravan starts, the driver's place is taken by an old quiet camel, to whose tail the halter of the young animal is tied ; the first journey is performed with an empty pack. For a good result to be obtained it is best for the caravan to go a long way. When the young camel is used to its pack, and to the discipline of the march, it is first given a light load and afterwards its burden is increased in proportion as it grows stronger.

TRAINING RIDING CAMELS. — The author reproduces the rules, followed by the Touaregs and Meharists of the higher districts quoted by MM. VENEL and BOUCHER in their " *Guide de l'officier mehariste*, and then he describes less gentle and progressive methods employed by the Scherof, Bischiari, and Beni-Amer tribes.

The animal to be trained is provided with a halter which is very tight round its muzzle, so that it can neither open its mouth nor scream. Two ropes are attached to the halter, one on each side ; these are fixed to the ground by means of stakes placed 2 metres apart and this obliges the animal which is kneeling down and unable to move, to keep its head down. The camel remains for 3 days in this position, without eating or drinking. On the fourth day, it is untied by two men who each take one of the ropes ; the halter is loosened from the muzzle and the animal is given food and water. Then it is led about by the two men and finally taken back to its place to be tied up again. This is done for several days, until the camel is accustomed to be handled, then it is untied for 3 or 4 hours daily and put out to grass, but it is still hobbled. Subsequently, the camel is saddled.

When it is used to the saddle, it is necessary to accustom it to the rider. The camel is held by one man only while the rider mounts ; he remains in the saddle for a longer time each day, and after a few days takes the reins himself ; the reins are the 2 ropes of the halter which always remains tight round the muzzle during exercise. For some time the young camel is guided by 2 reins, but later on only one is used. This single rope is attacked to the left side, and the animal learns to turn to the right or the left, according to the movement of the rider's hand, coupled with a slight pull of the rein. When the training is finished a ring is put into the camel's nose and a thin cord attached to it, this acts as a curb. The camel is not guided by the reins alone, but also by a long curved stick with which it is struck on the neck, but this has no effect if it is often used.

It is only when the camel is quite broken to the saddle, accustomed to obey orders, and no longer thinks of returning to its companions, that it is trained to run. First a well-trained animal must be procured, and the two camels are taught to walk together in step, the young one being led by its driver. Then it is taught to amble along in company with the other camel, the distance being increased every day, and afterwards it is

accustomed to keep up the same pace bearing a rider on its back. Finally it is exercised alone.

The Beni-Amers breed pack-camels almost exclusively ; only very special animals are set apart for riding-purposes, and these have no real training. The young camel is tied behind an old riding-camel, and exercised in running ; then, without further preparation, it is saddled and mounted ; recourse is often had to a stick in order to make it obey. Such a method of training is very faulty it turns out noisy, obstinate beasts that refuse to be separated from their companions, though otherwise these camels have often good points, being well-shaped and strong.

In the Agordat region, the author has nearly always seen the young camel with a rope round its neck ; this rope is attached to the neck of an old camel with an expert rider on its back. The young camel is made to run along tied in this fashion for at least 2 hours for several days. There a child mounts astride on its back, and holds on by the hair of the humps. When the camel has learnt a proper pace and is accustomed to a rider, it is saddled and guided by reins but always in the campany of its saddle-companion. Finally a man is substituted for the child, and once in the saddle, he soon teaches the young camel to go alone, to obey, and above all to keep the same even pace.

1019 – **Castration of the Camel.** — Droandi, I., in *L'Agricultura coloniale*, Year XIV, No. 7, pp. 289-301, figs. 4 Florence, July, 1920.

In the coastal regions of Tripolitania, neither horses nor camels are castrated, and as no care is taken in selecting animals for breeding, these districts possess no special type of camel proper to them. On the other hand, in the Central regions and especially among the Touaregs, castration is much practised, only males with exceptional qualities being kept entire. Therefore, there is a characteristic type of Touareg camel, and these people alone have succeeded in producing the riding-camel or " mehari ".

The author describes the method of castration (extirpation of the testicles) that he saw practised by the Touaregs and gives his opinion as to the best means of performing the operation. He advises the castration of all male camels not required for breeding purposes ; this is best done in the spring, because at that season, the animals are in good condition and not suffering from cold, or tormented by ticks, flies, or other insects. He describes the operation which consists in limited twisting of the seminal cord, and advises that the wounds be stitched.

FARM ENGINEERING

AGRICULTURAL MACHINERY AND IMPLEMENTS

1020 – **The Use of Tractors in Cochin-China.** — Magen, R., in the *Bulletin de l'Institut scientifique de Saïgon*, Vol. II, No. 8, pp. 225-227. Saïgon, Aug., 1920.

An article by the author has already been published in the *Review* (1). dealing with " Motorculture in the Colonies ". In this article he gives the

(1) See *R.*, June, 1920, No. 685. (*Ed.*)

results of the first agricultural experiments made with the machinery of the Agricultural Section of the Institut Scientifique.

Caterpillar tractors on the rice farms at Nang-Rên. — The work was done at the end of the dry season of 1919-1920, from April 16-30, 1920. The ground was full of cracks, very hard, and covered with rushes and other herbage. With a 3-furrow plough, using a helical mould board, an average depth of 15-20 cm., was worked. The earth was completely turned and all vegetation buried, Using second speed (6 km., per hour(20 ares can be covered per hour, only half the available power being used.

The planters of the region stated that the results were very good both in cultivated land and in virgin soil covered with thick herbage, the herbage being destroyed.

Moreover, the rice crabs and rats are exposed, enabling the coolies to kill them.

The staff of each outfit consisted of the tractor driver, the plough driver and an assistant driver in charge of the hauling.

Tractor with two driving wheels. — Very good results have been obtained in the western rice fields (at Soctrang) with the tractor having two driving wheels and a plough with a cylindrical mould-board. The work is much better than hat do e by natives ; m chanical cultivation is certainly worth while ; the chief difficulty to be overcome is the grip on the soil, which though almost perfect on ground lightly covered with vegetation, when the ground is bare, wet, and stiff, conical grips should be fixed on to the wheels.

The working speed during ploughing was 1.5 to 1.0 km., per hour, the depth maintained was 8 to 10 cm., and the petrol consumption was 5 to 6 litres per hour.

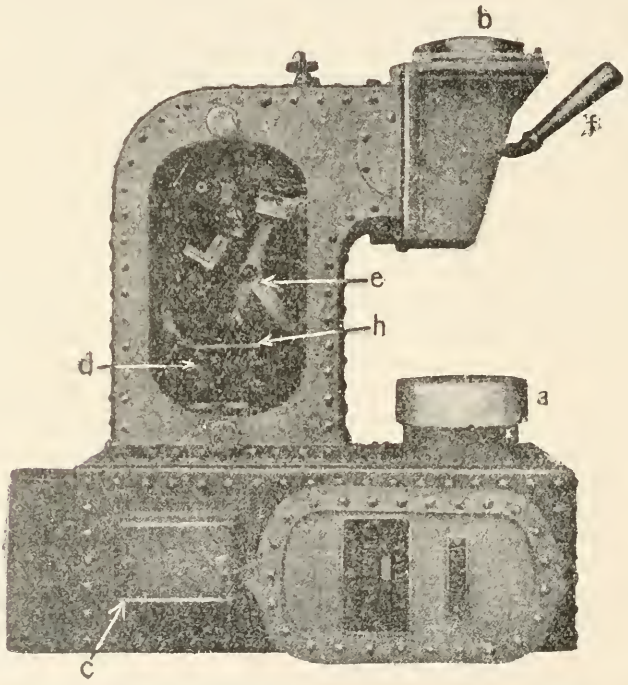
Banking up rice. — The method employed for banking-up rice is to turn up the humus and herbage over a track 2.60 metres in width with a tractor hauled plough, then to ridge up the clay sub-soil with a simple Brabant plough with a helical mould-board, otherwise the furrow will not be deep enough. The earth is now in fair clods ready for the final work, which is done by the coolies.

Various trials of tractors. — Tractors are also used for drawing wagons unloaded or loaded with paddy, or towing boats. The author stated that, the rainy season having started, these tractors continued to work in 30 cm. of water.

1021 – **Automatic Weighing and Felling Machine.** — Bertarelli, E., in the *I. I. I. Rassegna della produzione italiana, Numero specialmente dedicato all'Agricoltura all'Alimentazione ed alle Industrie derivanti*, Vol. IV, Sect. D. No. 6, p. 29, figs 2. Milan, June, 1920.

The determination of the weight of food products packed in boxes, bottles etc., and sold according to a declared weight is usually performed mechanically by fillers which measure volume and not weight. Thus, errors constantly occur, due to temperature, climatic conditions, etc. In the present article, a weighing and filling machine, to overcome these difficulties, designed by M. G. Cerlini of Parma, is described.

The machine consists of a movable stand *a* which acts as a weighbridge on which the box or boxes are put ; above it is a hopper *b* made of acid-proof bronze. The weighbridge is adjustable to the desired weight and as soon as the correct amount of produce has been fed from the hopper into the box below. the weighbridge *a* tilts and in so doing the revolving axle closes an electric circuit, through the switch box at *c*.



The closure of the circuit brings into action an electro-magnet *d* which attracts the metal rod *h* and releases at once the bell-crank which in turn operates on a spring catch which causes a double valve to fall, like a guil lotine, across the mouth of the hopper, thus stopping the fede at once. A switch (*f*) cuts off the current, the machine returns to normal, and is again ready for use.

The amount of electric current required is very small and the machine reduces manual labour to a minimum.

FARM BUILDINGS

1022 – **Construction and Fire Protection of Cotton Warehouses.** — WORKMAN, J. M., in the *United States Department of Agriculture, Bulletin* N°. 801, pp 1-79, Pl. 34, plans 7, Washington, 15 Dec. 1919.

The article includes the primary factors in warehouse design, and gives instructive details of the fire-resistive, slow burning, semi-slow burning, frame and iron-clad constructions now in use in the cotton warehouses in the United States. Useful plans are given illustrating the various construc-

tions as a basis for warehouse planning, and plates indicate the degree of success with which certain types have withstood the tests of fire.

Fire resistive construction is advised for warehouses several stories high, but the slow burning construction is sufficient for a single story warehouse.

An inexpensive method suggested of securing protection from exterior exposures is to use masonry for the exposed walls, and frame construction for walls not exposed.

RURAL ECONOMICS

1023 – **The Cost of a Vineyard in 1920 in Certain Regions of France.** — CHAROULET, A., in *La Feuille vinicole de la Gironde*, Year LXV, No. 9, p. 1, March 4; No. 10, p. 2, March 11; No. 17, p. 2, April 29. Bordeaux, 1920.

In the Libournais district. — In this article M. CHAROULET discusses the cost of a hectare of vineyard three years old, the cost of upkeep during the years following, and the yield.

First year	Fr.	
Per hectare of fallow or under cereals	8 000.00	
Digging up before planting	3 500.00	
Manuring (night-soil of farmyard manure)	1 500.00	
Superphosphate: 800 kg., at 30 fr., per 100 kg.	240.00	
Plants: 5 400 at 80 fr. per 100	4 320.00	
Planting	600.00	
Weeding and labour	200.00	
3 sulphate sprays and labour	80.00	
		18 440.00
Interest on 18 440 fr., at 6 %		1 106.00
Total cost per hectare		19 546.00

Second year	Fr.	
Carried forward	19 546.00	
Preparation	450.00	
Sulphating and sulphuring	250.00	
Replacement of 1/20 of non-sprouters, 270 plants at 80 fr., per 100	216.00	
Labour for replacing plants	24.00	
Interest on 19 546 fr., at 6 %	1 172.00	
Total cost per hectare at end of second year		21 658.00

Third year	Fr.	
Carried forward	21 658.00	
Preparation	450.00	
Replacements	80.00	
Staking: 5 400 stakes at 400 fr. per 1 000	2 160.00	
Iron wire. 3 rows No. 15, 480 kg., per hectare at 180 fr., per 100 kg.	864.00	
Pointing, stringing, supporting	250.00	
Willows for arching, labour	30.00	
Labour on stringing and wiring	250.00	

Four sulphatings :			
Spray mixture	495.00		
Labour	320.00		
		815.00	
Three sulphurings, sulphur, labour		130.00	
Interest on 21 658 fr. at 6 %		1 300.00	
Total cost at end of third year			27 987.00
Deduct : net gain 10 casks at 300 fr., per cask			3 000.00
Balance			24 987.00

Thus one hectare of vineyard cost, by the end of the third year, 24.987 fr., so that amount cultivated by the farmer, namely, five hectares has cost 124 935 fr.

Expenses per year from the 4th year	Fr.
Replacements of dead plants	200.00
Feed for one horse or ox	3 000.00
Preparation	2 500.00
Sulphating :	
120 barrels at 5 kg. = 600 kg., sulphate at 190 fr., per 100 kg.	1 149.00
300 kg., lime at 30 fr., per 100 kg.	90.00
Labour : 5 fr., per cask	600.00
Sulphur sprays :	
400 kg., sulphur at 110 fr., per kg.	440.00
Labour	100.00
Replacement of stakes, etc.	200.00
Harness, shoeing etc.	600.00
Rushes : 20 trusses at 2.50 fr.	50.00
Superphosphate 600 kg., to the hectare, i. e. 3,000 kg., at 27 fr. per 100 kg.	810.00
Manuring, etc.	500.00
Vintage : 25 fr., per cask	2 250.00
Two drawings (delivery March)	180.00
Taxes, Insurance, accidents, hail, etc.,	2 000.00
Interest on 124 935 fr., at 6 %	7 496.00
	22 156.00

The minimum expenses in the fourth and following years average, is then 22 156 fr. per annum, exclusive of the owner's time given to management.

The average yield of 5 hectares is 90 casks, which at 300 fr., per cask totals 27,000 fr., and at 400 fr., per cask totals 36 000 fr. Thus by selling at 400 fr., the cask, a gross profit of 13 844 fr., is made. Apart from the average net profit, account must be taken of sprays, casks, utensils, packing, transport, loss, disease, etc. which is by no means small.

In 1917-18-19 those who did not suffer from hailstorms notably benefited, but they had suffered badly before from long periods of oidium, phylloxera, mildew, black-rot, frosts, hailstorms, trade depression, etc.

The following table shows the increase in the working expenses of the vine growers from 1914-1919.

	1914	1919		1914	1919
Manual labour per day	3	10	Horse	1 000	4 000
Cost of ploughing per day	8	25	Cart	400	2 000
100 kg., sulphur	18	120	Pig, per 100 kilos	120	1 100
100 kg., copper sulphate	50	185	Boots	20	80
Iron sulphate	5	25	Clothes	100	400
Rushes	0.75	2.50	Meat (per pound)	1	4
Willows	4	20	Superphosphate (100 kg.)	6	27
Fodder	12	80	Sabots	125	10
Straw	7	40	Oxen	600	4 000
Plants, per thousand	60	800	Casks	14	180

In Blayais. -- The cost of vine-growing over an area of about 11 hectares worked by three vine-growers, living with their wives on the property, and having a horse and wagons:—

Cost in 1914.

Cultivation (pruning, training, etc.);
Two hoeings and twice ridging;
Two hoeings;
Raising, thinning out and topping;
Four sulphatings;
Three sulphurings.

At 75 fr., per day	2 250.00	Fr.
Cost of 500 kg. of copper sulphate at 60 fr., per 100 kg.	300.00	
Cost of 1000 kg., of sulphur at 20 fr., per 100 kg.	200.00	
Cost of manure, fertilisers, rushes, willows	400.00	
Vintage, 20 cutters and 10 men for 15 days, food included	2 000.00	
Horse feed at 2 fr., per diem for 365 days	730. 8	
Wine given to the vine growers, 2 casks per family (3 families) 6 casks at 70 fr., per cask	420.00	
Repairs and upkeep	300.00	
Taxes and insurance	400.00	
Rent of vineyard or interest on capital: 60 000 fr. at 5 %	3 000.00	
Total	10 000.00	

Cost in 1920.

Cultivation (pruning, training, etc.);
Two hoeings and ridging twice;
Two hoeings;
Raising, thinning out and topping;
Four sulphatings.

At 250 fr. per day	7 500.00	Fr.
Cost of 500 kg., of copper sulphate at 60 fr., per 100 kg.	850.00	
Cost of 1000 kg., of sulphur at 20 fr., per 100 kg.	1 000.00	
Cost of manure, fertiliser, rushes, willows	1 200.00	
Vintage time, 20 cutters and 10 labourers for 15 days feeding included	5 000.00	
Horse feed at 10 fr., per diem for 365 days.	3 650.00	
Wine given to the growers: 1/4 cask per diem at 300 fr., per cask, 7 1/2 casks.	2 250.00	
Repairs and upkeep.	1 000.00	
Taxes and insurance	500.00	
Rent of vineyard or interest on capital: 120 000 fr., at 6 %	7 200.00	
Total	30 150.00	

The Vineyards of Burgundy (Côte de Beaune). — The vineyards of Burgundy generally are very much subdivided and there are very few homesteads and vineyards combined, so that advantages such as exist on large farms are rare. The owners of these small vineyards do most of their own work, and during the busy season obtain help from those whose vineyards are not big enough to demand their whole attention. The cultivation of these small holdings is certainly the most advantageous ; there is no great expenditure of money, and it is to the direct interest of the grower to obtain the maximum yield at the minimum cost. The large properties are put either into the hands of middlemen, or kept under direct management which, although more troublesome, gives better results. In order to obtain a good idea of the cost of working a 10-hectare vineyard all the various factors concerned in its maintenance must be consider d.

If it is admitted that the vineyard has a life of about 30 years, 33 ares must be reconstituted annually, 1 hectare of 1, 2, and 3 year-old vines, is not in bearing, 8 hectares are yielding and 67 ares are resting.

Reconstruction. — This entails the following expenses :

		Fr.
Digging up : 33 ares at 1000 fr., per hectare		330.00
Grafts : 3300 grafts for 33 ares at 600 fr., per 1000		1 980.00
Staking : 560 stakes at 0.75 fr., each	420.00	
Iron wire : 300 kg., at 200 fr., per kg.	600.00	
		1 020.00
Manual labour for 8 days at 12.50 fr., per diem		100.00
Total cost of 33 ares,		3 430.00
Cost of 1 hectare roughly		10.000.00

Exploitation. — The " pinot " vines of *Bourgogne* need particular attention because of the nature of the variety, the climate and the quantity of the product.

Pruning starts with the first fine days in February, followed by tillage (3 or 4 times per year), training, which is done by removing the shoots growing on old wood, tying up, and topping. Next comes spraying with copper sulphate and manuring.

The cost of the 9 productive and non-productive hectares are as follows :

		Fr.
Pruning		1 625.00
Cultivation ; going over by hand 4 times		2 550.00
Cultivation ; ploughing four times		2 880.00
Training ; female labour		889.00
Tying and topping ; female labour		1 440.00
Sulphuring ; manual labour, 2 treatments		375.00
Sulphur ; 50 kg., per hectare at about 100 fr., per kg.		500.00
Sulphating ; manual labour, 3 treatments		1 050.00
Sulphate, 500 kg., at 200 fr.	1 000.00	
Lime or sulphur, 330 kg., at 30 fr.	100.00	
		1 100.00
Manures, fertilisers, 1/4 manuring		1 800.00
Transport of materials, manure, etc		1 000.00
Total cost for 9 hectares		15 200.00
Cost per hectare		1 700.00

The figures just stated are purely theoretical, and in practice they should be increased by at least ⅓ and, because of the scarcity of labour, the staff must be kept at full strength during the slack season, when only odd-jobs can be done. Nor has the cost of repairs to the tools, sprayers, and wagons, or the insurance taxes, or general treatment been included.

In short, it may be stated that the total cost per hectare is as follows:

	Fr.
I. — Cost of reconstruction (theoretical)	10 000
Increased by 1/3	3 300
Total	13 300
	Fr.
II. — Cost of exploitation	1 700
Increased by 1/3	560
Total	2 260
	Fr.
III. — Interest on Capital at 5 %	1 000

The value of the land for money interest and amortisation of the invested capital is calculated on an average of 20,000 fr., per vineyard of the best vintages, a value exceeded in the past but not guaranteed to day for an immediate liquidation.

The yield of the large Burgundy vineyards under favourable circumstances hardly ever averages more than 13 hectolitres of wine per hectare.

AGRICULTURAL INDUSTRIES

INDUSTRIES DEPENDING ON PLANT PRODUCTS

1024 – **Detection of Cider in Wine.** — Garino-Canina (R. Stazione enologica sperimentale d'Asti), in the *Giornale vinicolo italiano*, Year XLVI, Nos. 20-21, pp. 164-166. Casale Monferrato, June 6, 1920.

The author first briefly treats of the physiological and diagnostic properties of the gummy, pectic substances common to all fermented beverages, and in order to show how the presence of cider may be detected in wine, he describes the methods used by Scurti, A. Müntz and E. Laine for determining them. Afterwards he gives the data of his analyses of both grape and apple musts.

Table I. — *Analyses of grape musts.*

	Alcohol	Dry Extract	Gummy and pectic substances
Favorita must 1919	—	24.00	0.80
Ordinary red wine 1919	11.50	23.40	1.94
» » of the south 1919	13.00	27.00	3.84
Old red wine 1915	10.25	21.00	1.85
Fine red wine (Barbera) 1919	12.25	25.00	1.91
Dry white wine. 1919	11.75	20.00	1.75
Sweet » » 1919	6.25	26.00	2.58
Red Piquette	7.30	12.50	1.40

Table II gives the composition of sweet and of acid apple must obtained from 10 kg., of apples that were cut into quarters, left to stand for 24 hours, and then well pounded with a wooden pestle before being pressed.

TABLE II. — *Analysis of apple must.*

Density of must at $^{15}/_{15}$	1.0466	Total acidity in cc. N/1 per 1000	73.50
Reducing sugars gm., per 1000	83.20	Combined acidity per 1000	23.00
Saccarose	12.40	Total tartric acid	0.00
Extract	30.00	» malic »	90.20
Extract, sugars deducted	125.00	» tannic »	0.30
Pectic substances	0.990	Total nitrogen (N)	0.112
Ash	2.40	Total phosphorus (PO^4)	0.100

A certain portion of this must, after being thoroughly sterilised, was sown with yeast that had been selected for Champagne, on November, 23, 1919; 12 days later it was filtered once, and on analysis, gave the results set forth in Table III.

It is not possible to make a serious comparison based on the pectic and gummy substances alone, for as may be seen, they are present in very small quantities. Tartaric acid, though not occurring naturally in apple-must, may have been added, by way of adulteration, and the saccharose afterwards found in apple must becomes inverted later and disappears during the fermentation process.

Density of cider at $^{15}/_{15}$	0.9993	Total acidity in cc. N/1 per 1000	80
» » distilled cider	0.9915	» volatile acidity	3.65
Residue brought up to volume	1.0084	» combined acidity	27.09
Alcohol in volume %	6	Total tartaric acid	0.00
Extract in gm., per 1000	20.16	» malic »	73.00
Reducing sugars in gm., 1000	0.97	» lactic »	4.60
» » after inversion	1.55	» tannic »	0.25
Dry extract in gm., per 1000	18.61	» succinic »	7.80
Pectic substances	0.960	Total nitrogen (N)	0.0999
Ash in gm., per 1000	2.15	Total phosphorus (PO^4)	0.100

The author thinks that the best method to adopt in these investigations is the one used by MM. MEDINGEN and MICHEL; 15 cc. of wine are tested by adding a concentrated solution of nitrates of sodium and potassium. If there is cider present, the liquid assumes a colour varying from dark-green to blackish-brown, and after a short time, blackish flashes appear; these are insoluble in water and alcohol but soluble in alkalis, in which they produce a red coloration.

In white wines made from grapes, this treatment gives rise to a coloration varying from orange-yellow to dark-yellow, but no precipitate is formed. Sulphurous acid retards the reaction, which, however, appears more clearly after a certain time. Pasteurisation is without any effect.

This test is less decisive in the case of red wines, owing to the colouring matter present, which on being acted upon by strong acid, makes the wine turbid, and produces a brown deposit, thus masking the colour reaction to a large extent.

1025 – **Cider from Wild Apples of Tran-Ninh (Laos Indo-China).** — See No. 989 of this *Review*.

1026 – **The Use of Rice in Distilling and Brewing.** — SAMUEL, M. (Chef de fabrication à la Société Française des Distilleries d'Indochine), in the *Bulletin agricole de l'Institut Scientifique de Saïgon*, Year II, No. 4, pp. 109-116, plates 2. Saïgon, April, 1920.

In those countries of the Far East where rice is grown, this cereal is used as raw material for the manufacture of alcoholic beverages, especially brandy, saké (Japanese beer), choum-choum (Indo-Chinese brandy) etc. European manufacturers have installed themselves side by side with native producers, whose methods are always of an empirical nature.

The author makes a comparative study of the native methods and modern methods. He also studies the products obtained by both: — Alcohol and its by-products (rice-vinegar, acetone, and butyl alcohol), and discusses the question of using rice in brewing pale ales. The rice is employed as a substitute for malt, and sometimes replaces it to the extent of nearly 30 %.

1027 – **Beet Syrup.** — GRÉGOIRE, A. (Directeur de la Station de Chimie et de Physique agricoles de Gembloux), in *Annales de Gembloux*, Year 26, Part 6, pp. 265-271. Brussels, June, 1920.

The author advocates a more extensive use of beet syrup, which is a very nutritive, tasty, wholesome and economical article of food. It would be possible, with suitable methods, to obtain 12 000 kg., of syrup per hectare of beets. At first the slightly bitter taste of the syrup is not very agreeable, but persons soon get accustomed to it.

The manufacture of beet syrup is not a new thing, it has long been made in those districts where apple syrup is used and is employed as a substitute for the latter. This is especially the case in the Province of Liège and in Westphalia, but as a rule it has remained a small industry that is little studied, and badly provided with apparatus.

The syrup factories at present use the sugar beet, which, in the author's opinion, is a great mistake as the raw material should consist of the semi-sugar beet, which has a high yield and produces a non-crystallisable syrup containing many impurities, especially pectic substances that give its special character to the product and at the same time, increase the output. Further the semi-sugar beet furnishes more than twice as much pulp per unit of surface than the sugar-beet, and its pulp, which is easily dried, is an excellent stock feed.

In making the syrup, it is necessary as far as possible, to prevent the cell contents (probably albumen) from finding their way into the syrup, as they impart to it a bitter flavour. In order to obtain syrups rich in pectic

substances, the beets must be boiled and the juice extracted by pressure.

Two processes are used. In one, the beets after being well cleaned, are cooked in a small quantity of water, then cut into pieces by a machine, and the mass is finally passed through the press. In the other, the roots are cut up into long narrow pieces or thin slices which are then boiled in water and subjected to pressure. The author remarks that the second process is probably preferable from the point of view of the quality of the product.

In the experiments it was found that by a second treatment of the residue of the first pressing and the addition of the juice from the first boiling, the yield of raw material is increased about 2.5 %. If this method is adopted, it is clear that the second extraction mentioned above will give a better result, and less of the cell contents will pass into the juice.

With a view to leaving behind in the pulp the nitrogenous substances causing the bitterness of the syrup, the author suggests trying the method employed by STEFFEN in sugar-making, that is to say, to allow the pieces or thin slices to fall directly into the boiling juice as they leave the rootcutter. In this manner the nitrogenous substances coagulate better.

With regard to a press, a hydraulic press, or one of the automatic mechanical presses now used for grapes can be employed.

In order to obtain a really fine product, the juice obtained should be purified in order to remove the pulp fragments, a small quantity of which is sometimes present, and also such soil as has not been completely washed off the roots. For this purpose a continuous centrifugal machine of the type of the BOURGMEISTER and WAIN cream-separators might be tried.

The juice should be evaporated by direct heating. This slight caramelling produced under these conditions is necessary to give the syrup its characteristic taste and aroma. A triple effect evaporator would perhaps give a product of better appearance, but less tasty. But the impure liquid is very effervescent, and treatment in a triple effect evaporator is not without difficulties.

In his experiments, the author used an apparatus calculated to hasten evaporation, while keeping the temperature of the liquid lower. At the same time, effervescence was prevented. This apparatus, of which the object was to increase the evaporating surface, was simply composed of an endless chain made of sheet-iron plates united by rings. The chain was mounted on a drum rotated by a handle, the free end being plunged into the liquid. Evaporation,when effected in this manner, takes less time, and the quality of the syrup is greatly improved.

The yield of syrup naturally varies with the quality of the beets used, the way they are treated, and also the concentration of the final product. It may be as much as 17 % of the raw material.

The syrup is put into little bowls, or earthen-ware pots. If sufficiently concentrated, it keeps indefinitely and even improves with age.

1028 – **Maize Sugar** (1). — VIEILLARD, P. (Directeur du Laboratoire de Génétique de l'Institut Scientifique de l'Indochine) and TRAN-VAN-HUU (Assistant at the Same Laboratory), in the *Bulletin agricole de l'Institut Scientifique de Saïgon*, Year II, No. 4, pp. 106-108. Saïgon, April, 1920.

The question of maize sugar has been studied since the beginning of the twentieth century in the United States, and it has also been investigated in India and South Africa. The preliminary experiments carried out in these countiries have shown that simply by removing the female ears at the moment when the seeds are about to become milky, the stem becomes full of sweet sap containing from 9 to 14 % of sugar, though normally there is but very little glucose and no saccharose in the stem of the maize.

The authors have made experiments which confirm these data. They consider that the sugar represents the reserve products elaborated by the plant, and that the removal of the ears prevents the sugar being transformed into starch in the grain.

The author's experiments were carried out at the Phumy Selection Garden, and were made on maize sown by M. CARLE for selection; therefore, in order not to interfere with his work, only 4 or 5 stems per lot were used. The dates of the removal of the heads and of the harvest were chosen so as to allow from 7 to 34 days' interval, according to the lot, between these operations.

The analyses were made by M. VERNET, Director of the Chemical Laboratory at Saïgon, as soon as possible after the harvest (in the case of lot 3, six days were allowed to elapse between the gathering of the stalks and their being sent for analysis, which would perhaps explain certain anomalies).

The accompanying table which gives the results of the analyses classified in ascending order of the interval between the removal of the heads and harvest, shows that if the maize stem yields much less sugary juice than the sugar-cane (the yield being only 38 to 48 % in the case of the former, as against 80 % in that of the latter) the bagasse contains a very large amount of sugar that could be extracted by maceration or diffusion. The total yield of saccharose, as compared with the weight of the stem stripped of its leaves, varies from 7.25 to 10.27 %, whereas that of the glucose varies from 1.33 to 3.11 %.

If the saccharose were extracted by the ordinary processes employed in sugar-factories, only ⅓ of the amount would be obtained, since the large quantities of ash and glucose present would prevent the crystallisation of the sugar. It is, however, quite possible that new processes could be devised.

Further, these difficulties would not exist, if it were a question of manufacturing alcohol; for this purpose, the total sugar content, saccharose + glucose would alone have to be considered.

The total sugar obtained by the authors from the fifth lot amounted to 13.38 % of the weight of the stems. It may be that the optimum

(1) See *R.*, Dec., 1914, No. 1104 and *R.*, May, 1915, No. 540. (*Ed.*)

interval between the removal of the female heads and the harvest is longer than 34 days, and that a still larger yield might be obtained by prolonging it. The authors intend to continue their experiments.

Results of the Analysis.

In plantations supplying a factory where sugar, and alcohol are both made, experiments in growing sugar-maize, should be made, if only with a view to using the distillery plant during the dead season. In Cochin-China, maize is sown, according to the districts, either in November and December, or in April and May. The sugar-maize would therefore be harvested in February and March and in July and August, and as the sugar-canes are gathered from November to February, the two maize crops could be intercalated in the period when the sugar-canes are left to rest.

Although it is difficult to estimate *a priori* the alcohol yield of maize per hectare, at least 20 000 kg., of stripped stems can be reckoned per hectare, and taking the average sugar yield at 10 % of this weight, we should have 2 000 kg., of sugar or 1 000 kg., of alcohol at 100°, allowing for losses.

These yields could be greatly increased by improved cultural methods and the use of fertilisers. It most also be taken remembered that, though they seem small in comparison with the yield of the sugar-cane, these returns are obtained 100 days after the maize is sown, whereas the sugar-cane is only ripe, at the earliest, 8 months after the cuttings are planted out.

1029 – **Tunisian Olive Oil ; Detection of Tea Oil in Olive Oil.** — I. Dybowsky, J. and II. Millian, E., in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. VI, No. 23, pp. 577-581. Paris, June 16, 1920.

I. — The olive tree was not grown at all in Tunis before that country became a French Protectorate. Since then, the French, inspired by the work of the ancient Romans, have popularised the olive industry, which has become of very great importance.

Large areas of land sold by the Administration of Agriculture at 10 francs per hectare, on the sole condition that 10 olive trees should be planted, have become valuable beyond the most sanguine expectations. With the expenditure of a few hundred francs, a hectare was planted with 18 olive trees, which it supported till the time of bearing. The foliage of the trees was very fine, and the average yield amounted to from 8 to 10 litres per tree.

At the present time, as prices have risen to 6 and 7 fr. per litre, each tree is worth several hundred francs, The olive groves of the south have acquired a value that exceeds the most optimistic previsions.

There is still unoccupied ground, where more olive-trees could be planted.

In 1917, Tunis produced 24 400 000 litres of oil ; in 1919, 21 433 000 litres : this includes olive-oil of first quality and oil from olive-pomace.

As all matters relating to this industry are of great interest, M. Dybowsky made a communication to M. Millian on the subject of the adulteration of olive oil by the addition of tea oil, which is said to be practised in England.

Care must be taken in France to prevent the olive-oil from French North Africa from being tampered with, lest it should lose its well-deserved reputation. The following is a summary of the communication in question.

II. — The adulteration of olive oil with tea oil, which greatly resembles the former in its physical and chemical characters, has been greatly facilitated by the progress made in industrial rectification and deodorisation, and much encouraged by the high price commanded by olive oil. Of the various methods of detecting this fraud, 3 alone are worth mentioning :

(1) 50 % *Mixture.* — The difference in the fatty acid content permits of the detection of the addition of 50 % or more of tea oil (this is not a very reliable method, as the fatty acid content of olive-oil itself is not invariable).

(2) 10-20 % *Mixture.* — *Action of nitrous fumes.* — Test-tube 2.5 cm. in diameter ; 20 gm. oil ; 6 drops sulphuric acid at 66° C. ; shake for a minute ; 9 drops nitric acid at 40° C. ; shake for a minute ; plunge the tube into boiling water for 5 minutes ; put the tube into a cold bath at from 8 to 10° C. Examine the contents after 2 hours. The most interesting results are as follows :

(*a*) Isometry is complete with 20 % mixture, and the mass remains entirely liquid.

(*b*) If 10 % of tea oil is added, the mixture solidifies, but the mass has not the consistency and hardness obtained with pure olive oil.

(3) 5 % *Mixture.* — *Characteristic Reaction.* — This is obtained by using the old method adopted by CAILLETET : 5 cc. of pure sulphuric acid at 66° C. ; 3 cc. nitric acid at 40° C. ; 3 cc. water ; shake vigorously to mix ; add 4 cc. oil ; shake for 30 seconds ; plunge the test tube into water at 5° C. for 5 minutes ; leave standing in water for 15 minutes and then examine :

Name of oils	Oily stratium	Acid stratum
Pure olive oils	Straw-colour, clear	Colourless
Pure tea oil	Sooty-black, turbid	Do
Olive oil 90, tea oil 10 %	Dirty dark chestnut	Do
Olive oil 95, tea oil 5 %	Dark straw-colour, turbid	Do

By this method, all commercial quantities of tea oil in olive oil can be rapidly and surely detected.

1030 – **The Distillation of *Blumea balsamifera* (Camphreaceae).** — BUSSY, P. (Chimiste principal du Laboratoire de Chimie de l'Institut Scientifique de l'Indochine), in the *Bulletin agricole de l'Institut Scientifique de Saïgon*, Year II, No. 6, pp. 181-182. Saigon, June, 1920.

The apparatus used by the author for distilling this plant, and which was made in the above-mentioned laboratory, only differs from the ordinary still in the form of its condenser ; this consists of the following parts :

(1) An external cylinder of about 1 metre in height, and with an external diameter of 30 cm. It has a double wall, the cold water circulating in the space between the walls ; this cylinder is provided at the ends

with conical detachable bottoms forming hydraulic joints ; both are supplied with two tubes for attaching to the water supply.

(2) A cylinder 15 cm. in diameter, in which cold water also circulates ; this cylinder, which is placed inside the other, is surrounded by discs that are incorporated with it ; on these discs are placed covers acting as baffles.

The apparatus is put vertically on a stand and connected with an ordinary still with hydraulic joints.

The object of the discs attached to the central cylinder is to retard the movement of the vapours and to lengthen the time of their passage through the apparatus, thus ensuring more complete condensation.

The camphor sublimes in heating and becomes deposited, owing to the cooling action, on the sides of the centre cylinder and on the first discs.

The essential oil and the water of condensation flow away through the lower tube. These liquids are caught in a Florence flask in which they separate.

The distillation experiment carried out by the author at Nui-Chua-Chang, in the Province of Bienhoa, with this condenser attacked to a DEROY still, gave the following results with fresh leaves :

Weight of fresh leaves distilled	54 kg.
Crystallised camphor obtained	0.250
Essential oil collected.	0.025
Camphor yield per 1 000 of fresh leaves	4.63
Yield of essential oil per 1 000 of fresh leaves	0.83

This camphor, which is of laevo-rotatory Borneol, when treated with dilute nitric acid, gave an oxidisation product with the smell of ordinary camphor.

The essential oil is of a fine amber colour. On cooling, it deposits crystallised camphor.

1031 – Concentration of Tobacco Extracts by Freezing. — FERRETTI, U., in the *Rivista del Freddo*. Year VI, No. 3, p. 87. Rome, March. 1920.

The author, quotes the work of PARENTY and MONTI (1) on the concentration of vegetable extracts by freezing; the last-named author has shown the importance of this method to Italian industry; he has invented and patented a rotary concentration, which according to the author, gives much higher yields than those given by the usual system employing ice,

The author advised that the MONTI system should be used for concentrating tobacco extracts by the Italian Department of State monopolies, for, taking into consideration the present price of coal, it is much quicker and cheaper, than concentration by evaporation. With a MONTI direct expansion rotary freezer, 500 kg., of ice is separated per hour from 1000 litres of solution. The MONTI apparatus has been in use at the oenological station at Asti for several years and has been utilised with great success in various industries, e. g., for the concentration of must.

1034 – **The Development of Acidity in Milk** (1). — STEUART, D. W. (University College. Cardiff, Wales), in *The Journal of Dairy Science*. Vol. III, No. 1, pp. 52-59, Bibliogr, of 7 publications. Baltimore, Jan. 1920.

These experiments were designed by the author to cast some light on the bacteriology of the keeping properties of butter, and of the ripening of cheese. The cause of the natural acidity of milk had been previously proved as not due to lactic acid. A fairly complete summary of earlier experiments on the subject will be found in LAFAR'S. *Handbuch der Technischen Mykologie*, and in Dr. FASCETTI'S, original article in our *Review*, February 1915.

When milk is retained for some time the acidity increase is due to the production of acids from the milk sugar by bacteria. After intermediate phases when the acidity reaches about 0.3 %, the milk will curdle on boiling, and when it reaches between 0.60 to 0.86 %, the milk coagulates spontaneously.

The author shows as a result of his own experiments, the change in the acidity of milks retained at three different temperatures in the accompanying graphs. In cold storage it should be noted that the acidity increases somewhat slowly and the maximum attained is about 1 %. At blood heat the acidity increases very much quicker and may attain to as much as 3 % in one week. The lowest acidity reached in one week at this temperature was 1.6 %. At room temperature the acidity increases at an intermediate pace, but the maximum attained varies very greatly, any thing from 1 to over 3 %. The explanation lies in the type of germ encouraged.

The principal acid producing bacteria in milk may be conveniently divided into four groups (LÖHNIS) as follows :

(1) *Lactic streptococci* ; a good strong culture of these germs, seeded into pasteurised milk should produce an acidity of 1 % in 12 hours, at 72° F (1 % inoculation).

(2) *Intestinal lactic bacteria*, which originate from excrement. They are over numerous in milk which has been ripened without the aid of a good starter.

(3) *Lactobacilli* (including *Bacillus bulgaricus*). At 1 %, inoculation of " lactigen " into pasteurised milk will produce about 1.2 % acidity in 12 hours at 98° F.

(4) *Lactic micrococci*, principally found in milk held in cold storage.

All four groups are found in commercial milks, and the author states that it is because the *lactobacilli* develop quickly and strongly that milk at blood heat develops so much acidity. They do not develop in cold storage, and it is not certain at room temperature. When the acidity of

(1) See *R.*, Sept. 1918, No. 1046 and *R.*, Dec. 1918, No. 1418. (*Ed.*)

milk exceeds 1.25 %, it can usually be proved that they are present and when they do develop, the high acidity produced favours the growth of yeasts, which subsequently reduce the acidity.

Experiments with subcultures from milks held in cold storage, at room temperature and at 98° F, indicate similar results, and agree with the results obtained by ORLA JENSEN, ROSENGREN and others on the bacteriology of butter.

Other organisms sometimes taking part in the final reduction of acidities were moulds, *Oidium lactis, Penicillium*, etc.

Experiments with pasteurised milk showed that the 4 groups of lactic bacteria do not form spores, and so do not survive pasteurisation. When milk is pasteurised, spore forming rods survive. When held subsequently at almost any temperature within reasonable limits, these milks finally curdle and at that time may or may not show an increase of acidity compared with fresh milk. The curd, however, begins to digest and the acidity of the milk will then rise.

1035 – **Decomposition of Hydrogen Peroxide by Micro-Organisms Extracted from Pasteurised Milk.** — FOUASSIER, M., in the *Comptes rendus de l'Académie des Sciences*, Vol. CLXX, No. 2, pp. 145-147. Paris, Jan. 12, 1920.

It is well known that hydrogen peroxide is decomposed when added to fresh milk. This is brought about by the influence of diverse catalases, some of which, physiological and some microbial. Amongst the latter the catalytic power of lactic ferments in particular has been carefully investigated, chiefly by SARTHOU (*Comptes rendus de l'Académie des Sciences*, Vol. CL, pp. 119, 1910). Whatever may be the origin of these catalases, they are destroyed, at least as regards their effects by pasteurisation. If to increase the length of preservation, hydrogen peroxide is added to milk which has just been pasteurised, the hydrogen peroxide disappears after a few hours and that, so the author has found, before the acidity of the milk thus treated shows any modification. It thus seems reasonable to suppose that in the pasteurised milk there are germs which resist pasteurisation and possess a strong catalytic action.

This is what the author tried to establish and his results are given in this article.

Cultures were made on lactose agar with several pasteurised milks in daily use. Besides the lactic ferments, the author has isolated several organisms, amongst which *Bacillus subtilis, Tyrothrix tenuis, Oidium lactis*, and a lactic yeast, have been met most frequently. In order to determine the comparative action of these organisms on hydrogen peroxide the pure cultures were made on a liquid lactose medium, peptonised and sterilised in a series of test tubes. One sample was kept as a control, one received 1 % of hydrogen peroxide of 12 volume strength, another received 4 % of hydrogen peroxide, then they were all kept to 30° C. in an incubator.

In all the tubes in which organisms developed, no hydrogen peroxide was found, but the opposite was the case when no organisms had developed.

B. subtilis and *Tyrothrix*, which are active catalysers, rapidly decomposed the hydrogen peroxide, even when it was added in large quantities, with the same intensity as the control.

The other organisms exhibited an increasingly feeble catalytic action, falling to zero for the lactic ferments under the experimental conditions. Thus, the smallest addition of hydrogen peroxide was sufficient to prevent the development of this ferment. It was indisputably proved in these experiments, that decompcsition was brought about by diastatic action. This action was manifested even after the culture medium was filtered through a porcelain " candle " and was only arrested when heated to 80° C.

The organisms with the strongest catalytic power are those which produce spores which resist pasteurisation.

1036 – **Experiments with, and Practical Application of Heat Sterilisation for All Parts of Milking Machines.** — HART, G. H. and STABLER, W. H. (Department of Veterinary Science; University of California. Berkeley, California), in the *Journal of Dairy Science*, Vol. III, No. I, pp. 33-51, tables 7. Bibliog. of 13 publications. Baltimore, Jan. 1920.

A great many experiments have been initiated to ascertain the mechanical difficulties and the relative production that can be secured with the use of milking machines (1) as compared with hand milking. The authors have, however, devoted their attention to ascertaining the best method of eliminating excessive numbers of bacteria in machine drawn milk. They mention the most important works already published on bacteria in machine drawn milk and the use of various sterilising agents. Results are then given of tests carried out by the authors with C. H. Mc CHARLES (Chemist of State Food and Drug Laboratory) to show the reduction in chlorine content by oxidation in the presence of milk or rubber.

Three 1 ½ gallon glass jars were each partially filled with one gallon of water to which chlorine solution was added in the proportion of 3 or to 5 gallons. This is about the proportion usually recommended for milking machine parts. The chlorine solution before dilution showed 2.35 % available chlorine, and when added to the water in the above proportion, the fluid in the jars contained about one part of available chlorine to each 10,000 parts of water. Jar I was not disturbed; Jar 2 had 2 cc. of milk added daily; Jar 3 had some rubber tubing placed in it. Titrations for chlorine content were made daily.

The tests show that both milk and rubber reduce the chlorine content of solutions containing it and the more milk residue that adheres to the tubing, the quicker the chlorine becomes utilised.

The original plan of sterilisation of the parts of the dairy in question was to put the tubes and teat cups in a low pressure steam steriliser, but depreciation of the rubber was rapid : the authors installed instead a gal-

(1) See *R.*, May 1917, No. 483, Aug. 1917, No. 763; Sept. 1917, No. 859; Nov. 1917, No. 1074; Dec. 1917, No. 1208; Jan. 1918, No. 71; Feb. 1918, No 221, June 1918, No. 695. (*Ed.*)

vanised iron tank 4 feet long 1 foot wide and 1 ½ feet deep, without any lid, and the parts placed in water in the tank and the temperature raised by steam to between 160° and 180° F. for 15 to 20 minutes.

Tests were conducted by running sterile water through the apparatus to be tested. The amount of water used in each test was 100 cc.

Milk counts over 7 days showed that sterilisation was sufficient to produce a milk well under 25,000 bacteria per cc., the limit for the grade.

The tinware on the ranch is regularly sterilised in an autoclave under pressure. In all, 113 samples of machine milked milk was collected and counted two samples were over 10,000; and the highest being 18,000.

The general superiority and efficiency of heat sterilisation is demonstrated and that it is the only way to successfully sterilise milking machine rubber parts under ordinary ranch conditions. Where it has been regularly done, no increased trouble with mammites has ever developed as a result of installing machines, and as low a bacterial count milk can be produced with milking machines as by hand milking. No chemical solution has been found successfully to accomplish these results under practical conditions.

1037 – **The Development, Production, and Trade of Italian Dairy Products.** — FASCETTI, G., in the *Giornale di Chimica Industriale ed Applicata*, Year II, No. 3, pp. 137-144, + 1 Diagr. Milan, March, 1920.

During the last 40 years the Italian cheese industry has made considerable and rapid progress in international trade, as is shown in the appended tables, and as this progress has only received a temporary set-back owing to the war, it seems opportune to offer a few remarks on the importance of the export of dairy produce and of considerations regarding the importing countries.

It is important to notice that the chief powers, such as the United Kingdom, France, North and South America, Austria, and Germany bought dairy produce on the Italian markets. England limited her demands to two principle articles, viz., Gorgonzola cheese and butter. This absorbed nearly half the total export of these products, but demanded but little in the way of herd cheeses such as " Grana " or " Caciocavallo ", which are in great demand in America. There is no doubt that the fault lies with the traders, and it is to be hoped that the industry will study and use the best means of putting before the British public the excellent qualities of the Grana and Provoloni cheeses. As the British have a special prediliction for fermented and piquant cheeses made from sheep's milk, like Roquefort, or from cow's milk, like Gorgonzola, they should most certainly like " Pecorino ", made from goats' milk. This last is a great table delicacy in North America, where the consumption amounts to 60 000 quintals every year. Italy has been very successful in the markets with imitation Swiss cheeses, of which France absorbs half the total export.

Year	Butter quintals	Cheese quintals

From this table, it is evident that Italy has made many openings in international commerce and is in a very favourable position, both agricultural and technical for the re-establishment her cheese export.

Already in 1919 there was an increase in exports compared with 1918, but unfortunately apthic fever in its worst form attacked the stock, and only the young were excluded from slaughter by Government order. However, the cheese production in 1919 was only slightly below that or 1918 and that for 1920 promises very well. Indeed the exports should rise by $^1/_5$ above those of 1919 and soon Italian dairy products should regain their favourable position in the international markets from which they had been cut off for more than 4 years (1).

1038 – **The Influence of Humidity Upon the Strength and Elasticity of Wool Fibre.** — HARDY, J. I. (Associate Wool Specialist, Wyoming Agricultural Experiment Station), in *The Journal of Agricultural Research*, Vol. XIX, No. 2, pp. 55-62, figs. 4, Washington, D. C., April 15, 1920.

In a preceding issue of this Journal the author published a preliminary report of his work on the influence of humidity upon the strength and elasticity of wool fibre (2) ; in the present article further studies are reported concerning scoured wool. As in the previous work, all samples were tested with a MACKENZIE fibre testing machine. Each sample has been extracted with ether and washed with hot water and tested at each of 5 relative humidities, 40, 50, 60, 70 and 80 %. The results are given in the Tables and may be summarised as follows :

The tensile strength of wool increases with the decrease in the diameter of the wool fibre. Fine wool has a breaking strength varying more

(1) See *R.*, 1914, pp. 842-849 note by Prof. C. BESANA entitled " The Dairy Industry in Italy at the Present Time. (*Ed.*)

(2) See *R.*, June, 1919, No. 780. (*Ed.*)

closely with the first than with the second power of the diameter. Coarse wool has a breaking strength varying with a figure which lies between the first and second powers of the diameter.

It is necessary to mix samples carefully before testing in a testing machine, if the best results are to be obtained.

The breaking strength and tensile strength of both scoured and unscoured wool decrease with an increase in relative humidity from 40 to 80 %, and show a tendency to increase from this point to that of saturation.

The elasticity of scoured and unscoured wool, increases with an increase in relative humidity from 40 to 80 %, and decreases from this point to that of saturation.

1039 – **The Rôle of Pentose-Forming Bacteria in the Production of Maize Silage.** — Peterson, W. H. and Fred, E. B. (Department of Agricultural Chemistry and Agricultural Bacteriology, University of Wisconsin. Madison), in *The Journal of Biological Chemistry*, Vol. XLI, No. 2, pp. 181-186. Baltimore, M. D., Feb. 1920.

The xylose-fermenting bacteria are present in large numbers in silage crops. Their optimum temperature for fermentation is about 27° C, which is approximately the average temperature found in maize silage ; in relation to oxygen supply, the pentose fermenters are most active when subjected to a low oxygen tension, and will ferment xylose under anaerobic conditions. They are particularly characterised by the ease and rapidity with which they ferment pentoses, producing chiefly acetic and lactic acids.

In the present article, the authors report on the results obtained by the inoculation of maize fodder at the time it was placed in the silo, including the micro-organisms present at the time.

The results of these experiments indicate the following points :

The pentose-fermenting bacteria are capable of bringing about decided changes in raw or in sterilised maize tissue. When added to raw maize fodder, these organisms are able to compete with the fermentation processes which normally occur. In sterilised silage, the pentose fermenters develop rapidly, and produce the substances commonly found in good silage ; *viz.* acetic acid, lactic acid, ethyl alcohol, and carbon dioxide. From the standpoint of temperature, oxygen sypply, and fermentable compounds, silage offers a suitable medium for the growth of pentose fermenters. This accounts for the fact that the authors conclude that these bacteria play an important part in the formation of maize silage.

1040 – **Effect of Humidity and Weather on the Ripening of Stored Apples and Pears** — See No. 954 of this *Review*.

1041 – **Export of Rice from Cochin-China to China and France.** — See No. 965 of this *Review*.

1042 – **Suggested Improvements in Methods of Selling Cotton Based on a Comparison of Cotton Producers and Consumer's Prices.** — McConnel, O. G. (Specialist in Cotton Marketing, Bureau of Markets), in *U. S. Department of Agriculture, Department Circular* No. 56, pp. 1-8. Washington, D. C., August, 1919.

Data prepared in accordance with a co-operative arrangement between the North Carolina Department of Agriculture, the North Caroline State College of Agriculture and Engineering and the Bureau of Markets of the United States Department of Agriculture, based on a comparison of cotton producers prices and those paid by the consuming mills for the same grades and staples of cotton on the same days.

During the period from December 14, 1916 to May 1, 1918, over 15000 samples were collected and specified and a form was furnished showing the date of purchase, price paid on delivery, and stipulated grade and staple. During the same period the county classers in the State classed about 120,000 bales of cotton for producers in North Carolina, and obtained information as to the date and place of sale, and the price received for a large portion of this cotton.

A comparison of all coinciding sales selected from the sale of approximately 200,000 bales sold in the States of North Carolina, South Carolina, and Georgia showed that the mills paid an average of $11.60 per bale more than the average price received by the farmer on the same date for cotton of the same grade and staple. Whether sold through buyers or dealers or direct to the mills, there are usually certain legitimate expenses of selling which would reduce the actual saving below the amount indicated, less $2.50 for freight and other charges per bale.

The suggested improvements in methods of selling cotton include the following points : farmers should grow only the quality of cotton such as the mills need; a compress and ample storage and shed space should be provided ; a disinterested classing service and cooperative selling should be instituted ; better ginning facilities are needed ; less damaged cotton should be shipped to the mills ; varieties that produce a better staple should be grown.

DISEASES OF PLANTS

DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS

GENERAL

1043 – **Researches on the Presence of the Hyphomycete *Endoconidium temulentum* in the Seed of Darnel.** — D'Ippolito, J., in *La Riforma agraria*, Year I, No. 7, pp. 259-262. Parma, July, 1920.

MM. Guerin and Vogl discovered between the integument and the aleurone layer of the seed of darnel (*Lolium temulentum*), a mycelium that has since been the subject of many researches, the results of which, however, have been far from agreeing. The fungus was given the name of *Endoconidium temulentum*, but was subsequently identified as *Fusarium metachroum.*

According to some writers, the seeds of *L. temulentum* are always and everywhere infested by this fungus; while others maintain that whereas seeds from some localities are infected, there are certain places where the seeds are always free from the hyphomycete.

The author set himself the task of ascertaining whether the immunity enjoyed by certain seeds is due to the hyphae being unable to penetrate into the tissues, owing to some special power of resistance characterising the latter, or whether these seeds belong to some particular immune variety of darnel hitherto confused with another kind which is subject to the disease. He therefore tried to ascertain whether the healthy seeds came from completely immuned plants, or only from infected individuals with some isolated immune seeds, and found that all seedlings grown from healthy seeds were free from disease (some of these seeds came from Rome and others from Russia), whereas those raised from diseased seeds were wholly infected, or partially so in the sense that it might be limited to a portion of the aleurone layer. Further he found that it was not probable that the infection was transported through the air. Microscopic examination revealed no difference in the structure of healthy and diseased seeds; it is therefore impossible to explain how the mycelial hyphae have found an entrance in some cases and not in others. In addition, no difference was to be observed in the germinating power. On the other hand, morphological differences did exist, some of the spikelets being awned and the others not. The seeds of the former were all immune, whereas those of the latter were all infected. It thus appears that the two varieties of darnel, the awned and

the awnless, also differ in the fact that the one is a host of the fungus, and the other is free from it, which is a matter of great practical interest, given the toxic character of seeds infected with *L. temulentum*.

1044 – **Temperature Relations of Certain Potato Rot and Wilt Producing Fungi.** — Edson, H. A. (Pathologist) and Shapovalov, M. (Asst. Pathologist. Cotton Truck and Forage Crop Disease Investigations, Bureau of Plant Industry, United States Dept. of Agriculture), in *The Journal of Agricultural Research*, Vol. XVIII, No. 10, pp. 511-524, figs. 9, Washington, D. C., Feb. 16, 1920.

As shown by Fawcett (1917), correlation exists between the cardinal temperatures of certain fungi in cultures, and their geographical distribution and seasonal occurrence. There is, however, a regrettable lack of exact information regarding the temperature relations of different potato parasites. The following data secured in experiments with pure cultures of some of the most common potato rot and wilt fungi explain to a certain degree the predominance of these organisms in definite regions and seasons, and permit certain practical conclusions regarding the temperatures which may control or eliminate these fungi.

The following cultures were employed: *Fusarium coeruleum* (Lib.) Sacc.; *F. discolor* var. *sulphureum* (Schlecht) App. and Wollenw.; *F. Eumartii* Carp., *F. oxysporum* Schlecht, *F. radicicola* Wollenw., *F. trichothecioides* Wollenw., *Verticillium albo-atrum* Reinke and Berthold.

The figures in graph form show the daily accumulations of growth, and a table gives the seasonal prevalence of *Fusarium oxysporum* and *Verticillium albo-atrum* under special climatic conditions. Results show that more tubers were infected with the former in the early crop grown at higher temperature than in the late crop at a lower temperature, and vice versa with *V. albo-atrum*. The presence of the *Fusarium* infection in the control tubers indicates that probably the largest part of it came from the soil, while the infection of the new tubers with *Verticillium* came exclusively from the seed The latter was absent both in the control and *Fusarium* plots of each crop.

The fact that the growth of potato fungi was seriously inhibited at or somewhat below 5° C is of considerable practical importance. It may be reasonably be supposed that a temperature of about 40° F or slightly below will suffice to check the spread of the Fusarium potato tuber rots in storage. The requisite temperature for successful infection is, therefore, higher than the minimum temperature necessary for growth in cultures. The susceptibility of *Verticillium albo-atrum* to high temperatures suggests the possibility of heat treatment for infected seed tubers.

Temperature tests in certain cases may serve as a useful supplementary method for the identification of fungi exhibiting contrasting thermal relationships.

1045 – **Preliminary Study of the Inheritance in Rust Resistance in Oats.** — Parker, J. H., in the *Journal of the American Society of Agronomy*, Vol. 12, No. 1, pp. 23-38, pl. 2, Bibliogr. of 19 publications. Washington, 20 Jan. 1920. RESISTANT PLANTS

This study was undertaken with the idea of attempting a determination of the genetic behaviour of the character rust resistance, in a cross between resistant and susceptible oat varieties of the two groups: (1) Red Oats

(*Avena sterilis*) and (2) Common Oats (*Avena sativa*), namely the pedigree lines of the two varieties Burt and Sixty-Day, with a large number of F_2 generation hybrids between them. Most of the inoculations were made on seedlings, but similar results were obtained on plants at the time of heading, using crown rust. *Puccinia Lolii Avenae* McAlpine on the upper leaf blades and stem rust. *Puccinia graminis Avenae* Erikss and Henn, on the upper sheaths and peduncles.

A plant was recorded as resistant when few or no normal uredinia ruptured the epidermis. If the uredinia were numerous, large and normal, but no very marked signs of resistance were present, the plant was classed as susceptible. If a limited number accompanied by flecks were noticed and no other indications of semi-resistance, the plant was classed as intermediate.

Everything tested was found to be readily susceptible to stem rust. All plants of the Sixty-Day were uniformly susceptible to crown rust. Of 223 inoculated plants of Burt, 48 were classified as resistant, 152 as intermediate, and 23 as susceptible. In the F_2 generation there was definite segregation, and the seedlings were classified as 17.3 % resistant, 13.0 % intermediate, and 69.7 % susceptible. Crown rust in this cross is partially dominant, and resistance is recessive. The outstanding contracted characters are due to definite genetic factors.

On this preliminary work the author does not consider it possible to attempt the construction of a factorial hypothesis to fit the results, owing to the fact that F_1 generation plants were not observed, nor the F_3 plants, as the F_2 plants were not grown to maturity. Also one of the parent varieties was heterozygous with regard to rust resistance. It is stated, however, that as the above results were obtained in the Burt × Sixty Day Cross, it seems likely that similar ones would follow in other crosses between varieties resistant to crown rust in the *A. sterilis* group and those which are susceptible in the *A. sativa* group.

A brief review is given of previous literature on disease resistance, and rust resistance in cereals.

1046 – **Correlation between Size of the Fruit and Resistance of Tomato Skin to Puncture; Relation to Infection with *Macrosporium tomato* Cooke.** — Rosenbaum J, and Sando, C. E., in *The American Journal of Botany*, Vol. VII, No. 2, pp. 78-82, tables 2. Brooklyn, Feb. 1920.

The fact that artificial infection with *Macrosporium tomato* Cooke from tomato on uninjured tomato fruit can be obtained, provided fruit of a certain maturity as measured by size is used, has previously been established. The question now under consideration is to ascertain the cause of this apparent immunity or resistance in the fruit after it reaches a certain maturity Previous investigations show that it is apparent that there is good evidence that some parasitic plants make their way into their host plants by breaking through the tissues mechanically and that the main factor in this penetration is the growth pressure of the fungus filament. Experiments by Hawkins and Harvey with *Pythium* on potatoes supports this evidence.

The results obtained by BLACKMAN and WELSFORD with *Botrytis cinerea* on *Vicia Faba* show that the piercing of the cuticle is due solely to the mechanical pressure exerted by the germ tube as a whole or by the special outgrowth from it.

The methods employed by the authors were as follows. The tomatoes were grown in a commercial way in the fields of southern Florida. At first fruits of various sizes were selected at random. Inoculations were made from tagged blossoms at the end of each week.

The *Macrosporium* cultures were isolated from tomato fruit. Spores were obtained according to the KUNKEL method.

The resistance of the skin of the fruit to puncture was determined by use of the JOLY balance as modified by HAWKINS and HARVEY. Generally ten punctures were made on each fruit where tomatoes of different sizes were used. The average of these readings gives fairly accurately the pressure necessary to puncture a particular fruit. The authors give Tables showing the relation between resistance of skin to puncture and *Macrosporium* infection on different sized tomatoes, at 23°C and showing the relation between these on tomatoes of different age.

The evidence obtained shows that: (1) while a chemical difference is found in the analysis of young and old fruits, this is not the limiting factor in infection with *Macrosporium*. The fungus grows just as readily on the pulp and extracts of old fruits as on those obtained from young tomatoes. Moreover, positive infection has been obtained on fruits of all degrees of maturity when the skin is injured or removed previous to infection; (2) surface sections of old and young fruits failed to reveal the presence of stomata or other natural openings in the skin; (3) in the development of a tomato fruit, the cuticular layer increases in thickness with the age of the fruit. Measurements to determine the resistance of the skin have shown that there is a definite and direct correlation between age and the resistance of the skin to puncture. Infection experiments have shown that the amount of infection which it is possible to obtain decreases with the age of the fruit.

While the results do not prove absolutely that the inhibition of infection is a purely mechanical one, the resistance of the tomato skin to puncture may explain, at least partially, the ease with which infection without previous injury is obtained on the young fruit but not on the older fruit.

1047 – **Riesling Rhenan Grape Variety Resistant to *Dematophora* sp. in Italy.** — See No. 944 of this *Review*.

1048 – **White Rot Disease of Onion Bulbs.** — COTTON, A. D. (Mycologist to the Ministry of Agriculture and Fisheries) and OWEN, M. N. (Botany School, University of Cambridge), in *The Journal of the Ministry of Agriculture*, Vol. XXVI, No. 11, pp. 1093-1099, pl. 2. London, Feb. 1920.

Until recently, this disease has not attracted serious attention, and the only previous account which deals in any way clearly with the White Rot disease is that by VOGLINO (1902) who records the occurrence in garlic in

various parts of Italy and gives a description of the microscopic characters of the fungus. As a result of further studies and experimental work carried out at the Ministry's Pathological Laboratory at Kew, during the past 2 years and the fact that the life history of the causative organism is properly known, has led the authors to state that it is now possible to suggest methods for controlling the spread of this disease.

The destruction of onion bulbs by a fungus producing a white mould was observed by BERKELEY in 1841 and was called *Sclerotium cepivorum*. An examination and comparison of these specimens shows that they are precisely identical with the White Rot fungus so prevalent to-day. The fungus has itself been found to be quite distinct from the two fungi *Sclerotinia bulborum* and *Botrytis cinerea*, both of which have at one time or another, been regarded as the cause of the trouble in question. White Rot was first correctly distinguished in England in the *Annual Report of the Plant Disease Survey of the Ministry of Agriculture, for* 1917. The popular name is derived from the abundance of white mould at the base of the diseased bulbs in the early stages. Onions become attacked when the soil in which they are sown or planted is contaminated with the fungus. They usually first show symptoms of attack at the end of May or early in June. If the soil is heavily contaminated, practically all the beds will be effected. Autumn sown plants appear to be the earliest to suffer but spring sown onions suffer equally, and, being smaller, are more quickly killed and are sometimes destroyed in large numbers. The earliest visible symptom is one of wilting and yellowing of the foliage. The roots are invaded by fungus mycelium or spawn, and are almost entirely destroyed, probably in all cases attacked before the bulb. Warm, damp weather appears to be specially favourable to the growth of the parasite, and the fungus then develops rapidly round the base of the bulb showing a mass of fluffy white fungus spawn or mycelium. This is very characteristic of the White Rot disease and distinguishes it at once from all other diseases of the onion. Later this is replaced by a more closely fitting weft which penetrates also into the tissues of the bulb. At this stage the surface of the bulb shows the presence of numerous, black spherical bodies (0.5 mm. diameter) and termed "sclerotia". It is by means of these that the parasites persist in the soil from year to year. The fungal threads continue to penetrate the bulb tissues, and finally the bulb becomes dried up. It would appear that under natural conditions, the sclerotia on the diseased bulbs, remain dormant during winter, germinate in late spring and thus bring about infection of the next crop.

The conidia or microspores produced after germination, have not been observed to germinate.

It would appear, therefore, that the disease is spread solely through the agency of sclerotia. This accounts for the fact that the authors prefer to retain BERKELEY'S generic name *Sclerotium* rather than to transfer species to the ascomycetous genus *Sclerotinia*.

A point of great practical importance is the length of time the sclerotia

retain their vitality. No exact statement can yet be made in this respect.

Method of spread. — The introduction into new localities obviously takes place through such means as (1) the distribution of soil containing sclerotia ; (2) the planting of diseased plants and sets ; (3) the careless disposal of contaminated refuse or manure.

As far as the present observations go, most of the common varieties of onions appear to be subject to White Rot. Shallots are usually resistant and leeks are not commonly affected.

Distinctions between White Rot and other diseases. — (1) « Onion fly » *Phorbia ceparum* distinguished by presence of maggots in the bulbs, the absence of white fungus mycelium, and black sclerotia.

(2) « Milaidev » *Peronospora Schleideni* distinguished by whitish black or grey mildewon the leaves bulb free from attack.

(3) « Onion Smut », *Urocystis Cepulae* streaks of black spore masses in leaves and the outer scales.

(4) *Botrytis Allii*. The leaves and top of the bulb attacked, with grey mould and not white ; and disease commences later in the year. This disease and White Rot are occasionally found in the same bulb.

In England, White Rot is very widespread. It is evidently also serious in Italy but little is known as to its exact distribution on the continent. It has not been reported in America.

Methods of control. — The only means at present known is by starving out the fungus from the soil, and this can only be effected by keeping the ground free from onions and allied crops for a number of years. During this period the soil should be worked as much as possible and the utmost care taken that contaminated soil is not conveyed to clean land.

Diseased plants should be carefully dug up and burned before the formation of sclerotia takes place. No success has been obtained yet with the use of soil fungicides.

There is therefore still room for further investigation especially with regard to fungicides and trials as to the susceptibility and resistance of different varieties of onions.

1049 – **Rot of Date Fruit.** — Brown, J. G. (Agricultural Experiment Station, University of Arizona. Tucson), in *The Botanical Gazette*, Vol. LXIX, No. 6, pp. 521-529. figs. 5. Chicago, June, 1920.

Examination of the infected orchards at Yuma and Tempe, led the author to observe that the fruit showed two main symptoms of disease. Some were flecked with rusty brown spots, others showed soft spots varying in size and partly translucent, as though soaked with water or oil. In both cases, the ruptured epidermis allowed excessive water loss, resulting in the final mummy stage. Mummified fruits sometimes remained for a time *in situ*, but finally fell to the ground. The brown spots on petioles and ribs

of leaves, and on the rhachi of fruit clusters suggested a relation between fruit spot and leaf spot. This appears to be conformed by laboratory experiments so far completed. Cultures gave typical *Alternaria* spores similar to those found in pustules in all three cases, also two species of *Aspergillus* and one species of *Penicillium*. The same saprophytic molds that occur in infected petioles, rhachi and fruits are likely later to ruin the packed crop.

Attack of the spot fungus, unaccompanied by the saprophytes, results in mummification without the appearance of rot.

The fungi *Sterigmatocystis* and *Meliola* have not yet appeared on any of the Arizona material examined. These fungii have previously been reported as connected with date rot in Africa, according to other investigators.

Further study is now being made by the author to determine the three species mentioned: *Alternaria*, *Aspergillus* and *Penicillium*, isolated in cultures, together with histological investigation and inoculation.

INJURIOUS INSECTS AND OTHER LOWER ANIMALS

GENERAL

1050 – **Invasion of Locusts in Uruguay in 1917-18 and 1919-20** (1). — REPÚBLICA ORIENTAL DEL URUGUAY, MINISTERIO DE INDUSTRIA, DEFENSA AGRÍCOLA: I. *Memoria correspondiente al año* 1917, passim. Montevideo, 1918. — II. *Memoria de los trabajos realizados contra la langosta. Invasión de* 1917-1918, pp. 89, maps, 4 diagrams. Montevideo, 1919. — III. *Boletín mensual*, No. 2, pp. 8-9. Montevideo, 1920.

In June, 1917, the Directorate of the Uruguayan " Defensa Agrícola " drew up a general scheme of work to be carried into effect, should the territory of the Republic again be invaded by locusts (*Schistocerca paranensis*) This scheme having been approved by the Central Commission, the Directorate took steps to re-organise the Commissions appointed in each Department for the purpose of collaborating with the officials of the Defensa Agricola, and to co-ordinate their work with a view to rendering it more efficacious. To this end, the Commissions were divided into three categories: " Comisiones de Zona " " Comisiones Seccionales ", and " Comisiones de Distrito "

The first regulation defined the powers of the Comisiones de Zona, another defined the functions of the two other categories of Commissions, while a third provided for the nomination of Honorary Inspectors having the same powers as the members of the " Comisiones Seccionales ", and the " Comisiones de Distrito ", thereby still further enlarging the circle of the collaborators of the Defensa agrícola.

With the aim of enlisting the services of the rural population in the campaign against the locusts, circulars were sent to all institutions which had to do with agriculturists asking them to collaborate and urging them to second the efforts of the " Defensa Agrícola ". The Directorate had a coloured plate made, depicting in a striking manner the characteristics of the " langosta " in the different phases of its life-cycle (egg ; " mosquita ",

(1) See: INTERNATIONAL INSTITUTE OF AGRICULTURE. *La lutte contre les sauterelles dans les divers pays*. Rome, 1916, passim. *R.* July, 1917, No. 690. (*Ed.*)

" saltona ", and voladora "), and giving the general principles on which are based the control measures adopted in the case of each of the stages in the life of the orthopteron. Another plate was also prepared, in order to help to intensify the control operations during the " mosquita " stage (when the insect is just hatched), for this is considered the best and most economical time for operations against the locust. These plates together with propaganda literature were distributed throughout the country.

In order to awaken popular interest, and to provide the commissions with a practical guide, the laws and regulations to be observed and enforced were collected in a single volume.

Suitable measures were also taken to increase the staff working directly under the " Defensa Agrícola ", and that to be dispatched to the invaded Departments.

With a view to regulating and rendering uniform the measures adopted by this staff during the campaign against the locusts, regulations were published dealing with the infringements of the rules in force for the destruction of the pests, the penalties to be inflicted on persons transgressing them, and the carrying out of the control work by official bodies of workers at the expense of the guilty party.

Another regulation was drawn up for the arrangement and coordination of all matters relating to the administration of the funds necessary for the control campaign.

On August 27, 1917, the first winged swarms (" voladoras ") of the insects, coming from Brazil, reached the territory of Uruguay by way of the Department of Artigas. The following day others came from Argentina and Brazil to the Departments of Salto and Artigas. From this date, these swarms of winged insects continued to invade the Republic; they gained ground gradually, and finally on November 20, reached the south frontier of Uruguay and spread over the Department of Montevideo up to the Capital and to the Departments on the banks of Rio de la Plata. In the meanwhile, in the districts first invaded by the " voladoras " the eggs laid at once by the latter began to hatch out and produce " mosquitos ", which continued to make their appearance until early in January, 1918. Towards the middle of December, 1912, large swarms of " saltonas " (locusts still in a wingless condition) coming from Brazil arrived in the Department of Rivera. Recently metamorphosed winged insects were not seen until the end of January either in this Department or in the Department of Cerro Largo. In February, however, they were observed in the other Departments of Paysandú, Minas, Tacuarembó, Florida, and Rio Negro. In short, all the Departments of the Republic were invaded, and everywhere the locusts had laid their eggs and the larvae were hatching out. The persistent drought prevailing during the months of the invasion of the locusts, and the time when their eggs were hatching, caused many of the latter to perish while others produced " mosquitas " out of season. These larvae died in large quantities in some zones as soon as they were hatched, and in certain places all succumbed to the unfavourable atmospheric conditions and to lack of food due to the dryness of the ground. The first rains brought

forth new " mosquitas ", it was therefore necessary to resume control operations although they were supposed to be finished, which entailed two consecutive campaigns.

From the time of the arrival of the first swarms of locusts in Uruguayan territory, that is to say, from September, 1917, to March, 1918, all the necessary material for the control campaign was distributed throughout all the Departments. This material, which was the property of the " Defensa Agrícola ", was lying ready for use in the depôt at Sayago. It chiefly consisted of a large quantity (387 949 kg.) of wire netting, (*barrera metálica*) 5343 special blowlamps (*máquinas langosticidas a fuego*), and 12 000 were nets fixed to a wooden grip (*látigos de alambre*) with their accessories (1). Further, measures were taken for the purchase of 2000 cases of naphtha, for fuel for the blow-lamps (*máquinas*). Most of these cases of naphtha were re-sold to persons requiring them at half-price, and a smaller number were distributed gratuitously to poor farmers. In order to do away with the difficulties experienced in previous campaigns connected with the distribution, and still more with the collection, at the close of the season, of the material lent to private individuals, the Directors of the " Defensa Agrícola " published a special regulation urging that due attention should be paid to the provisions it contained. In spite of the greater punctuality with which, thanks to these measures, this material was returned, the Directors find it increasingly necessary to insist upon private persons providing their own material, the " Defensa Agrícola " only undertaking to furnish it in exceptional cases, and as each occasion arises.

The National Army contributed efficaciously to the destruction of the locusts, and its co-operation was enlisted in nearly all the Departments; in some cases bands of workers were formed consisting almost entirely of soldiers. The railway companies also contributed to the success of the campaign by transporting workers and material free of charge.

During the time of the invasion in question, a special commission appointed by the Government carried out three successive experiments in applying the biological method (*Coccobacillus Acridiorum*) in the control of " saltonas " and " voladoras " (2). This Commission, though it considered the results obtained in these researches to be satisfactory, expressed the opinion that, in order to arrive at definite conclusive as to the practical value of the method, it would be necessary to carry out further experiments, especially as regards the treatment of wire " langosta " in open country.

A second Commission was appointed to undertake experimental investigations with a view to the industrial use of locusts (3).

The campaign of 1917-1918, considered as a whole, gave satisfactory results. The agricultural districts of the Republic were defended against the locusts and protected from their voracity, the injury they caused

being reduced to a minimum and negligible in the total estimate of national production.

The direction of the work must also be regarded as better, than that of previous years. The more complete and uniform character of the regulations, and the distribution in all the Departments of a picked staff of workers chosen by and directly under the control of the " Defensa Agrícola " facilitated the execution of the control operations and permitted of greater regularity in the supervision of the various services. Although the invasion of 1917-1918 was one of the most widespread, yet only half the funds voted by the Assembly (120 000 pesos) was expended on the operations.

Contrary to what occurred in the above-mentioned period, the 1919-1920 invasion, according to the information so far published (February 1920), was not very severe in Uruguay. The first winged swarms found their way into the Republic at the end of July (27 and 29) across the Departments of Salto and Rivera ; they came from Argentina and Brazil, respectively Early in the following August, however, the locusts that had invaded the Department of Rivera returned to Brazil. The arrival of small swarms was afterwards notified in the two above-mentioned Departments. A swarm composed of a few insects was reported on October 9, 1919 at Tacuarembó ; this was the only one that stopped in the country. The measures necessary for protecting the invaded estates were carried out with promptitute and energy by the owners in collaboration with the " Defensa Agrícola ".

INSECTS ETC. INJURIOUS TO VARIOUS CROPS

1051 – ***Empoasca mali*** **and** ***Empoa rosae*****, Two Leaf-Hoppers Injurious to Apple Nursery Stock in the United States.** — ACKERMAN, A. J., in *United States Department of Agriculture, Bulletin* 805, pp. 1-35, figs. 2, pl. 5, tables 21, Bibliogr. of 28 publications. Washington, D. C., Dec. 15, 1919.

The Apple Leafhopper (*Empoasca mali*), both in the nymph and adult stage, causes serious injury to apple nursery stock by extracting the plant juices from the terminal leaves of the host. As a consequence the leaves curl, become undersized, and fail to function normally, thereby retarding the growth of the trees. In southern Pennsylvania this species is three-brooded and hibernates only in the adult stage. Eggs are laid within the leaf tissue on the underside of the leaves. This leafhopper is widely distributed over the United States, and attacks a variety of plants.

In literature, the above species has been confused with another leaf-hopper which also attacks the foliage of nursery apple trees, namely, the rose leafhopper, *E. rosae*. The latter insect is two-brooded, and winter is passed in the egg stage. Winter eggs are deposited under the bark of apple trees ; these hatch out about a month earlier in the spring than eggs deposited by wintered females of *E. mali*.

E. rosae may be distinguished from *E. mali* by its lighter colour and by the absence of the six or eight white spots present on the frontal margin of the pronotum of the latter species. Distinction between the nymphs of the two species is more difficult. The distinct types of injury produced by the two insects, however, is a ready means of distinguishing them.

E. rosae feeds on the lower leaves and produces white or yellow spots on them, while *E. mali* attacks the terminal leaves, curls them, and stunts the growth of the trees.

Parasites seem to play a far more important rôle in reducing the numbers of the rose leafhopper than those of *E. mali*. Larvae of drynid parasites are quite common on the adults of the former, while they have only rarely been founds attacking the latter. Two parasites of the winter egg of *E. rosae* have been observed, namely, *Anagrus epos* Girault and *A. armatus* Ashm. var. *nigriventris* Girault, and these help considerably in checking the numbers of this species. No parasites have been reared from the eggs of *E. mali*.

A single spraying with 40 % nicotine sulphate at the rate of 1 to 1.500 combined with soap will so materially check an infestation by *E. mali*, when applied against the first-brood nymphs, that injury caused later by those that escape, will be of little consequence. The same treatment made two or three weeks earlier is effective against *E. mali*, although this species is seldom sufficiently injurious to justify a special application.

INJURIOUS VERTEBRATES

1052 – **Rats in Sugar-Cane.** — Skaife, S. H. (Entomologist, School of Agriculture, Cedara, Natal), in *Journal of the Department of Agriculture*, Vol. I, No. 1, pp. 55-57. Pretoria. April 1920.

The rats causing the trouble are not the cane rats (*Thryonomys swinderenianus*), but are nearly all allied to the common house rats. On the sugar farms of the Umfolozi Flats they cause great damage by gnawing through the base of the cane, causing it to fall and dry out. This particular species has previously been associated with the cottonfields, but this new and unprecedented form of attack, amounting to 75 % or more crop losses, is considered probably due to the floods, as it is obvious that the worse infested farms are those which suffered most from these floods.

The " Pâte verte " from the Pasteur Institute, Paris, although highly effective against rats in the trenches during the war, was found to have no effect on the species in question. The fact should not however be forgotten that the virus. was used when at least 2 months old. Poison baits soaked in 2 % solution of strychnia hydrochloride were more effective but impracticable under field conditions. The practice of the planters to burn the trash and dead vegetation before cutting the cane was more advisable. The rats were dazed and stupefied and were easily caught and destroyed.

The planters are, however, very anxious to have the speedy use of a virus which will start an epidemic among the rats and eventually wipe them out, and which, contrary to certain types of virus already put on the market, will prove as equally effective in the cane fields as elsewhere. Such a method of eradication would be distinctly advantageous to the burning process which involves injury to the roots of the cane by digging, etc.

Alfredo Ruggeri, *gerente responsabile*.

DEVELOPMENT OF AGRICULTURE IN DIFFERENT COUNTRIES

1053 - **Agricultural Development in India.** — I. CLOUSTON, D. (Director of Agriculture Central Provinces and Behar). The Possibilities of Agriculture in India within the next Twenty Years, in *The Agricultural Journal of India*, Vol. XV, Pt. III, pp. 239-249. Calcutta, May 1920. — II. HOWARD, A. (Imperial Economic Botanist). The Improvement of Crop Production in *The London Corn Circular*, Year, 77, No. 62, pp. 4-5 and No. 64, pp. 3-6. London, July, 1920.

I. — The Presidential address to the Agricultural Section of the Seventh Indian Science Congress, Nagpur 1920.

The speaker starts by giving a brief survey of the history of agricultural development in England showing the manner in which difficulties similar to those now experienced in India were overcome. The value of agricultural science is becoming more and more evident, and the Indian Industrial Commission States that the striking results which followed quickly and directly after the employment from about 1905 onwards of scientific specialists, demonstrates the wisdom of investing in modern science. The activities of the Department of Agriculture extend over a wide field now including not only crop improvements, but also the introduction of better and more intensive methods of cultivation.

The introduction of superior varieties and strains of seed and the cultivation of cotton (2 ½ million acres), of wheat (1 million acres) and of rice (1 million acres) and the annual profit accruing from their cultivation all points to a marked progress.

To meet the growing demands satisfactorily, there is now an urgent need of : 1) Assistance in devising suitable implements; 2) depôts for demonstration generally; 3) investigation and means of combating the fungoid

diseases and insect pests ; 4) adequate provision for experiment and research. Each talug or tahsil (agricultural association) and union should have its own Government Farm and should be the centre for help, advice and instruction. District talug agencies organised carefully would be a medium through which legislative measures for the advancement of agriculture, and the amelioration of the people would be carried out.

The speaker closes by mentioning the great future possibilities, and considers that the successes will undoubtedly surpass the highest expectation if the process of reconstruction is dealt with in an adequate manner.

II. — Paper read before the Royal Society of Arts. The necessary steps which should be taken in connection with general improvement are entirely in accordance with the statements made by CLOUSTON but the paper includes further additional remarks worthy of note.

1. IMPROVEMENT OF VARIETIES: SOME VARIETAL CHARACTERS. — Modern industry demands a uniform product. The first stage of improvement lies in the cultivation of an even product free from admixture. Although yield is of such paramount importance in India, the growing period is much more strictly limited than in other countries. Early sowing is impossible and late sowing means a great slowing down in growth, and the crop cannot ripen in time. A great improvement in yield has been obtained by introducing a wheat of shorter growing period which can use up the limited time to the best advantage and can produce a well developed grain even in unfavourable years.

Adaptability is the essential to the successful variety. Replacement must be carried out according to plan, and admixture with inferior types easily detected. Accurate mathematical investigations to determine which of a set of varieties is the best yielder, although probably extremely useful in England, are often inapplicable to Indian conditions.

Although quality combined with quantity is a difficult matter, high yields can be united with quality far above the average *e. g.* varieties of cotton, wheat and tobacco ; but the greatest attention must be paid to the prevention of cross fertilisation in the field, otherwise improved cotton etc. will rapidly degenerate. Hence the importance of well organised seed supply. The local centres have mostly been managed privately or by District Boards etc, but with the newly aroused interest in general development, the talug agencies are likely to aid progress to a large extent. The best methods of finance are still under consideration, and the method has not yet been satisfactorily solved.

2. FACTORS INFLUENCING PLANT GROWTH. (a) *Soil aeration*. — The author deals with three cases in which progress has been obtained through the recognition of the importance of this factor :

1) *Canal Irrigation* : — To overcome the difficulty which arises owing to the fact that irrigation supplies water but tends to deprive the the soil of air, it was important to arrive at a working compromise. A large number of experiments were carried out. The following is a brief summary of the results obtained : —

1. *Average yield of wheat grain per acre at Quetta with single irrigation.* Maunds 17 Seers. 29. (One Maund = 40 Seers = 82. 27 lb).

II. *Introduction of new limiting factors after irrigation.*

Number of waterings	Area in acres	Total weight of produce lb	Total weight of grain		Yield of grain per acre		Percentage reduction
			m.	s.	m.	s.	
One	3.99	10.367	52	6	13	2	0
Three	2.65	6.620	25	15	9	23	26

Similar results were obtained in Punjab in Sind and in the United Provinces. A consideration of all these results indicates that over the canal irrigated areas of North West India, a vast volume of water is annually poured on to the land to no purpose. At a comparatively early stage in irrigation, the soil aeration is interrupted, after which any further addition of water does not affect the yield. Consequently, water has been wasted and natural soil fertility lowered, as is seen by the gradual falling off in yield in new canal areas, and by the increase in the area of alkali lands. Payment by volume would remedy the defect to a very considerable extent.

2) *Development of waste lands.* — The second practical application of soil aeration. Reference is made to the work of CLOUSTON in the Central Provinces, who was the first to make practical use of the fact that soils possessing great porosity often prove to be of the greatest value. In these Provinces, large areas of poor laterite soils possess this porosity and hence with proper administration, the present results. Crops of over 40 tons of stripped cane per acre have been grown, and also heavy yields of cotton, groundnuts, indigo seed and fodder, more especially on the poor *bhata* soils than on the richer black neighbouring soils which were far less permeable.

3) *Drainage.* — That the loss of fertility is largely due to denitrification is shown by the results of an experiment at Pusa in 1910. A plot of heavy land was water logged during September to compare its behaviour with normal plots on either side. Across the middle of the plots 4 cwt., of nitrate of soda per acre was applied previous to sowing with wheat. The effect after a month's water logging was to reduce the yield by about 16 bus, per acre. The Botanical area at Pusa has been transformed by improving surface drainage, and the experience there during the last 15 years has thrown light on the nitrogen problem in India (1).

(1) Surface drainage, by checking erosion and by reducing denitrification in the rains has had the effect of increasing the fertility with a comparatively small expenditure of organic matter. One plot during 15 years produced 13 heavy cereal and 2 good pulse crops (manurial treatment 3 crops of green manure, single dressing of castor cake 1/2 ton per acre). The land improved and in 1919 gave a record crop of wheat, viz 40 bus., per acre. Similar results have been obtained at Quetta and in the United Provinces. This suggests that nitrogen fixation is much greater in the plains of India than is commonly supposed. (*Author's Note*)

A detailed drainage map of the area to be improved is obviously the first condition of success, and a settled policy for investigation and action is essential.

b) Soil Temperature. — A practical demonstration has shown that the cause of the damage to crops in Bihar is not the white ants, as is sometimes supposed, but the high temperature of the subsoil, leading to partial destruction of the root system. Afterwards the white ants devour the sickly plants. By lowering the soil temperature, leaving the furrows open for sufficient time to cool the soil by evaporation and postponing the sowing, the necessary remedy is effected. Futher investigations are certain to lead to results of great economic importance.

The author points out that science is the instrument by which the advance is made, and the importance of the combination of the scientific investigator with the cultivator from the point of view of trade, is essential if success is to be ensured.

RURAL HYGIENE

1054 – **Research on the Sewage Water of Milan.** — Bernardi, B, in *Reale Isituto Lombardo di Scienze e Lettere, Rendiconti*, Series II, Vol. III, Parts 6-7, pp. 222-243, Milan, 1920.

In 1900, the municipal authorities of Milan appointed a Commission to study the state of the sewage of the city as much from the hydrotechnic and hygienic standpoint as from that of construction. The examination of the degree of purification of the sewage was entrusted to Prof. Celli and Prof. Menozzi and their report (A. Celli and A. Menozzi, *La depurazione agricola delle acque di fognatura di Milano*, Modena 1902) stated that the system employed for the purification of the sewage and its utilisation for irrigation purposes was extremely efficient and that it was satisfactory from the hygienic standpoint.

As it was feared that the system had not moved with the times the author repeated his esperiments in 1916 and 1917 and the results are given in the present article.

In 1915 the area, irrigated or irrigable by the Vetabbia canal, which carries away the sewage water was that shown in the following table: —

Table I. — *Land irrigated by the purified sewage water of Milan in* 1915.

	Meadows irrigated	Land under rotation crops	Total irrigated	Not irrigated	Total
	Hectares	Hectares	Hectares	Hectares	Hectares
Irrigated	3 298	1 100	4 398	500	**4 898**
To be irrigated	476	300	776	150	**926**
Prepared for irrigation	2 109	900	3 000	250	**3 250**
Suitable for irrigation	2 000	1 100	3 100	470	**3 570**
Total	**7 874**	**3 400**	**11 174**	**1 370**	**12 644**

The authors' researches show the purification of the sewage water to be very thorough. All substances such as sulphuretted hydrogen, faecal matter, ammonia, are reduced or disappear entirely owing to the water having been spread over the meadows. The same thing occurs with organic nitrogen, ammoniacal nitrogen and phosphoric acid. Bacteriological examination also shows purification to be very complete. On the other hand, the chlorides remain constant or even increase due to non absorbtion by the soil and evaporation.

In Table II, the analysis made by CELLI and MENOZZI, in 1900-1901 with those made by the author are compared :—

TABLE II. — *Comparison between the analyses made by* CELLI & MENOZZI *and by* BERNARDI.

	Analyses by CELLI and MENOZZI	Analyses by BERNARDI
Residue at 100° per litre	0.322 to 0.488	0.419
Residue at 280° » »	0.319 » 0.483	0.378
Residue « au feu »	0.279 » 9.425	0,371
Loss on calcination	0.023 » 0.068	0.027
Oxygen required to oxidise the organic matter	0.010 » 0.018	0.0154
Chlorine	0.005 » 0.0173	0.0273
Phosphoric anhydride	0.026 » 0.041	0.0139

Comparison of these two analyses shows that the purification of the sewage water of Milan is in the same state as in 1900. Moreover, on comparing the averages of a the authors' analyses with data supplied by KÖNIG on the composition of the sewage water of the big European cities, it becomes evident that the total amount of organic and mineral matter dissolved or held in suspension, as well as those which are the most important contamination (organic and ammoniacal nitrogen, chlorine, and signs of phosphoric acid etc.) is less than that of Paris, Berlin Dantzig, etc.

The agricultural use of sewage water gives rise to a few causes of disturbance but they can easily be obviated. In certain meadows irrigated with Vettabia water, certain bare patches can be seen which are covered with a brilliant greenish incrustation, from 1-3 mm thick, formed by algae. This trouble is overcome by preventing the irrigation water from stagnating. Also paper and débris accumulate and prevent growth, but this can be removed during the dry weather.

The greatest danger from a hygienic point of view is the contamination of the drinking water supply by drainage through the soil, but this has not happened yet and could easily be overcome.

In conclusion, it can be said that the irrigation of the meadows with sewage water is a cheap and effective way of combining hygiene and agriculture.

1055 – **Consumption of Milk and its Relation to Infectious Disease.** — *Communication from* Dr. KALLBRUNNER, *Austrian Correspondent of the International Institute of Agriculture.*

Before the war, British and German scientists found that an increase in the consumption of milk was accompanied by more cases of scarlet-fever but they where not able to find out the cause of this correlation. Austrian medical men and statisticians who had attempted in vain to discover the correlation before the war but during the war they were successful. In Vienna, the singular discovery was made that in the same degree as the towns' milk supply decreased, so did the cases of scarlet. fever, this confirming British observations. Statistics collected by the Office of Hygiene at Vienna show that the number of cases of scarlet-fewer were as follows :

Year	Number of Cases	Year	Number of Cases
1910	4 038	1915	5 093
1911	4 006	1916	4 534
1912	4 216	1917	3 134
1913	5 752	1918	2 832
1914	4 614	1919	1 234

The cause of this phenomenon is unfortunately not yet known, but it is thought that the constitution of children nourished on milk is more open to attack by the fever microbes, as they do not possess enough natural organic means of reaction to combat the disease. A considerable amount of research work on this subject is still necessary.

Typhus has almost disappeared in Vienna since the construction of the 2 large conduits which ensure the increased supply of pure fresh mountain water. Unfortunately isolated cases still occur and these apparently indicate the important part played by milk as the transmitting agent, the victims' having often been found to have obtained their milk from the same dairy. This observation was naturally of great importance to the medical experts, and at the appearance of each new case they immediately concentrated their attention on the dairies which had supplied the victims' milk. The success of these precautions is shown by the continual decrease of sporadic cases of typhus as well as small epidemics (certainly the cases of typhus in Vienna could not be prevented from increasing and it speaks very well for the efficiency of the measures taken, that the isolated cases did not develop into epidemics owing to soldiers who were on leave or had deserted, passing through the town).

The interesting cases cited further on, which were registered prior to the war and which led to the re-organisation of the dairies during serious times, prove how well justified were the rigorous measures taken by the sanitary police, in regard to the milk industry. Naturally these measures

were taken in complete accord and collaboration with the dairies, which are always eager to produce and deliver the milk under irreproachable hygienic conditions.

Previously no special importance had been attached to the state of health of the personnel of the dairies, periodical washing and visits to the doctor being considered enough. Some years age, a "koster" (a man who had to taste the milk from each can sent to the dairy) contracted typhus. Without falling seriously ill himself, he infected part of the milk he had tasted. About 3 weeks after the man fell ill 90 persons who had bought milk at this dairy became ill one after the other. The first to catch the disease were some employees who were in the habit of drinking milk from this diary at lunch time. A careful search was at once made, and the case of the "koster" 9 was discovered; about the end of 3 weeks, the epidemic of typhus disappeared automatically, but not before it had caused the death of a dozen persons.

In another dairy where a pasteuriser was broken, doubtful milk was sold during 3 or 4 days without being pasteurised. Although the time was so short, this negligence unfortunately caused a small epidemic, which broke out 3 weeks after, but although it was of short duration, it nevertheless proved fatal to many persons.

In Austria it is generally believed that tuberculosis is transmitted from the cow to man through the milk, but this fact is not scientifically established for certain and, although public opinion is to the contrary, primary intestinal tuberculosis is rare. In Dalmatia, where milk is not drunk, tuberculosis is very common, whilst in places where milk- drinking is on the increase, the disease is decreasing. In Vienna, where the milk consumption is decreasing, tuberculosis is increasing, obviously on account of other factors), as can be seen from the following Table:

Year	Milk consumed per day litres	Deaths due to tuberculosis litres
1914	900 000	6 223
1919	40 000	10 606

But in spite of the bad feeding and poor attention that the cattle received during the war, bovine tuberculosis is on the decrease. One reason of this was the requisitions from the farmers, who, being paid extremely low prices with no reference to weight or quality, delivered the worst they had got, the animals being usually those most susceptible to tuberculosis Some livestock owners even applied BEHRINGS inoculation test for tuberculosis so that they could dispose of animals shown to be infected..

This elimination of poor and doubtful animals has certainly had a beneficial effect on the general state of health of the cattle and this is shown by the fact the number of insurances paid by the "Nieder-Oesterreichische Landes-Vieh-Versicherungs-Anstalt" (Cattle Assurance Company of Lower-Austria) for cattle slaughtered owing to tubercolosis

has been steadily decreasing since 1913. Thus, out of 100 insured animals killed by order the number of cases from 1913 to 1918 where slaughter was due to tuberculosis was as follows :

1913–1914	1 305 cases
1914–1915	1 129 »
1915–1916	952 »
1916–1917	790 »
1917–1918	553 »

In 1918, the number of cases slaughtered increased slightly but cannot be taken as an average, owing to the small number of cattle on which insurance was paid that year ; observations made elsewhere confirm this statement.

This fact, which necessitates still further stastistical confirmation, suggests that there is no correlation between bovine and human tuberculosis as statistics collected by the Ministry of Health at Vienna and the reports of the Nieder-Oesterreichische Lands-Vich-Versicherungs-Anstalt of Vienna show that while bovine tuberculosis is diminishing, human tuberculosis is increasing.

1056 - **Study on the Antiscorbutic Value of Honey.** — FABER, H. K. (Laboratory of Pediatrics, Stanford University Medical School, San Francisco), in *The Journal of Biological Chemistry*, Vol. XLIII, No. 1, pp. 113-116. Baltimore M. D., August, 1920.

The recent paper of DUTCHER (*Journal of Biological Chemistry*, Vol. XXXIII, No. 1, p. 551, 1918) has demonstrated that honey contains a small amount of antineuritic vitamine (probably due to included pollens rather than to the soluble constituents).

This naturally raises the question whether honey contains other vitamines as well. No investigation regarding antiscorbutic vitamine in honey has yet appeared, and it was to throw light on this point that the author undertook the present study with guinea pigs.

In 9 out of a series of 10 guinea pigs fed on a diet of oats, water, and honey, severe scurvy developed in 4 to 6 weeks. Ii is probable that no antiscorbutic vitamine is therefore present in honey.

CROPS AND CULTIVATION

AGRICULTURAL METEOROLOGY

1057 - **Temperature Influence on Sowing and Harvest Dates of Spring Wheat, Oats, Potatoes, Maize and Cotton in the United States.** — KINCER, J. B., in *Monthly Wheather Review*, Vol. XLVII, No. 5, pp. 312-323, figs. 20, Washington, May, 1919.

There are certain restricted limits of time within which crops must be sown, defined by the temperature conditions of the locality, and a definite amount of heat is required to bring the crop to maturity and ensure good quality and high yield. The length of the period decreases in general with increase in latitude.

A certain amount of warmth is necessary for germination of seeds, the amount required differing for seeds of different plants : wheat and oats germinate at a much lower temperature than maize and may therefore be sown somewhat earlier than the latter. Maize in its turn requires less

warmth for successful germination than cotton, which must necessarily be sown later. In addition, a definite amount of heat is required after sowing to ensure normal development to bring the crop to maturity.

As a rough measure of this heat there may be used what is known as the " thermal constant " taking the starting point as the mean temperature at the date of sowing. The method for obtaining the thermal constant is quite simple ; taking for example the maize, if it is desired to compute this value in a locality where the normal temperature is 55 °F, at the average date of sowing, and the mean temperature for any month during the growing season is 75°F, the thermal constant for that month would be 75°F-55°F = 20°F multiplied by the number of days in the month. But if the normal daily temperature for any portion of a month should be less than 55°F, these days should be omitted, and only those days used which have a mean daily temperature of 56°F or higher.

Spring Wheat. — The principal spring-wheat belt comprises the States of Minnesota and the Dakotas-sowing usually begins in the Dakotas and Nebraska when the normal daily temperature rises to 37°F, and in Minnesota and Wisconsin when it rises to 40°F. The sowing period begins in the southern portion of the belt about March 20 and progresses northward at the rate of about 20 miles a day, reaching the northern areas about the middle of April, the isochromal line keeping on a level with the isotherms indicated.

Spring Oats. —This crop is grown more or less in nearly all sections of the United States. The principal spring oat belt, however, consists of a crescent-shaped area, extending from New England to North Dakota, bounded on the north by the Great Lakes, and on the south and west by a curve extending across central Ohio, Illinois, eastern Nebraska, and from thence northwest along the Missouri River. Sowing starts north of the Gulf States, when the normal daily temperature rises to 43°F, except in an area comprising Oklahoma, Kansas, Missouri, and the lower Ohio Valley, where it begins when the temperature is lower i. e. about 40°F.

Sowing starts in the central and southern Gulf States at higher temperatures than 43°F for the simple reason that the normal daily temperature never falls as low as 43°F. in that area.

The date of sowing is earlier in Georgia and the other Gulf districts (early part of January) compared with the late sowings in April in the extreme northern areas. (Dakota, Maine, etc.).

The mean daily isotherm (43°F) usually corresponds to the average date of sowing, viz. February 15, and progresses northward following along latitude 35 ; as it moves near the north, the date becomes continuonsly later, until in the States of Maine and Wisconsin, etc. the end of April and the beginning of June is reached.

Similar to wheat, the isochronal lines keep on a level with the isotherms.

Early Potatoes. — Early potato planting begins as a rule when the normal daily temperature rises to 45° F, except in the Gulf coast section where the temperature is always higher than 45°F. In the more southern districts planting dates from the latter part of December in

central Florida, to about February 10 in the central Gulf States i. e. 50° to 60°.

The 45°F. isotherm crosses North Carolina (Gulf States) about February 15 and moves thence north-east to south-east until it reaches central south Texas: it moves northward simultaneously with the isochronal line of the beginning of early potato planting, to the northern border States, (Dakota, Wisconsin, Maine) by May 1. Thus the planting of early potatoes usually begins in northern Mississipi about February 15, and in northern Wisconsin 2½ months later.

Maize. — Sowing begins as a rule when the normal daily temperature reaches 55°F. It should be noted that a mean temperature of 55°F in spring corresponds to the average date of the last destructive frost.

The 55°F isotherm crosses the district lying furthest south in Texas, following the northern latitude 30, on February 15, and gets later and later as it approaches northwards, until in Dakota, Wisconsin and Maine, May 15 is reached.

Cotton. — Planting does not begin in the eastern portion of the belt until the normal daily temperature rises to 60 or 62° F, and not in the western portion until 61 to 83°F is reached (west of the Mississipi). The dates vary from March 1 in extreme south of Texas to the last decade in April in the northern portion of the belt.

Thermal Constant. — The behaviour of the thermal constants has already been mentioned. The adjoining Table shows the data collected for maize and oats in selected localities.

The Table shows that the thermal constant for maize in the principal producing areas ranges from 1600°F to 1800°F, but farther north in Southern Michigan and in eastern South Dakota for example, it is from 1400° to 1600°F, due to the sowing of early-maturing varieties, and possibly also due to some extent to the longer summer days in the North. In some southern localities, where slower maturing varieties are sown, it runs as high as 2800°F.

The potential thermal constants for cotton calculated for the period extending from the average date of sowing to the average date of the first fatal frost in the autumn are as follows: Devils Lake (North Dakota), 1260°F (May 15-20 to September 11-15); Lincoln (Nebraska) 2017°F (May 1-10 to October 11-13); Memphis (Tennessee) 3696°F, (March 23-31 to November 1-2) and for Thomasville (Georgia) 4096°F (March 1-10 to November 11-14). While the thermal constant is thus evidently deficient in the north of the belt, for successful commercial growth of maize, it is interesting to note the large surplus available in the South, which is more than double the amount necessary to mature the average variety of maize.

The thermal constants for cotton in selected localities are as follows:— Raleigh, N. C., 1860°F; Thomasville, Ga., 1975°F; Montgomery, Ala., 1900°F; Little Rock, Ark., 1910°F; Oklahoma, Okla, 1820°F; and Galveston Tex., 1810°. The mean daily temperature at the average date of the beginning of the sowing season in these respective areas is: Raleigh

60° F, Thomasville, 61° F, Montgomery, 62°F; Little Rock 62°F, Oklahoma 61° F; Galveston 63° F.

The area in which cotton can be successfully grown is limited by the thermal constant 2000°F between the normal daily temperature at the start of the sowing season and the average date of the first fatal autumn frost, as is shown by the records for the following localities near the northern limits of the cotton belt: Norfolk, Va., 2010°F; Raleigh N. C. 2190°F, Chattanooga, Tenn, 2000°F; Fort Smith, Ark., 2040°.; Oklaoma, Okla., 2140°F.

As previously stated, sowing usually starts when the mean daily temperature rises to 40°F, that is to say, before the advent of the vegetative period, which corresponds to a normal daily temperature of 4208°F. Computing the thermal constant for spring wheat from a 43°F temperature base or the beginning of the vegetative period, we find the following results: Bismarck, N. Dak., and Huron S. Dak, 1970°F; Moorhead, Minn., 1940°F; Madison, Wis. 1980°F.

1058 – **Effect of Snow on the Yield of Winter Wheat in Ohio, and in Illinois, U. S.** — I. Smith J. Warren, in *Monthly Weather Review*, Vol. XLVII, No. 10, pp. 701-702. II. Root C. J., *Ibid*, pp. 700, Washington, Oct. 1919.

I. — Snowfall and winter wheat. — A heavy fall of snow is generally thought to be favourable for winter crops, especially if it comes late in the spring. Observations made by the author seem however to contradict this idea, as shown in the following table which gives the correlation coefficients between the snowfall and the yield of wheat in Ohio, 1892-1914 (January, February and March.)

Month	County	Correlation coefficient	Probable error
January	Fulton	0.42	± 0.13
February	»	0.12	± 0.15
March	»	— 0.84	± 0.04
»	Mayne	— 0.69	± 0.08
»	Seneca	— 0.48	± 0.11

This indicates that in north western Ohio, a heavy snowfall in January has a slightly favourable effect; in February, scarcely any effect, whilst in March it has a decidedly adverse influence. This unfavourable effect in March as evidenced in Fulton County (S. W. Ohio) is verified by the records for Wayne and Senaca counties (both in Northern Ohio.)

On the other hand, March with a heavy snowfall is cooler than normal, while a warm March is usually accompanied by a light snowfall. It has already been shown that a warm March, in Ohio is, always favorable for winter wheat. The correlation coefficient between the average March temperature for Ohio and the average yield covering a period of 60 years is ± 0.46 with a probable error of ± 0.06.

In view of the evident effect of March temperature and the relation between temperature and snowfall, the point has been raised that the damaging effect of the snow is more apparent than real and that it is due largely to low temperature.

To determine the real facts the author has calculated the partial correlation for the 3 factors, temperature, snowfall and yield, as indicated in the following equations:

Let r_{sy} indicate the correlation coefficient for the March snowfall and wheat yield in Fulton County, Ohio. $= 0.84 \pm 0.04$.

Let r_{ty} indicate the correlation coefficient for March temperature and wheat yield $= + 0{,}62 \pm 0.62 \pm 0.08$.

Let r^{st} represent the correlation coefficient for the March snowfall and temperature $= - 0.678 \pm 0.08$.

To eliminate the effect of the temperature and shown the influence of the snowfall alone the equation may be written:

$$r_{sy.t} = \frac{r_{sy} - r_{st}\, r_{ty}}{\sqrt{(1 - r_{st}^2)\,(1 - r_{ty}^2)}}$$

Inserting the various correlation coefficients and making the necessary calculation, we have $- 0.73 \pm 0.07$ as the correlation coefficient between the snowfall in March and the yield of wheat, after eliminating the temperature influence.

The snowfall influence is eliminated from the temperature correlaton in a similar manner as follows: —

$$r_{ty.s} = \frac{r_{ty} - r_{st} - r_{sy}}{\sqrt{(1 - r_{st}^2)\,(1 - r_{sy}^2)}}.$$

Inserting the values and making the correlation coefficient between the March temperature and wheat yield is reduced from 0.62 ± 0.09 to the suprisingly low value of $0.13 + 0.14$, after eliminating the effect of snowfall.

The dominating influence of the March snowfall as compared with the March temperature is therefore plain.

Snow covering and winter wheat. — A heavy fall of snow may melt quickly and leave the ground bare a good part of a the month. On the other hand, a light fall may remain on the ground some time during continued cold weather. Hence the study of the effect of a covering of snow on wheat must be entirely separate from the study of the effect of snowfall on wheat.

The general opinion is that winter crops should be well covered with snow during cold weather and more especially when freezing and thawing conditions prevail. The observations made by the author and his collaborators in Fulton County, Ohio, show little to substantiate this opinion, and it is evident that the matter should be dealt with district by district, taking into consideration the numerous prevailing local conditions.

A correlation between the number of days with snow on the ground from December to March inclusive and the yield of wheat gave a coefficient of only — 0.14 ± 0.14. A correlation between the yield and the number of days in March with freezing weather, while the ground was bare, gave a coefficient of only — 0.01. Here again no real effect is shown although the calculation has been limited directly to March when there is always a greater danger of freezing and thawing on ground laid bare.

A correlation of the yield with the number of days during the whole winter with the ground bare and the temperature below 20°F produced a coefficient of 0.28 ± 0.14.

In every case, as a consequence, the relation between the yield and the duration of the snow covering is, contradictory to the generally accepted opinion, only slight or extremely limited.

There is on the other hand some evidence to indicate that it is more advantageous to wheat if it is not covered by snow during the month of January. A correlation by Cox between the number of days without a snow cover when the temperature was below freezing in January and the yield of wheat in Wayne County, Ohio, gave a coefficient of ± 0.49 probable error ± 0.11.

II. — In Illinois, cold winters with heavy snowfall are followed by light yield and vice-versa the winters with little snow are followed by good yields.

The author admits that this may be due partly to the fact that the temperature is less severe in winter seasons with light snowfall.

1059 – **Effect of Conditions of Temperature and Sunshine on the Development of Cultivated Plants.** — See No. 1073 of this *Review*.

1060 – **Quality and Value of Important Types of Peat Material:— Classification of Peat Based upon its Botanical Composition and Physical and Chemical Characteristics.** — DACHNOWSKI, A. P. ((Physiologist, Soil Fertility Investigations) in the *United States Department of Agriculture, Bulletin* No. 802, pp. 1-40, Bibliogr. of 27 publications. Washington, Dec. 29 1919.

SOIL PHYSICS, CHEMISTRY AND MICROBIOLOGY

Up to the present time investigations have been entirely confined to European countries from the standpoint of interests combining agricultural and technical utilisation, and points to the importance of similar proceedings in the United States. Attention is drawn to the necessity of observing two essential qualifying factors in classification and selection for purposes of utilisation of these peat materials:— 1) Botanical composition and stage of disintegration in a deposit ; 2) Controlling basic factors to the degree of success obtainable.

Although surface vegetation of any unstable stage is significant in the determination of latent possibilities of peat land areas, it is equally necessary to note the profile structure of peat deposit, and the climatic and geological differences of these areas.

A number of features of peat deposits in Europe and in the northern portion of the United States are identical (1).

(1) See *R.* Sept. 1914, No. 848 ; *R.* Oct. 1916, Nos. 1060, and 1075 ; *R.* Dec. 1916, Nos. 1258 and 1323. (*Ed.*)

A tentative classification is given of important types of peat material with Tables showing their chemical and physical characteristics and was collected from Europeans sources for use comparatively in America.

Undrained deposits of peat are found to contain about 90 to 95 % of water which should not be reduced to less than 65 % of the area to be used for agricultural crops. The dewatering of peat materials, especially macerated types and well disintegrated phases of other types to a water content of approximately 25 to 30 % is an essential requirement before they can be used for technical purposes.

No economical and feasible process has yet been found to combat the problem of dessication, and further investigation in the United States is important in every respect.

1061 – **A Method for Measuring the Ammonifying Power of Cultivable Soil.** — PEROTTI, R., in the *Atti della Reale Accademia dei Lincei, Serie Quinta, Rendiconti, Classe di Scienze fisiche, matematiche e naturali*, Vol. XXIX, Ist. quarter, Pts. 6-8, pp. 251-256. Rome, 1920.

There are two methods of measuring the micro-organic properties of cultivable soil. The first consists in the determination of the action of the micro-organisms in solutions inoculated with a limited weight of soil, whilst in the second the same action is determined by adding a limited volume of solution to a soil sample.

The use of solutions for the study of the vital properties of the soil has been long known and is even now the most widely-used method, but the results obtained have not always been accepted as accurate. The author has tried therefore to control this method rigorously in order to ascertain its accuracy. He now describes his researches with the object of determining the best conditions under which the ammonifying power on fertile soil can be measured by means of solutions.

The best conditions, according to the author are as follows: — Place 10 cc. of a 1.5 % solution of peptone in a test-tube and add 5 cc. of a mixture of 50 gm., of earth in 500 cc. of distilled water. This is placed in an incubator at 20 to 25° C and after 4 days the amount of ammonia produced is determined by distillation with calcined magnesia.. The average of four determinations is taken for each test.

1062 – **Cultural Studies of Species of Actinomyces.** — WAKSMAN, S. A., (Department of Soil Bacteriology, New Jersey Agricultural Experiment Station) in *Soil Science*, Vol. VIII, No. 2, pp. 71-215, pl. 4, Bibliography of 47 works. Baltimore, M. D., Aug. 1919.

The actinomycetes form a large and important group of micro-organisms both in number and activity. They have been isolated from wounds, air, water and foodstuffs, but chiefly from soil (1). The author has made a study of the same as regards the origin, nomenclature, and classification into groups, the representatives of which have common morphological, physiological, and cultural characters. He has identified 41 species of *Actinomyces*.

1063 - **Nitrogen Fixation, Ammonification and Nitrification on Embanked Soils in India.** — See No. 1074 of this *Review*.

1064 - **Field Comparison of Hydrated Lime with Limestone of Different Degrees of Fineness.** — HARTWELL, BURT. L., and DAMON, S. C., in the *Agricultural Experiment Station of the Rhode Island State College, Bulletin* No. 180 pp. 4-18, figs 4, tables 4, Kingston, Dec. 1919.

A comparison was made between slaked and hydrated lime which contained 50.99 % calcium oxide and 22.43 % magnesium oxide, and 10-mesh ground limestone from the original rock. The following siftings also entered into the comparison namely 10-20, 20-40, 40-80 meshes. On certain plats the ground limestone was used in an unsifted condition. Applications were made on the basis of equal neutralising value, Beets carrots, alfalfa and barley, all sensitive to soil acidity were grown on assigned sections of a dry gravelly loam to test the possible cumulative effect of this acidity wich would be reflected on the growth of barley, this being finally cultivated over the entire area. Fertiliser ingredients were employed to maintain as far as possible the initial acidity of the check or unlimed plats.

The regular application of lime in whatever form was equivalent to 1 200 lb. calcium oxide per acre. Only in certain cases, three times this amount was applied, and in no case in sufficient quantities to neutralise completely the large amount of soil acidity.

Effect of the lime on the different crops, considered collectively. — The relative response was as follows: beets 4.4, carrots 2.6, alfalfa 1.9, barley 1.6. More acid soil was evident during the sixth year with barley grown over the entire field and with lettuce grown in pots. When the acidity was reduced, the four crops affected succeeding crops comparatively uniformly. During the first season the 80-mesh limestone had the same growth effect as the hydrated lime, and practically the percentage of this grade contaned in the 10-mesh limestone was a measure of the efficiency of the calcium oxide equivalent of the unsifted material for the crop immediately following its application. The fine material first entered into the reaction, and had the effect of greatly lessening the attack on the coarser particles.

Where lime is much needed, about 2.5 parts in weight of ground limestone depending upon its fineness is required to exert the same first effect as one part of hydrated lime.

The experiment showed that there was practically no difference in the average effect during a period of years between the 80-mesh and the coarser unsifted limestones. The effect of the 10-mesh limestone was greater than the equivalent amount of hydrated lime, but the greater activity of the latter in the first years placed the average slightly in its favour.

A selection of these two kinds of lime according to the authors shoul depend mainly on the relative cost per calcium oxide equivalent delivered on the land. There are many indications that it is not economical except for certain quite sensitive crops to neutralise entirely the so-called soil acidity. It is advised under many conditions to make a rather small application of an active kind of lime for the crop especially requiring

attention, and then to apply more a little later when a similar need arises arises (1).

1065 – **The Influence of Lime on the Nitrificatien of Farmyard Manure in Arable Soil.** — BARTHEL, C. and BENGTSSON N. (Central Agricultural Experiment Station, Stockholm, Sweden) in *Soil Science*, Vol. VIII, No. 3, pp. 243-258, bibliography of 10 works, Baltimore, M. D., September 1919.

It is well known that the part of nitrogen in solid manure that is first nitrified in the soil is the ammonia nitrogen, but only a part is nitrified during the 1st year of growth, even under the most favourable conditions. Hence the desire to ascertain whether the fertilising action of the manure could be enhanced by the application of any of the chemical fertilisers easily obtainable.

The first factor considered was lime, and a record was kept of the exact methods adopted. The following ingredients were mixed with the soil : 1) ammonium sulphate, ; 2) sulphate of ammonia and calcium carbonate ; 3) farmyard manure ; 4) manure + lime ; 5) no admixture (control). The various mixtures were then placed in glass jars holding 5 kg., each, and these were then sealed down to prevent evaporation. At regular intervals samples were analysed for their content of nitrate-nitrogen, ammonia-nitrogen and moisture.

All the experiments tend to show that on the addition of lime in the form of calcium carbonate, and farmyard manure to cultivated soil of both neutral and acid reaction, no favourable action of the lime on the nitrification of the farmyard manure resulted, but on the contrary an impeding effect occured in the cases where the lime was applied in large quantities, larger probably than that applied in ordinary practice.

It is not easy to explain the cause of the impeding action of lime, but at any rate, it may be concluded that the lime does not have either an impeding or stimulating action on nitrification of the manure in the soil when supplied in recognised quantities.

1066 – ***Sesbania sericea* as a Green Manure Crop.** — *Royal Botanic Gardens Kew. Bulletin of Miscellaneous Information*, No. 7, pp. 282-254, fig. 1 London, 1920.

Specimens have been received at Kew sent by J. S. DASH, Director of the Agricultural Station Guadeloupe, West Indies, of a leguminous herb characterised by silky leaflets and straight very narrow pods which were found growing wild on an islet in the harbour and were put under experimental cultivation as a possible green manure crop. The plant proved to be *Sesbania sericea* D. C. The following details were also forwarded : the nodules on the roots are in size and quantity superior to those of any other leguminous plant. The plant seems capable of reaching a height of 4 ft., or more in good moist soil, but then has a natural tendency to become woody, and the time for turning in as a green manure crop should be judged accordingly. Sown thickly it will produce a heavy yield of green material when 2 to 2 ½ ft high.

(1) See *R.* Feb. 1920, No. 176. (*Ed.*)

Analysis of the Plant %.

In *stems* only: Moisture 69.17; albuminoids 3.69 (0.59 nitrogen); amides 1.39 (0.25 nitrogen); mucilage 3.50; cellulose 5.80; woody fibre 14.27; ash 2.18 (phosphoric anhydride 0.24 in stems and 0.29 in roots and potassium oxide, K_2O, 0.20 in stems and 0.20 in roots).

Total nitrogen 0.84 in stems and 0.83 in roots.

	Kilos per hectare	N.	P_2O_5	K_2O
Stems	14 103	1.18	34	28
Roots	1 710	14	5	3,5
Total . . .	**15 813**	**1 32**	**39**	**31.5**

There are in the Herbarium, specimens from the following places, and the former information might be used advantageously there: *West Indies*: Porto Rico, sea shore and Mayaguez; moist fields near Anasco. Jamaica; on the road from Kingston to Spanish town: Bahamas, near Nassau, *British Guiana*: sea shore. *French Guiana*: Cayenne. According to URBAN (*Symb. Antill. IV.* 286) it occurs also in Hispaniola, St Thomas, Antigua and Martinique. A single gathering has also been made in Ceylon, near Colombo.

On the west coast of Africa there is also what appears to be almost an identical species, namely *Sesbania pubescens*. This occurs in marshy places from Senegambia to Lake Chad, and on the shores of St Thomas Island.

In western Australia found at Flinders River, Sturts Creek, Depuch Islands and between the Ashburton and De Gray Rivers, is another plant which scarcely seems specifically distinct from *S. sericea*, and named by BENTHAM, *S. aculeata* Pers. var. *sericea*. There seeems no reason why in both cases the species could not be used as green manure.

1067 – **Tobacco Oil Cake as a Fertiliser.** — See No. 1107 og this *Review*.

1068 – **Studies in the Chemistry of Sugar Cane.** — VISWANATH, B., in *Agricultural Journal of India*, Vol. XIV, No. 3, pp. 440-457 charts 2, tables 5. Calcutta, 1919.

AGRICULTURAL BOTANY, CHEMISTRY AND PHYSIOLOGY OF PLANTS

The author has devised a method of extracting and examining small quantities of juice from sugar cane, without harming the cane to any appreciable extent. The sharp open end of an ordinary hypodermic needle was plugged with molted tin, and a small hole was bored in the side of the needle. The needle when inserted in a slightly slanting position into the internode, ruptures the neighbouring cells during its passage and two drops of juice from these cells pass into the needle by the side hole. This only permits the determination of the index of refraction of the sample of juice and the deduction therefrom of the percentage of total solids calculated as sucrose (ABBE refractometer).

By this method the author was enabled to determine the total sugar content of each point of the sugar cane during the various stages

of its growth, thus obtaining a glimpse into the life-history of the cane. The following condlusions have been drawn : —

In a young cane the maximum amount of total sugars is found at the basal joints. As the cane becomes older the maximum sugar content moves higher and higher till it is at the highest dead leaf joint.

A large increase of sugars occurs in the internode after the death of its attendant leaf.

It appears that the formation of sucrose in the cane is not due to such a simple process as the direct polymerisation in the stem of reducing sugars translocated by the leaf.

1069 – **Chemical Composition of *Desmodium leiocarpum* and *D. triflorum*.** — See No. 1097 of this *Review*.

1070 – **The Crescograph, a New Apparatus for Studyng the Growth of Plants.** — Bose, J. C. (Calcutta University), in *La Nature*, No, 2423, pp. 161-165. Paris, Sept. 11, 1920.

The Study of plant growth is a subject of extreme practical importance, for the nourishment of the world depends closely upon the growth of plants. The movement of stalks, leaves, and roots under the action of light, heat, and pressure are often due to small variations in the rate of growth. The discovery of laws bearing on the movements of the organs of growth thus depends on the accurate measurement of the rate of normal growth, and variations from it.

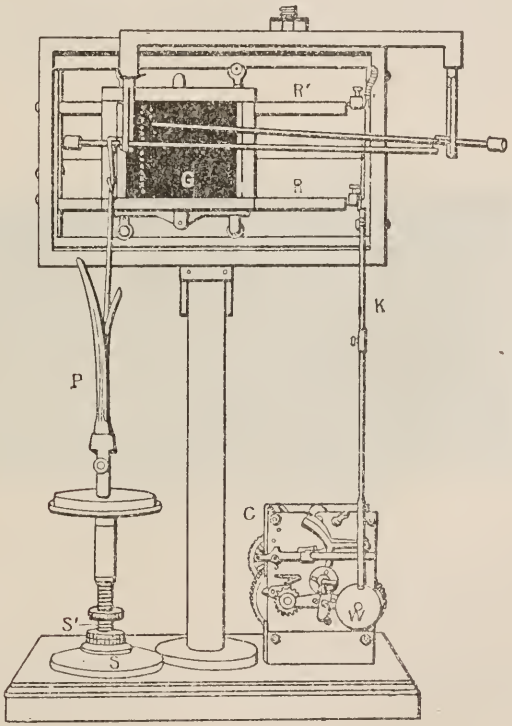
The great difficulty in these researches lies in the extreme slowness of the movements, these being of the order of about 1/40 000, mm. per second, which is about half the wave-length of sodium light. The auxanometers generally used amplify growth about 20 times and therefore several hours are needed before growth becomes perceptible, and, during this time, external conditions, heat and light, are varying the results ; in addition, autonomous variations appear during these long periods. Errors can only be avoided by reducing the experimental period to a few minutes, but for this, amplification must be very great and registration automatic. The author succeeded in doing this with his amplifying crescograph, by means of a system of 2 levers, the first multiplying 100 times, and the second again 100 times, thus obtaining a total amplification of 10/000. The difficulty of obtaining accurate registration of the growth movement, because of the continuous friction of the pen used for registering, has been overcome by an oscillating system, which brings the smoked glass up to the pen at regular intervals (Fig. 1). The registration thus appears as a series of dots at a distance apart corresponding to the length of growth during intervals of one second (Fig. 2*a*).

The graphs can be taken on a fixed metal sheet by means of two points, one in a normal condition before the test, the other after external conditions have been changed Fig. 2*d* illustrates a graph after an experiment, showing the varying distances between the dots which correspond to changes in rate of growth due to stimulation or depression caused by a factor under investigation.

The graphs can also be taken on a sheet moving at a uniform rate, the ordinates of the curves thus obtained representing movement and the abscissae, time.

A factor that increases the speed of growth will send the curve up or, if it slackens growth the curve will bend downward. (Fig. 2b).

Fig. 1. — *Amplifying Crescograph.*



P = Experimental plant.
SS' = Micronometer Screw fore moving the plant.
C = Clock work movement for producing periodic oscillations of the plate G.
W = Eccentric
K,R,R = Rods governing movement of plate **G.**

Precautions against physical disturbances. — Vibration is best overcome by using a strong table standing on rubber pads, or better still by using a stout shelf fixed to the wall. The author obtained an amplification of one million times with his magnetic crescograph before a London audience, the vibration due to the traffic in the street having no appreciable effect upon the instrument. Fig. 2c. shows the tracing produced on a moving plate by the amplifying crescograph; a dead stick was substituted for the growing plant, and the absolutely horizontal line showed

not only the absence of growth but also of all movements caused by external disturbances. There is another element of physical change in experiments on speed of growth which relates to artificial changes in temperature. In order to determine its character and order of magnitude a graph was taken of a dead stick subjected to an increase in temperature, amounting to 10°C.; the graph shows that expansion of the wood took place up to a certain limit after which the line of dots again became horizontal. The only precaution necessary in experiments on the influence of changes of temperature is to wait a few minutes until the temperature becomes stable.

Fig. 2. — *Graphs.*

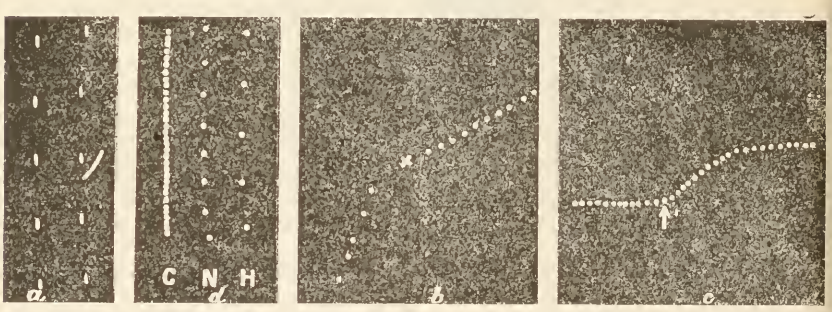


Fig. *a*. — Growth of *Scirpus* sp. at intervals of 1 second amplification 10,000, plate stationary.

Fig. *d*. — Influence of temperature.
N = normal graph.
C = retarded growth due to cold.
H = accelerated growth due to heat.

Fig. *b*. — Registration on a moving plate indicates retardation due to cold.

Fig. *c*. — Dead branch without movement indicates the action of heat.

Elongation due to physical dilatation is very rapid whereas physiological variation is slow and persistent.

Fig. 2*a* shows the rate of growth of *Scirpus Kysoor*, the speed of growth on the graph per second amplified 10,000 times being 9.50 mm. therefore the absolute rate of growth was 0.00095 mm. or 0.95, μ.

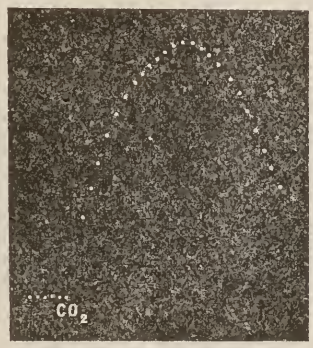
Effects of excitants on growth. — The general law has been found to hold good that all kinds of stimulants, mechanical, electrical, or luminous, retard growth, and if their intensity be increased may lead to a complete stop or even a contraction. As regards radiations, all except red and yellow, which produce photosynthesis, modify the rate of growth. Thus, the author has been able to register the reponse of plants to the long waves employed in wireless telegraphy.

Effects of sub-minimal excitants. — It was unexpectedly found that sub-minimal doses of excitants produced an acceleration of growth in

stead of the retardation caused by average doses. The same effects were observed with electric, luminous and chemical excitants, but, strikingly enough, certain poisons, which, given in normal doses, will kill the plant, cause the plant to grow vigorously and flower much earlier if given in infinitesimal doses.

It is only by discovering the laws of growth that considerable progress can be made in scientific agriculture. The author has only tested a few stimulants, whereas there are thousands that are quite unknown. The empirical methods used in determining the action of certain chemical reagents and of electricity have not always been successful, chiefly, it

Fig. 3. — *Effect of Carbonic Acid.*



The horizontal line in the bottom left hand corner represents the growth exactly balanced. The curve shows the effect of CO_2, dots being made at 10 second intervals.

seems, because proper account has not been taken of the quantity and strengths of the excitants.

The balanced crescograph. — The great sensitivity already obtained with the crescograph has been increased by using Noll's balance method, whereby the growth of the plant is exactly compensated by the lowering of the support. A train of years actuated by a falling weight lowers the plant at the same speed as it grows in length, the control of the speed being obtained by means of a screw. When the apparatus is correctly compensated, growth is just equal to the fall and the graph becomes a horizontal line, but it is so sensitive that the slightest external variation will influence the graph either positively or negatively. The speed of growth is indicated by a pointer fixed to the regulating screw. In this way, the author has been able to obtain readings of variations in growth up to one eight-millionth of a centimetre per second.

An illustration of the sensitivity of the method is given in Fig. 3, the excitant used being carbonic acid. An acceleration immediately took place and lasted 2 ½ minutes, being followed by a slackening. With very dilute carbonic acid, the acceleration may last a long time. The author also obtained clear response of a plant to a light of such short

duration as an electric spark lasting about one hundred-thousandth of a second.

The magnetic crescograph. — There is a limit to amplification by a system of levers, because each additional lever increases weight and friction. In order to obtain greater amplification for certain kinds of research work and for public demonstrations, the author has evolved a magnetic crescograph in which a light magnetic lever moves and rotates an astatically-suspended system to which a mirror is attached; on bringing the pointer of the system and the needle together an amplification can be obtained of from 1 to 10 million times. Some idea of this can be given by imagining the slow crawl of a snail multiplied 10 million times; a shell fired from one of the 15 in. guns of H. M. S. Queen Elizabeth has an initial velocity of 231 ft. per second; the amplification of the snail's crawl is 24 times more rapid. Amplification of 10 million times is obtained with a single lever, and a double lever would increase it another 100 times; giving an amplification of one milliard times. The importance of this apparatus for all kinds of research work is evident. Usually, an amplification of 1 million is sufficient. With ordinary precautions, mechanical trouble can be avoided

The physiological response of a growing plant was shown as follows: — The normal growth was shown by a movement of the spot of light from the galvonometer through a distance of 6 metres in 10 seconds. On introducing chloroform vapour into the bell-jar, the light moved three times as quickly, then came a relapse followed by a slackening of growth and finally a quick contraction, which indicated death. The same effects were produced by various poisons, such as cyanide of potassium.

General principles governing tropic movements. — In plants, the movements caused by external excitants (effects of variations in temperature, attraction or repulsion due to light, diametrically opposed responses of weight to stems and roots, and the diurnal and nocturnal positions of the organs of plants, present such a diversity, that it seems hopeless to try and discover a fundamental reaction applicable to every case. Usually one is content to admit that there are various forms. of sensibilities specially adapted to the individual needs of the plants, but the arguments of teleologists or simply descriptive terms such as the expressions of positive or negative tropisms fail to give a true explanation of these phenomena. The following experimental results seem to make it possible to deduce the general law which governs the tropic movements of plants.

Direct effect of excitation — In the motor yield of the mimosa, excitation provokes a rapid decrease in the turgidity and contraction of the cells. The cause of the decrease in turgidity is not exactly known, but it may be due to a sudden decrease in the osmotic pressure of the cell sap or to an increase in the permeability of the outer layer.

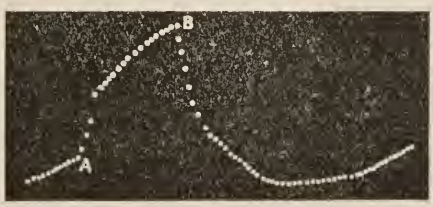
The effect of excitation on plant tissue was shown: — (1) By a decrease in turgidity; (2) the contraction and fall of the mimosa leaves;

(3) negative electromotive variation ; (4) variation in electrical resistance; (5) retarded speed of growth.

Continuity of the physiological reaction in the growing and non-growing organs — The author has found, during his researches on all the methods of excitation (mechanical, electric, luminous etc.) that stop growth or cause an " incipient " contraction, when the intensity of the excitation increases there is immediate contraction, exactly similar to that of the motor yield when directly stimulated. This explains the similarity between the tropic movements in the growing and motor organs

Indirect effect of excitation. — When the excitant is applied at some distance from the motor or growing organs, it produces increased turgidity, an expansion, accélerated growth, an erectile movement in the mimosa leaf, and a positive electromotor variation.

Fig. 4. — *Effects of direct and indirect excitation on growth.*



A. Indirect excitation accelerating growth.
B. Direct excitation retarding growth.

This effect is particularly noticeable in tissues that are semi conductors of stimulations. The opposite effects of direct or indirect stimulation are tabulated as follows. —

Direct excitation	Indirect excitation
Decrease in turgidity, contraction	Increase in turgidity, expansion
Fall of mimosa leaves	Erection of leaves
Slackening of growth	Acceleration of growth
Negative electrical variation	Positive electrical variation

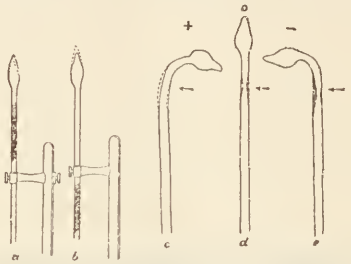
The law can therefore be deduced that direct excitation causes contraction, whereas indirect excitation causes expansion. The same law holds good when excitation is applied to only one side of the organ.

When the excitant acts from the right side (Fig. 5*c*), the side directly excited contracts, and the other side expands, being indirectly excited, so that a positive tropic curvature takes place towards the excitant This explains the twisting of tendrils and positive heliotropism.

Negative heliotropism. — When the light is very strong and of long duration, the hyper-excited organ may react in the inverse direction.

How does this come about ? The author's researches tend to prove that strong excitations traverse the organ and cause a contraction of the opposite side, thus neutralising the primary curvature (Fig. 5*d*). The organ takes up a position perpendicular to the light and this reaction has been termed " dia-heliotropism ".

Fig. 5. — *Effects of direct and indirect excitation.*

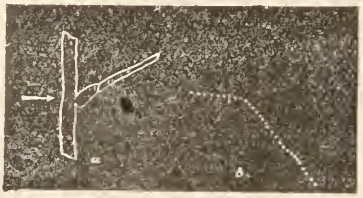


LEGEND :

(*a*) Direct excitation on growing region (shaded), showing shrivelling or contraction (stippled).
(*b*) Indirect excitation (shaded) away from growing region, showing acceleration or expansion.
(*c*) Excitation from the right contraction on this side (stippled), expansion of left (stippled) ; curvature towards the excitant.
(*d*) Transverse transmission through the organ ; neutralisation.
(*e*) Strong, transverse excitation : curvature on the side away from excitant.

In certain cases the transversal conductivity of the organ is considerable ; the result is a contraction of the opposite side, whilst that of the face directly exposed is diminished, because of the fatigue occasioned by a too strong excitation ; the organ, therefore, curves in an opposite direction to the light and shows a negative heliotropism (Fig. 5*e*). These effects are increased when one of the faces is more excitable than the other.

Fig. 6. — *Continued action of light.*



(*a*) Scheme of the result of giving indirect excitation (T) to a mimosa leaf.
(*b*) Graph of the leaf's response : erection (descending curve) followed by fall (ascending curve), due to transverse conduction of the stimulus.

Thus it may be stated that the action of continuous light first brings about a movement towards the source of the light, then causes

shrinkage and finally a movement in the opposite direction. Therefore the plant possesses no specific sensitivities, either positive or negative, to the action of light.

The graph shown in Fig. 6 illustrates these phenomena. A ray of light was thrown on a stalk diametrically opposite to an indicating motor-leaf ; the leaf first became erected as turgidity increased. If the excitation is weak and prolonged, the response is erectile or positive only, but if the excitant is strong the leaf droops, owing to decreased turgescence.

Proximal direct excitation	Distal direct excitation
Decrease of turgidity	Increase of turgidity
Concave contraction	Convex expansion
Negative electric variation	Positive electric variation

These results tabulated in brief are as follows :

If the excitation is strong and of long duration it neutralises or reverses the primary response.

[The author's book " *Life Movements in Plants* " Vol. II, deals fully with nyctitropism].

Geotropism. — Another seemingly inexplicable tropism is the opposite effect that weight has on roots and stems. The straightening of a stalk lying horizontally may be due either to the expansion of the lower surface of the contraction of the upper one.

To study this the author used the galvanometric method. The displacement of a stalk from a vertical to a horizontal position is immediately followed by a clear electrical indication that the upper side was excited. The electrical variation increases with the sine of the angle of inclination. This excitation causes the contraction of the upper surface and consequently curvature upwards.

Localisation of the zone sensitive to weight by electrical investigation. — A very thin platinum wire electrode, enclosed in a capillary tube except at the end, was pushed into a stalk in such a way as to enter by one face and protrude through the other ; the galvanometer shows the irritation thus caused to the surrounding cellular tissues. If the stalk is vertical, the galvanometer deflection is slight or nil, if the stalk is displaced towards the horizontal position, the layer sensitive to geotropism shows the maximum irritation and gives a corresponding deflection in the galvanometer ; as the stalk is raised the irritation disappears.

The author has also been able to locate the sensitive layer of the endoderm.

The only anomaly as regards geotropism is the curvature of the roots as opposed to that of the stalks.

Each zone of growth in the stalk is sensitive to weight and movement, geotropic excitation of the stalk is, therefore, direct. This is not

the case in the roots, where the sensitive zone is terminal, whilst the region of curvature is at some distance from the tip. The electrical researches of the author go to show that the root is excited directly, whilst the zone of growth which responds is only indirectly excited. Thus geotropic excitation only acts indirectly on the roots ; then, as the direct and indirect effects are inverse the responses of the roots and stems are opposite.

The different movements of plants are thus satisfactorily explained by the general law that direct excitations induce contraction and indirect stimuli, expansion.

The author has also shown the extraordinary similarity between the physiological reactions of plants and animals. Thus, this work on the movements of plants forms a chapter on general problems relative to the irritabilities of all living tissues without the study of which the future theories and investigations would be far from complete.

1071 – **Some Factors in Plant Competition.** — Brenchley, W. E. (Rothamsted Experimental Station), in *The Annals of Applied Biology*, Vol. VI, Nos. 2-3, pp. 142-170, Pl. I, figs. 10, tables 16. Cambridge, Dec. 1919.

Up to the present most of our knowledge of competiture influence has been purely empirical and derived from observation and deduction from plants grown under various cultural conditions not under strict control. Consequently little information is available as to the relative importance of the different factors that come into play, when one plant enters into competition with another, or of the interaction between these factors. During the past 5 years a number of experiments have been carried out at Rothamsted which aimed at isolating some of the more important of these factors and establishing their relationship to the growth of the plant.

Pot cultures were carried out with mustard and barley. Results show that the mutual action of one plant to an another when grown in juxtaposition, is a very complex phenomenon. Among the factors which come into play are competition for food, water, and light and also the possible harmful effect to toxic excretions from the roots.

Other things being equal, the total growth as measured by the dry matter produced is determined by the nitrogen supply. Irrespective of the number of plants drawing on the resources With limited food supply the efficiency index of dry weight production (1) decreases with, the number of plants.

The decrease in light caused by overcrowding is a most potent factor in competition even when there is abundance of food and water for each individual plant. The effect on barley shows: (1) Reduction in number of ears ; 2) great irregularity in number of tillers produced ; 3) reduction in amount of dry matter formed ; 4) rise in the ratio of shoot to root ; 5) increase in variation in the efficiency indices of dry weight production of

(1) See *B.* January 1920 N° 26. (*Ed*).

a number of crowded plants, lowering them on an average ; 6) decrease in the power of the plants to make use of the food supplied to the roots.

With adequate illumination (in barley) there is a tendency towards the production of a standard type of plant in which the relation between the number of tillers, and ears, dry weights, efficiency indices, and ratios of root to shoot approximates in thin variable degrees to a constant standard. This disappears with overcrowding.

1072 – **Formative Effect of High and Low Temperatures upon Growth of Barley: a Chemical Correlation.** — WALSTER, L. L. (Hull Botanical Laboratory), in *The Botanical Gazette*, Vol. LXIX, No. 2, pp. 97-126. Chicago, Feb. 1920.

The investigation here reported is a study of the effects of high and low temperatures and concomitant variations in the supply of nitrogen, phosphorous, and potassium respectively upon the course of development of the barley plant. A chemical correlation has been established between temperature and nutrition effects.

Method. — The method of sand culture was used throughout these experiments, the sand was pure Ottawa silica sand, and the water content of each jar was approximately 13 % dry weight of the sand.

Tottingham's culture solution was used in diluted form. *Solution A :* potassium nitrate 0.0034 M (0.3437 gm. per litre) + potassium phosphate 0.0108 M (1.4692 gm. per litre) + magnesium sulphate 0.0081 M (0.9750 gm. per litre. *Solution B.* Calcium nitrate 0.0101 M (1.6573 gm. per litre). A mixture of the AB solution is termed " normal ".

Three other solutions were then made up lacking entirely phosphorous, nitrogen and potassium respectively and three more containing only ¼ concentration of these three elements respectively. All cultures were run in triplicate.

About 30 seeds of Oderbrucker barley were sown per culture and the cultures thinned to 25 plants per culture.

Temperature and humidity control. — The greenhouse temperature was controlled by means of automatic thermo-regulators. The lower temperature selected was 15°C and the higher, 20°C. The samples for chemical analysis were taken in mid April.

Some of the differences noted in chemical composition may be due to the higher evaporating power of the air in a warm house. To ascertain, if possible, the character of the internal higher temperature in the presence of high nitrogen supply the WADEMAR KOCH method of tissue analysis (modified by F. C. KOCH) was used.

Comparison Tables were made showing the effect of temperature upon : 1) The amount and percentage of dry matter and water on barley leaves ; 2) the distribution of extractives and insoluble matter ; 3) the accumulation of soluble carbohydrates ; 4) the accumulation of polysaccarides ; 5) the amount of nitrogen, phosphorus, protein and phosphoprotein phosphorus ; 6) the amount and distribution of nitrogen ; (7) the amount and distribution of phosphorus ; 8) the solubility of F_3 nitrogen digested with 1 % Na OH for 48 hours at 37 to 40°C. (F_3 = mate-

rial insoluble in ether, alchohol and water); 9) the solubility of F_3 phosphorus under similar conditions; 10) on the amount of cell wall material etc. F_3 expressed as percentage of total dry weight of leaf.

The experiments reported in this paper, as well as the results of earlier investigators, re pen the question as to just what is meant by an optimum germination temperature. The classical investigations of HABERLANDT on germination temperature place the optimum at the temperature which most quickly permits the emergence of the radicle and plumule; in fact, practically all germination studies have been based upon this as the optimum. These optimum temperatures, at least for the cereals, are evidently too high to insure a future normal development. The writer believes that the course of development is to a large extent predetermined at a very early stage in the development of the plant by the chemical equilibria within the seedling, especially the nitrogen-carbohydrate ratio. These equilibria within the plant, like chemical reactions *in vitro* are conditioned by the temperature and concentrations of the reacting substances. It seems likely that a high temperature and high nitrogen supply at an early stage in the development of the barley plant so shifts the equilibrium toward excessive vegetation as to prevent the normal tendency toward reproduction. Some other factor must be altered therefore, as for example the water supply, if such plants are to be thrown into reproduction.

An investigation of the nitrogen carbohydrate ratio at a different stage in the development of seeds and seedlings furnished with varying concentrations of nitrogenous compounds will probably throw considerable light upon these questions.

RESULTS AND CONCLUSIONS. — The excessive leaf productions shown at the high temperature is caused by the high concentration of nitrates in the nutrient supplied.

Nitrate nitrogen in the nutrient begins to affect the subsequent course of development at high temperatures at the time of germination, or at least at a very early stage in development. This tendency cannot be counteracted by the addition of phosphorus or potassium salts.

High heat supply + high nitrogen supply in nutrient solution = high soluble nitrogen in leaf + low soluble carbohydrate = excessive vegetation and little culm formation.

Low heat supply + high nitrogen supply in nutrient solution = low soluble nitrogen in leaf + high soluble carbohydrate = normal vegetation and normal culm formation.

1073 – **On the Relations between Growth and the Environmental Conditions of Temperature and Bright Sunshine.** — BRENCHLEY, W. E., (Rothamsted Experimental Station *in The Annals of Applied Biology*, Vol. VI, No. 4, pp. 211-244. London, April 1920.

It is fully recognised that the amount of growth made by any crop in the field, and the rate at which maturity is reached is influenced by many factors such as temperatures, rainfall, season, sunlight, soil conditions and available plant food

It is difficult or even impossible to gain definite information as to the influence of each of these factors on a plant at various stages of growth, and the changes in the actual rate of growth at different periods, from crops growing under normal conditions. There is too great a difficulty in the disentanglement of the intimately associated actions of these factors.

The author has used the method of water culture, as it enables a strict control to be placed on the food and water supplied, and permits of the roots being observed and weighed with far greater accuracy than in soil experiments, and its compactness allows of a large number of plants to be given individual treatment at the same time.

It is also possible to keep a close watch on the temperature variations to which the plants are subjected, and to observe the effect of these variations on a number of individuals at different stages of growth.

Environmental conditions. — The experiments were carried out in a roof greenhouse, and extended over a period of sixteen months from September 1915 to January 1917. It should be noted that light conditions were good for any given period; it was proved by Gregory in experiments on cucumbers near London, in a district subject to fogs, that with high temperatures, light becomes a limiting factor

Artificial heating was installed, and the minimum temperatures kept above freezing point throughout the winter months, so that the results, so far as they refer to the effect of minimum temperatures, are only applicable in cases where the latter do not fall below 32°F. For the whole period of 16 months the prevailing conditions of temperature and light, as indicated by the weekly means of maximum and minimum temperatures, and the weekly hours of bright sunshine are summarised as follows:—

	Mean	Standard deviation
C. Mean maximum temperature	66.5°F	11.7°F
D. Mean minimum temperature	45.9°F	4.66°F
E. Hours of bright sunshine	20.3	16.6

The mean maximum temperature is naturally greatly influenced by the amount of sunshine; the minimum is much less variable, as during the winter months special care was taken to keep the right temperatures at a reasonably high level by means of artificial heating.

The small effect of sunshine on the range of mean minimum temperatures shows that the relatively constant range of mean minimum temperature over prolonged periods is of great importance to the healthy growth of plants under these conditions of life, and that a comparatively slight increase above a certain level is very detrimental.

Method. — At intervals of a few weeks, sets of 160 pea seedlings were put into water cultures Usually two parallel tests were carried out in one of which the nutrient solution was changed weekly and in the other the original solution was retained throughout the experiment. Ten extra seedlings were prepared for drying, to obtain the initial dry

weight of the plants and 10 seeds of the grade used were weighed to give the relation between seed and seedling after germination. At weekly intervals 10 plants were removed and after a cleaning and removing of the roots and shoots separately and when in the fruiting stage, the pods were removed, dried and weighed separately.

With nutrient solutions changed weekly, 8 series of peas were grown. The chief variable factors influencing growth were probably: —

(1) Temperature (maximum and minimum);
(2) Bright sunshine and light intensity;
(3) Humidity of air.

Growth may be divided conveniently into two well marked periods: (1) From the seedling stage till the time that the plant regains its initial weight after loss by respiration; 2) succeeding the former during which the plant is obviously making growth, and which continues till the latter ceases and desiccation sets in.

The length of the first period varies inversely with the mean maximum temperature as the rate of assimilation increases directly with the rise of temperature, up to a certain limit.

Results show that the possible amount of growth depends directly upon the bright sunshine and temperature at all periods of the year, but that beyond a certain point these beneficial factors become harmful and result in the premature death of the plant.

During the first period the rate of growth as shown by the "efficiency index" (the rate % at which fresh material is continuously added to the plant over a definite period) was associated with relatively warm days and nights. During the second period, the rate was associated strongly with sunshine and warm days, but not significantly with night temperatures (never below 32° F).

Results bear out the observations that growth is divided into two distinct periods and that the tendency is for the maximum rate of growth to be attained at the beginning of the second period and to fall off afterwards.

Plants with a restricted food supply make less total growth than those with abundant food, but broadly speaking the response of plants to the environmental conditions is similar whether the food supply is abundant or restricted, though the mean rate of growth is lower when food is scarce. The mean differences in the rate of increase in the presence of abundance and scarcity of food during the second period are strongly significant in favour of the well supplied plants.

During the early weeks, the shoot root ratio falls, owing to the steady increase in root weight, which is associated at first with a decrease and later with an increase in shoot weight. During the second period the shoot increases in weight far more rapidly than the root; and thus the shoot root ratio rises steadily.

Root growth is much affected by low mean maximum temperature and practically ceases from mid November to January, when the mean maxima are consistently below 60° F.

Cessation of root increase is a constant phenomenon and always occurs some time before the shoot stops growing.

Increase in shoot growth is closely associated with rise in temperature.

In a few series the water culture solutions were sampled at intervals, and the nitrogen estimated as potassium nitrate. Results showed at first that the amount of nitrate absorbed by the plant is relatively large in comparison with the dry matter produced, but later more dry matter is formed in proportion to the same amount of nitrate, owing to the accumulation of the products of assimilation.

TABLE. I. — (*Solutions not changed*).

Date	After week's growth	KNO_3 lost from 6 litres solution	Dry weight of 10 plants produced in period	Ratio of KNO_3 lost to dry matter produced over whole period

TABLE II. — (*Solutions changed*).

Date	At end of week	KNO_3 lost in the week from 6 litres solution	Dry weights of 10 plants produced in the week	Ratio of KNO_3 lost to dry matter produced in the week
		grs.	grs.	
Series K:				
April 14th	5th	2.34	3.176	1 : 1.36
April 21st	6th	1.65	5.738	1 : 3.48
May 12th	9th	3.72	6,650	1 : 1.79
May 19th	10th	4.14	20.984	1 : 5.07
May 26th	11th	3.52	5.847	1 : 1.66
Series M:				
May 10th	2nd	1.29	0.737	1 : 0.57
May 17th	3rd	1.89	2.409	1 : 1.27
May 24th	4th	2.46	2.792	1 : 1.14
June 23rd	8th	4.44	16.509	1 : 3.72

Ratio column of Table I shows that as the plant gets older the increase in dry matter produced becomes less dependant on the amount

of nitrate absorbed by the roots. Also in Table II there is an indication of a similar process though the evidence is less conclusive than where semi-starvation occurs.

1074 – **The Biological Aspects of Wheat Cultivation on Embanked Soils.** — PLYMEN, F. J. (Department of Agriculture, Central Provinces) and BAL, D. V. (Bacteriological Assistant) in *The Agricultural Journal of India* Vol. XV, Pt. III, pp. 289-300. tables IX. Calcutta, May 1920.

It was brought to the notice of the Agricultural Chemist, Central Provinces, that the embanked wheat soils of the Jubbulpore tract were said to be gradually deteriorating and giving low yields. The plants appeared weak and yellow in the early stage of growth but recovered later.

Mechanical analyses indicated that the soil is a heavy sticky clay, black in colour, with a maximum saturation capacity of 60 % by weight, with a soil layer 1cm., deep (HILGARD'S method). It was noted that it gets very hard and forms tenacious blocks on drying after rains.

A biological analysis showed that the soils appear to be very energetic in nitrogen fixation, followed by considerable ammonifying power, but are rather slow at nitrification. Further experiments showed that apparently about 20 to 25 % of moisture in soil is the required amount at sowing time. The nitrifying power increases gradually after rainy weather cultivation. Wheat seedlings from plots receiving this cultivation do not present the sickly appearance mentioned above, and the crop returns on embanked soils are increased. An interesting comparison is made with the black cotton soil of the Deccan undergoing similar experiment, but which is given an open cultivation and experiences a lower rainfall. From the figures quoted it may be noted that the nitrifying power of black cotton soil is very superior to the soil under consideration, even under similar conditions regarding water content, temperature etc. The maximum amount of nitrogen converted into the form of nitrate within a period of 8 weeks was only 50 % (after incubation with cake = 60 mgm. nitrogen per 100 gm. dry soil) compared with 85 % in the case of the black cotton soil.

From the results obtained it appears that young wheat plants in embanked fields are subject to some factor which retards their growth, but it is evident that the cause is removed by cultivation and aeration during the monsoon months. Experiments to determine this factor and also the most economic form of cultivation are now in progress. Former experience has shown the difficulty of using pot cultures in very heavy soils and the impossibility of reproducing field conditions by employing such a method.

1075 – **A Practical Method for Discovering the Free Nitrogen Fixing Power of the Schizomycetes.** — CAUDA, in *Le Stazioni sperimentali agrarie italiene*, Vol. LIII, Parts 1-3, pp. 79-80 Modena, 1920.

For the determination of the free nitrogen fixing power of Schizomycetes, the author suggests a simpler and more rapid method than chemical

analysis; this new method is based on the coloration of the chloroleucites present in unicellular algae. If the algae are grown in a medium containing no nitrogenous compounds, they never become green, even when exposed to the light. *Chlorella vulgaris* and the genera *Protococcus* and *Chlorococcum* are the algae most sensitive to this treatment. When one of these decolorised algae is placed under suitable conditions as regards nitrogenous food, it very soon assumes a green colour.

This property of blanched algae to turn green in the presence of nitrogen affords an excellent test of the nitrogen-fixing power of a micro-organism. Thus, if both are grown together in a medium free from nitrogen, and the algae becomes green, the necessary nitrogen has been fixed by the micro-organism.

1076 – **The Sterility of Hybrids from the Mendelian Standpoint.** — MALINOWSKY, E. in the *Zeitschrift für Induktive Abstammungs und Vererbungslehre*, Vol. XXII, Part. 4, pp. 225-235. Leipzig, May, 1920. PLANT BREEDING

Hybrids between different species of plants are often more or less sterile. This sterility is due to the fact that the pollen grains and the embryo-sacs develop in an abnormal manner, and are incapable of fertilisation. In the case of completely sterile hybrids, all the pollen-grains and embryo-sacs develop abnormally, and no seeds are formed; in that of partly sterile hybrids on the contrary, only some of the pollen-grains and embryo-sacs are degenerate, so that there is a larger or smaller percentage of properly-formed seeds.

In certain cases, the degree of sterility depends on the sex. Thus, for instance, in the hybrid *Antirrhinum siculum* × *A. majus*, all the ovules are sterile, whereas the pollen is active; it is thus possible to fertilise *A majus* with the pollen from the hybrid. The crosses between *Nicotiana Tabacum* (var. *atropurpurea*), and *N. sylvestris* have entirely sterile pollen, and only a few of the ovules are fertile; hence, in order to obtain any seed, it is necessary to have recourse to artificial fertilisation; the pollen of *Nicotiana sylvestris* can be used, if desired. Hybrids between wheat and rye (*Triticum sativum* × *Secale cereale*, behave in a similar manner.

Occasionally some entirely fertile offspring occur amongst the F_2 of partially-sterile hybrids. From *Pisum Palestina* × *P. sativum*, SUTTON obtained only sterile individuals with the exception of 2, which produced a small amount of seed. From these seeds, wholly fertile plants were grown.

In the cross *Stizolobium Deeringianeum* × *S. hassjoo*, BELLING observed, in the F_1, a high percentage of plants with sterile pollen and badly formed embryo-sacs. In the F_2, completely fertile and partially sterile plants occurred in the ratio of roughly 1 : 1, with a slight numerical predominance of the partially-sterile individuals; there were, in fact, 157 of the former and 167 of the latter in one case, and 169 and 229, respectively in the other. BELLING is of the opinion that this partial sterility may be due to the presence in the gametes of 2 genetic fac-

tors, which he calls K and L. If one of these factors is absent, the pollen and embryo-sac develop normally. Hybrids of the F_1 having the genetic constitution Kk Ll, would produce 4 different kinds of gametes: KL, Kl, kL, and kl, of which two, KL and kl, would develop in an abnormal manner, thus being incapable of fertilisation. Only half of the gametes Kl and kL develop normally, and theoretically we should therefore expect to find fertile and partly sterile plants in the same proportion (1 : 1). Such is the hypothesis, which, however, the author proposes to disprove.

TABLE I. — *Zygotes of the* F_2.

AB AB	Ab AB	aB AB	ab AB
AB Ab	Ab Ab +	aB Ab	ab Ab +
AB aB	Ab aB	aB aB +	ab aB +
AB ab	Ab ab +	aB ab +	ab ab +

If it is admitted that the simultaneous presence K and L (K L) causes the abnormal development of the gamete, it is not easy to understand how their absence (kl) should bring about the same result. The biometric data reported do not quite correspond to the ratio 1 : 1, for in either case there is a predominance of partially sterile individuals.

Taking as a basis the experimental data obtained by. BELLING, and also the general results, of his own experiments on wheat hybrids, the author has elaborated another hypothesis which, in his opinion, provides a better explanation of the facts in question.

It is admitted that the partial or total sterility of the hybrids is due to the presence in the zygote, at the same time, of two or more elements that are not in harmony with one another.

Let us consider the most simple case of two elements, A and B. The genetic composition of one of the parents will be **A A b b**, and that of the other **a a B B**. In the F_1, we shall have **A a B b**. These will be the same amount of sterility in all the types of gametes; there will also be fertile **A B** gametes and infertile **A B** gametes. Thus, we shall have fertile gametes of 4 types: — **AB**, **A b**, **a B**, and **ab**. These gametes, on uniting, will produce in the F_2 generation the 16 zygotes given in Table I.

Of these zygotes, 7 are fertile (marked in the Table with a + sign), whilst 9 are partially sterile, given the simultaneous presence of A and *B*.

Instead of the ratio 1; 1, we should have the ratio 9: 7, which is nearer the true one, and also explains the numerical predominance of partially sterile individuals.

Now let us take a more complicated case, in which in addition to A and B, there are two other elements, C and D, and where A and C on the one hand, and B and D on the other, represent contrasting characters.

The degree of sterility in a plant containing the four factors A, B, C, D, will clearly be higher than in the case of another plant having only two factors, such as A and C. In a similar manner, a plant **A A B B C C D D** will be more sterile than another plant **A a B b C c D d** or one with the genetic formula **A A b b C C d d**.

From **A A B B c c d d** × **a a b b C C D D** is obtained the partially-sterile hybrid **A a B b C c D d**. It must not, however, be supposed that this abnormal development is confined solely to the macrospores and microspores that have a given genetic composition; on the contrary, it may also be found in the macrospores and microspores of all the types. The F_1 hybrid forms 16 kinds of gametes: **A B C D; A B C d; A B c D; A b C D; a B C D, A B c d; A b c D; a b C D; a B C d; a B c D; A b C d; A b c d; a B c d; a b C d; a b C D; a b c D.**

From these gametes, in the F_2, 256 combinations are obtained, of which 49 are entirely fertile and the others are sterile to a greater or less extent. The percentage of wholly sterile and partially sterile individuals in the F_2 increases when the number of incompatible factors exceeds 2. A case of this kind was studied by the author in the offspring of *Tritcum vulgare* Vill × *T. dicoccum* Schrk.

The following crosses were effected:—

No. 1) *Triticum vulgare* ♀ with rather loose ears (local Wysokie Litewskie variety) × *T. dicoccum* ♂ with ears of average compactness.
No. 2) *Triticum vulgare* ♀ (as in No. 1) × *T. dicoccum* ♂ with rather loose ears.

No. 3) *Triticum dicoccum* ♀ with rather loose ears × *T. vulgare* ♂ with fairly compact ears (Solmann's glatter Square-head).

No. 4) *Triticum vulgare* ♀ (as in No. 3) × *T. dicoccum* ♂ with rather loose ears.

No. 5) *Triticum vulgare* ♀ (as in No. 1) × *T. dicoccum* ♂ with ears of average compactness.

No. 6) *Triticum vulgare* ♀ (as in No. 1) × *T. dicoccum* ♂ with rather loose ears.

No. 7) *Triticum vulgare* ♀ with rather loose ears (Zandomir wheat) × *T. dicoccum* ♂ with rather loose ears.

The author determines the degree of the fertility of each plant by dividing the number of seeds by the number of spikelets. Thus for an ear with 20 spikelets and 15 seeds, the degree of fertility is $\frac{15}{20} = 0.7$.

Table II gives the results obtained from the 7 crosses mentioned above :—

TABLE II. — *Results of the 7 Crosses.*

Cross N.	Degree of fertility of F_2 plants															
	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0	1.1	1.2	1.3	1.4	1.5	1.6	1.7
1	—	3	2	4	1	2	4	1	1	—	—	—	—	—	—	—

7	1	4	7	3	1	—	1	1	—	—	—	—	—	—	—	—

From the morphological standpoint, the F_1 of *Triticum vulgare* × *T. dicoccum* presents intermediate characters. In the F_2, on the contrary many new forms made their appearance of which the most important were : *Triticum vulgare*, *T. dicoccum*, *T. Spelta*, *T. durum*, *T. turgidum*, and two other forms, *T. lanceolatum* and *T. ellipticum*, regarded by the author as new species. In the characters of the ear, *T. lanceolatum* resembles *T. vulgare*, but is distinguished from it by its narrower, longer glumes ; *T. ellipticum*, on the other hand, recalls *T. dicoccum*, but the elliptical paleae are twice as long as the glumes. All these forms, which appeared in the F_2, proved to be hereditary.

In the F_2, partially sterile plants were much more numerous than fertile ones, and the percentage of wholly sterile plants was also very high (see Table II).

The numerical predominance of sterile or partially sterile individuals over fertile ones was still greater than in the above-mentioned theoretical data ; hence the author infers that the number of the incompatible characters, factors, or elements, must be still higher.

1077 – **Experimental Studies on Self-incompatibility in Hermaphrodite Plants.** — STOUT, A. B. (New York Botanical Garden), in the *Journal of Genetics*, Vol. 9, No. 2, pp. 85-129, pl. 2. Bibliogr. of 19 publications. Cambridge, Jan. 1920.

Experimental studies of the compatible and incompatible relations of the sex organs (including germ cells) in the fertilisation of hermaphro-

dites continue to yield evidence that these relations are highly fluctuating in the progeny of a single cross or self-fertilised descent. It seems clear that self-fertility is more primitive than cross fertility just as hermaphroditism is obviously the more primitive condition out of which dioecism has developed.

Evidence supporting this general conclusion is given by the author as the results of his own experimental studies of physiological incompatibilities. Experiments were made with the following plants in order to note the relation of vegetative vigour and maturity to variations in self-fertility and self-sterility: *Verbascum phoeniceum; Echscholtzia californica, Nicotiana Forgetiana* (Hyb. Hort), *Brassica pekinensis, Raphanus sativus, Lythrum Salicaria, Linum grandiflorum, Cichorium Intybus* (especially with red-leaved Treviso).

I. The evidence is conclusive that in the various so-called self-incompatibile homomorphic species, there are individuals that are to some extent self-compatible, and that there is among these, wide variability as to the number of sex organs that will function together. This is true at least of nearly all species whose self-fertility has been studied. The same general conditions were found in cases of cross incompatibility within such species.

One family of chicory was studied in detail, and showed grades of vegetative degeneracy, the viability of seeds containing embryos was low, many plants were weak, small and short lived, and many of those that lived, were entirely impotent in respect to the development of stamens and pistils. However there is yet no definite proof that degenerate plants or strains are more frequent in species which show self-incompatibility than in those that do not. The condition in this one family of chicory is like that reported by DARWIN (1869-1877) for the offspring of illegitimate crosses in the trimorphic species *Lythrum Salicaria*.

Perhaps the most significant fact from the standpoint of hereditary analysis is that the proportion of self-fertile to self-sterile plants in the progenies of self-fertile plants seems to fluctuate about a 1 : 1 ratio. This simulates a condition of so-called hybridity or heterozygosity involving selective elimination of the homozygotes. In making such a ratio, however, many grades of self-fertility are classed together. Continued variability and reversibility of characters in inbred lines are best interpreted as marked deviations in quantitative values or potencies of the ultimate units which Mendelian analysis and description may give.

II. Incompatabilities do not arise in species as a condition induced by self-fertilisation and inbreeding.

In considering the fertility of any one stock, the author agrees with DARWIN that there are involved :— 1) The production of perfectly formed sex organs, and 2) the relative functioning of the organs formed. The latter is especially involved in what DARWIN calls "relative fertility", and the former is especially represented in "innate fertility". Experiments proved that there is an extreme type of loss of "relative fer-

tility" in self and cross-incompatibility of plants of such species as *Eschsholtzia californica, Nicotiana Forgetiana* and *Cichorium Intybus*.

According to the statement made by East and Park (1918), the number of flowers and fruits is often increased, but no data have appeared which indicate a decreased percentage of non-functional gametes, and there was an increased seed production observed in certain cross-bred progeny due solely to an increase in the number of sex organs.

From this it cannot be definitely assumed that any observed case of decreased productivity in selfed stock involves an actual loss in relative fertility.

At the present time there is no direct or even conclusive indirect evidence that physiological incompatibility with selective fertilisation (at least selective for definite hereditary units) and variations in relative fertilities arise in species as direct results of inbreeding and repeated self-fertilisation.

The evidence from chicory shows conclusively that repeated self-fertilisation in line breeding does not lead to an increase of self-compatibility.

Conditions of incompatibility are not directly induced by repeated self-fertilisation, and are not to be ascribed to the condition of hermaphroditism as such, and this evidence is further proof that variation is operating in the physiological sex differentiation of sex organs.

III. Variations in morphological sex differentiation, especially recognised as phenomena of intersexualism, occur frequently in species prevailing either hermaphrodite or dioecious, and are quite analogous to those variations in physiological differentiation revealed by incompatibilities.

Concerning the relation between seed sterility from incompatibility and sterility from various types of impotence there is much need of further information.

It is characteristic of self-incompatible and cross-incompatible plants that the respective sex organs may be fully developed and potent. As a rule degeneration and impotence in hybrids seem to result from degrees of dissimilarity in the relative constitutional organisation and development inherent in the respective parents. Intersexualism differs from impotence in hybridity in that it exhibits a tendency to be one-sided. In respect to specialisation of the individual as a whole, intersexualism is a period of progressive variation.

There is a decided analogy between the variations in the physiological condition of sex organs as revealed by their relative functioning in incompatibilities, and those variations in the development of sex organs that are recognised under the term intersexualism.

Sex differentiation is hence widely variable in both its morphological and physiological aspects.

IV. Sex determination and sex differentiation in hermaphrodites are fundamentally a process of ontogenetic development, and may occur is various stages of ontogeny. The obvious sex differentiation may begin

in the development of entire branches, of flowers as a whole, or of stamens and pistils of the same flower, and is first strictly a somatic differentiation of like diploid cells. The sexual nature of these sporophytic structures is, however, seen in the intimate part which they play in the production and function of the haploid sex generation.

A self-incompatible plant is itself the result of a compatible fertilisation. Cytoplasmic and nuclear elements of an egg and a sperm fuse to form a zygote highly vigorous and of a high sexual potentiality, yet its sex organs fail to function together. The elements which were compatible in the fertilisation, and in the life of the resulting zygote became incompatible during ontogeny. Yet the incompatibility does not arise simply because of the element of constitutional similarity involved in hermaphroditism, nor because of sex-differentiation as such, for a sister plant with the same parentage and ancestry may be highly self-compatible.

Sexuality is a cyclic recurring condition which makes possible the fusion of cells and nuclei and the pairing of chromosomes. The incompatibilities exhibited in processes of fertilisation are due to physiological properties that are acquired during sex differentiation.

Whether the most successful fertilisation depends on some element or degree of similarity, or on some degree of dissimilarity, or on a proper balance of two, it is clear that the behaviour of incompatibilities both self and cross gives no proof that unlikeness in the sex organs favours the union of the gametes, or that some element of similarity leads to incompatibility.

1078 – **Selective Fertilisation in Pollen Mixtures.** — JONES, D. F. (Connecticut Agricultural Experiment Station, New Haven), in *Proceedings of the National Academy of Sciences of the United States of America*, Vol. 6, No. 2, pp. 66-70 Easton, Pa., Feb. 1920.

The method of mixed pollination in reciprocal applications is considered by the author as the simplest means of accurately testing the efficiency of two kinds of pollen in competition with each other, and experiments were performed with maize to prove the efficacy of this method.

Approximately equal quantities of pollen were collected from a number of plants of two distinct, but uniform types, thoroughly mixed in a bag, and applied to plants with the idea of having from 1000 or 2000 seeds per type. From the twenty mixed pollinations thus made, there resulted 63,694 seeds. There were classified, counted and a sample of each lot grown to test the accuracy of separation. A Table gives full details of the results obtained.

It is evident that in maize there is a pronounced preference for its own kind of pollen, and similar results were given in the case of tomatoes. This is notable in view of the great advantages which hybrid vigour gives immediately to the cross fertilised seeds, and the plants grown from them. In some cases, the weight of cross pollinated seed is increased as much as 50 %. This permits a comparative estimation of the amount of he-

terosis shown by various combinations involving different materials, and signifies a positive correlation between this amount and the preference shown by the plant for its own pollen. As the former is roughly proportional to germinal diversity, this is a remarkable result, because *in proportion as the cross-fertilisation benefits the progeny, the less effective are the germ cells in accomplishing fertilisation.*

In general terms, it has been implied in biological literature that the union of diverse elements, and the resulting lack of balance, stimulates growth. This hypothesis was used in theories of rejuvenation, explanation of hybrid vigour, and speculation concerning selective fertilisation. The author believes that this is not really supported by facts, and that homozygous combinations, according to the present theory, are more efficient than heterozygous combinations of the same factors, also that self-prepotency, except in those cases where a definite process has been developed to prevent self-fertilisation, indicates that unlikeness, instead of favouring fertilisation, is a hindrance. The prepotency of germ cells acting upon the same or similar individuals which produced them, is another indication that homogeneity, in protoplasmic structure is consistent with and favourable to the highest developmental efficiency.

1079 – **Varieties of Wheat from the Cereal Growing Station at Rieti, Italy: – "Sauro" (Soft, Awnless Winter Var.), "Bersagliere" (Soft, Awned, Winter Var.) "Principe Potenziani" (Soft, Awnless, Winter Var.)** (1). — STRAMPELLI, N. in *L'Italia agricola*, year LVII, No. 8, p. 242 + 1 plate; No. 9 p. 262 + 1 plate. Piacenza, August 15 and September 15, 1920.

"SAURO" WHEAT. — Obtained from a natural hybrid of the Japanese white "Shyrobozu" variety, of which the author had received an ear sent from Japan in 1912. It has the following characters:—

Ear red, square, pointed (or pyramidal), average density 29; average number of fertile spikelets 18, minimum 17, and maximum 20.

Spikelets with 3 or 4 fertile flowers (usually 4), average number of seeds per ear about 60, minimum 50, and maximum 65.

Glumes oval. lanceolate, slightly truncated, with distinct keel and small pointed beak, with 2 secondary veins one on either side of the principal vein. The three veins and the keel are fawn-coloured, whereas the glume is red.

Paleae oval-lanceolate, pointed, terminated by beaks or small awns, forming almost a right angle with the axis of the palea. These awns are 3 to 4 mm., in length and may even attain 8 to 10 mm., in the spikelets nearest to the top of the ear.

Kernels wheat-coloured, oval, measuring on an average 6 mm., in length, 2.9 mm., in width and 2.9 mm., in height or dorso-ventral diameter: fracture starchy; weight of 1000 grains 27,81 gm.; 1 hectolitre weighs 78 kg.

Culms 95 cm. high on an average.

Tillering poor.

(1) See: *R.* June-Aug. 1920, No. 732: *R.*, Sept. 1920, No. 851, *R.*, Oct. 1920, No. 956. (*Ed.*)

Ripening : in 1918, sown March 3, harvested July 11 ; in 1919, sown March 8, harvested July 15.

Yield : in 1918, 20 quintals per hectare ; in 1919, 19 quintals per hectare.

" BERSAGLIERE " WHEAT. — Obtained from a natural hybrid of the Japanese " Akagomyghi " variety. It is characterised by very early maturity and low habit of growth. Its characters are as follows :—

Ear red, square, slightly pointed ; density 38 ; average number of fertile spikelets 14, maximum number 16.

Spikelets with 3to4 fertile flowers ; on an average, 40 kernels per ear ; maximum 45.

Glumes oval-lanceolate, fawn-coloured, slightly keeled, with triangular, pointed red beak ; red spotted border at side of keel.

Palae oval, pointed, surmounted by awns of which the length varies between 8 mm. and 40 mm., the shortest being at the base and the longest near the tip of the ear.

Kernels of a light wheat colour, oval, slightly spindle-shaped, measuring on an average 5.8 mm., in length 3 mm., in width and 2.7 mm., in height ; fracture starchy ; weight of 1000 grains 28.84 gm. ; 1 hectolitre weighs 77 kg.

Culms 70 cm., in height.

Tillering very poor.

Ripening very early ; in 1918, sown March 5, harvested July 7 ; in 1919, sown March 8, harvested July 11 ; in 1920 (in Rome) sown February 15 and harvested June 9.

Yield : in 1918 and 1919, over 19 quintals per hectare ; in 1920 more than 17 quintals per hectare.

" PRINCIPE POTENZIANI " WHEAT. — Obtained by line selection from Japanese wheats. Its characteristics are :—

Ear red, square, density 32, bearing on an average 18 fertile spikelets maximum 20, and minimum 16.

Spikelets with 4 to 5 (usually 5) fertile flowers ; average of 70 kernels per head, maximum 80 and minimum 55.

Glumes oval, slightly keeled or with small beak with large external brown, border, similarly coloured border on side of keel ; and principal vein fawn.

Paleae oval, pointed, with small rostrum and external brown border.

Kernels of fine pale-wheat colour, oval-elliptical, full, with circular section, and slightly concave ventral surface ; average length 6 mm., average width 3.2 mm., maximum dorso-ventral diameter 3 mm. ; fracture starchy ; weight of 1000 kernels 34.46 gm. ; 1 hectolitre weighs 79.5 kg

Culms strong, about 90 cm. high.

Tillering rather poor.

Ripening. — In 1918, sown in the plain of Rieti on March 3, harvested on July 11, before the " Rieti " variety ; in 1919, sown March 8, harvested July 15, at the same time as the " Kiti " sown in October ; in 1920 (in Rome) sown February 15 and harvested June 9.

Yield — In 1918, 29 quintals per hectare ; in 1919 26.81 quintals per hectare ; in 1920 (in Rome), 22.88 quintals per hectare.

1080 – **Determination of Certain Hereditary Factors in a Wild Hybrid of *Phaseolus vulgaris*.** — SIRKS, M. J., in *Genetica*, Vol. II, Pt. 2, pp. 97-114. The Hague, March, 1920.

In a plantation of mottled kidney-beans from Prague with an epidermis buff-coloured with violet streaks the author noticed, in 1917, a plant with a dark reddish brown seed coat with bluish streaks. It was evidently the F_1 of a natural cross that occurred in 1916. With the seeds collected from this plant and purely by means of self-fertilisation, a large progeny was obtained in the F_2 and F_3.

An analysis of F_2 and F_3 led to the discovery of the following factors:

(1) P fundamental colour factor, necessary for the manifestation of all the colours, no matter what they may be; alone, it gives the buff colour; in the absence of factor P, the seed coat remains colourless, even if other colour factors are present.

(2) G: — yellow ochre factor which changes the buff colour to pale ochre.

(3) L: — deep reddish-brown factor; changes the yellow ochre to reddish brown, and in the homozygous state, becomes dark brown.

(4) B: — changes the buff colour to buff violet and the yellow ochre to brownish violet; the factor L is epistatic in relation to V, which makes it impossible to determine the presence of V in the case of the combination L l or L L.

(5) Gr: — grey factor; changes the fundamental colour into greyish buff, the pale ochre into greyish brown and the violet into greyish violet.

(6) B: — changes the violet into blue; this factor covers and hides all the others.

(7) S: — limits the blue violet, and grey zones to streaks which can be observed in the outer layer of the seed coat and makes it possible to see behind this the buff pale ochre, reddish brown, greyish violet or brownish-blue tints; if the inner layer is violet or grey, the factor S still takes effect and renders the violet mottled; the rest of the colours always gives a uniform shade; the factor S may be found in the cryptomerous state in the buff coloured, pale ochre, and reddish brown beans on which, however, it has no effect.

Correlations probably exist between some of these factors, as for example between P, V, and S on the one hand and G, L, B, and S on the other.

After examination of a large amount of material the author deduced the formula PPVVSS for the female type (mottled beans from Prague) and the formula pp GG Gr Gr vv LL BB ss for the male type, which when crossed with the former gives rise to the F_1 with a reddish-brown seed coat with blue streaks as obtained by the author in the autumn of 1917.

1081 – **Case of Complete Dominance of a Quantitive Character in Peas.** — KAPPERT, H. in the *Zeitschrift für Induktive Abstammungs und Vererbungslehre* Vol. XVII, Part. 3, pp. 199-209. Leipzig, March, 1920.

Results of crossing tall peas and dwarf peas from the point of view of such quantitative characters as total length of stem, number of internodes and average length of internodes.

It would seem that we have here a case of the complete dominance of the ordinary or common character (tallness) over the character of dwarfness.

As material for his researches, the author used Laxton's Vorbote, a normal pea 1.20 m., in height, and William Hurst, a dwarf variety growing to about 25 cm.

From the cross Laxton's Vorbote × William Hurst, three groups of hybrids were obtained in the F_2: — (*a*) Dwarf homozygotes; (*b*) tall homozygotes; (*c*) tall heterozygotes.

Had the dominance been incomplete the average length of group *c* would have been less than that of group *b*. In fact, however, the differences in favour of this last group are so slight, that they fall within the limits of error, while in some cases. the heterozygotes are taller than the homozygotes,

Data for 1914.

Type of hybride	Average height in cm.	Average number of internodes	Average length of internodes in cm.
Homozygote.	111.80 ± 3.83	14.60 ± 0.83	7.70 ± 0.28
Heterozygote	111.09 ± 3.60	15.67 ± 0.74	7.15 ± 0.29
Difference . . .	0.71 ± 5.26	1.07 ± 1.11	0.55 ± 0.38

The differences are in any case very small. In this case, the number of internodes is larger in the heterozygote; further, the heterozygote has the advantage as regards average height and the average length of the internodes. In all probability this is a case of the complete dominance of a quantitative (measurable) character.

1082 – **The Heredity of the "Adherent Seeds" Character in Peas.** — MEUNISSIER, A., in the *Journal de la Société Nationale d'Horticulture de France*, Series 4, Vol. XXI, pp. 118-119. Paris, March, 1920.

The variety of pea known as the "caterpillar pea" (pois chenille) which is distinguished by the peculiarity that its seeds when ripe, adhere more or less closely together in the form of a small crown, was obtained from a sample sent to Messrs VILMORIN by M. FROMMEL (Avenches, Switzerland). The peas are round, green. and adherent to one another, the leaves are of an emerald-green colour, The character of "seed adherence" is transmitted unchanged to the offspring.

The first crosses were made in 1908 by P. de VILMORIN, between a pink flowered variety ("pois de monie"), and a pea with white flowers ("Emereva"),

In the two crosses, the seed adherence disappeared entirely in the F_1, In the F_2, a small proportion of the seeds was united together. The in-

dividuals possessing this character transmitted it without exception to all their descendants.

Thus seed adherence is a recessive character,

By means of successive crossing, it was possible to introduce this character into several distinct varieties in correlation with the most different characters (absence of tendrils, fasciated stems, soft pods, etc.), and to obtain " chenille " peas with round, white seeds, or with wrinkled, grey or red seeds, etc.

There is, however, always complete correlation between the two characters " seed adherence ", and " emerald green leaves."

The proportion of adherent seeds varied much according to the season, therefore not only hereditary factors, but also environment have an effect upon this character.

The following are some of the data concerning the number of adherent seeds in certain plants manifesting this peculiarity in a special degree: —

In a plant with green, round seeds, there were two chains of 8 peas, one of 7, two of 6, one of 5, one of 4, one of 3, three of 2, and 5 free seeds,

Another plant, with round white seeds, had two small crowns of 8 peas, one of 7, one of 6, two of 5, one of 4, ten of 3, ten of 2, and 14 free peas.

Finally, in one plant with spotted, fawn-coloured seeds, there was one series of 8 adherent seeds, one of 7. one of 6, two of 5, two of 3, two of 2, and 2 free seeds.

1083 – **Heredity of the Colour of the Hilum of the Seed of *Vicia Faba*.** — SIRKS, M. J., in *Genetica*, Vol. II, Pt. 3, pp. 192-199. The Hague, May, 1920.

Plants with black hilums that were probably heterozygotes (appearing amongst white hilums) gave on self-fertilisation a mixed progeny of blacks and whites in the ratio of 3 : 1. Black is therefore the dominant character.

Plants which had flowered freely showed in their progeny the effect of spontaneous cross fertilisation. Thus the progeny of certain plants with a black hilum gave a numerical ratio very different from the normal ratio 3 : 1, whilst, amongst the progeny of plants with a white hilum, seeds with black hilums appeared sporadically, which is evidently due to a spontaneous cross.

1084 – **" 2714 POJ " and " 2725 POJ " New Javanese Varieties of Sugar Cane obtained by Crossing ; Their Introduction into Cochin-China.** — ERKELENS, F. A. (Directeur de l'Office Agricole, Industriel et Commercial Indochinois), in the *Bulletin agricole de l'Institut scientifique de Saïgon*, Year II, No. 9, pp. 278-282. Saïgon, September, 1920.

The extraordinary industrial and cultural results obtained by crossing different varieties of sugar cane have encouraged investigations to create new and still more rich hybrids.

In this connection, special mention should be made of the years 1917, 1918 and 1919 (especially 1917), for during this period of intense activity, many new varieties were obtained. Of these, the most interesting are

2714 POJ, and 2725 POJ, obtained in 1917 by MM. VAN HARREVELD and JESWIET at the "Proefstation Oost Java" (1). They have been studied at the Pasoeroean Scientific Institute, and have had considerable success in Java, where they have spread with great rapidity.

The author has presented to the Scientific Institute of Indo-China a certain number of cuttings he collected during his recent visit to Java. These were consigned to M. VIEILLARD, the Director of the Laboratory of Genetics and Selection of the Institute, and he had them planted immediately at the Phu-My Station in order that they might increase and that their adaptation to the rich soils of Cochin-China might be studied.

At the beginning of the study of the improvement of sugar-canes by crossing it was found necessary to make crosses between wild varieties and ordinary or selected cultivated ones. Later, however, it was possible to create much more complex hybrids starting from the old hybrids and determining the grouping and even the proportions of their respective essential characters.

Thus. the sugar canes 2714 POJ and 2725 POJ (which were the subject of the present work) have both come from seeds obtained by crossing 2364 POJ with E K 28. Their pedigree is therefore as follows:—

2714 and 2725 POJ
- Female parent 2364 POJ — *Cross* — 100 POJ × wild cane Kassoer
- Male parent EK 28 — *Probable Cross* — Bandjer masinhitam × Fiji cane

Cane 100 *POJ* is a dark-red hybrid Borneo × Lonzier (2); it has a high sugar content. and occupies about a tenth part of the area under sugar cane in Java.

The wild cane, Kassoer, was found by SOLTWEDEL at the foot of Mount Tjerémé in the Cheribon Residency, Java. The seed obtained by self-crossing did not produce offspring with fixed characters, which proves that we have here to do not with a pure variety, but with a natural hybrid, probably black Chéribon × Glagah (*Saccharum spontaneum* L.).

It is interesting to note that the wild Glagah cane is extremely resistant to "sereh" (3) and has hitherto always transmitted this character to its progeny, no matter with what variety it has been crossed. The Kassoer cane, which, as has been said, is probably a hybrid, also possesses this valuable character, and to such an extent that all inoculation experiments with this disease have had no effect either upon it or its hybrids.

Unfortunately, the Glagah cane contains no sugar and Kassoer but very little, so that the direct hybrids from these parents have not been able to pass the industrial test (with the exception, however, of Tjepiring 24,

(1) Many varieties of sugar cane are distinguished by a number followed by the initials of the names of the Stations where they have been obtained. Here, the letters P. O. J. are the initial letters of the Words "Proefstation Oost Java" (*Ed.*)

(2) See *R.*, Oct., 1920, No. 983 (*Ed.*)

(3) See *R.*, Oct. 1920, No. 983 note, (2). (*Ed.*)

the result of the cross black Chéribon × Kassoer ; but this hybrid is daily losing favour with sugar-cane growers, and now only occupies one per cent. of the area under cane in Java).

As the hereditary resistance of these varieties was considerable, especially against " sereh," it was possible as well as necessary to dilute still further the Glagah and Kassoer element by successive crossing with varieties rich in sugar, so as to obtain a hybrid with a high sugar content and also sufficiently resistant to disease. Thus the new varieties 2714 and 2725 POJ only contain ¼ of the Kassoer element or $^1/_8$ of the Glagah element,

The *Bandjermasin-hitam cane* owes its name to a Javanese word whose literal meaning is " Capital of Black Borneo " (1). It is called by the Dutch, the " dark-red Borneo cane." This variety has been used in the creation of several hybrids ; it is, for instance. the female parent of Cane 100 POJ.

The *Fiji cane*, of " dead cane." has been used in the creation of several excellent hybrids, two of which are 247 *B* and 247 POJ. It is a variety that has long been known in Java, where it was growing as long ago as 1891 on the plantations of Toelangan and Kremboeng (the Residency of Sidhoardjo, Java).

Thus 2364 and E K 28 are hybrids of these original varieties, some of which are themselves probably hybrids (2), whereas the new varieties brought to Saïgon by the author are both, as has already been pointed out, different products of the same cross, obtained in the first place from the above hybrids.

Their respective characters are as follows :—

Characters of Cane 2714 POJ. — *Stalk* :— Olive-brown, later brownish-yellow, like cane 100 POJ, but thicker.

Internodes long and straight.

Leaves grass-green, wide, very long, first erect then bent, with long thin apex.

Tuft with many shoots, and of rapid strong growth. The composition of the sap of the base and different parts of the stem is as follows :—

	Brix degree corrected	Saccharose Per cent.	Coefficient of purity	Extractable Saccharose Per cent.
Base June 18, 1918	19.2	17.4 ×	90.4	16.6 ×
Base June 3, 1919.	21.7	20.3	93.5	19.7
Middle, June 3, 1919.	20.9	19.6	93.6	19.0
Extremities, June 3, 1919	18.3	15.8	86.3	14.8

(1) Bandjermasin is the capital of the Dutch part of the island of Borneo.

(2) The hybrid character of E. K. 28, which is now the favourite sugar-cane in Java, was long unknown, and has only quite recently been established by the Pasoerean Scientific Institute. (*Author's notes*)

Different formulae have been suggested for the calculation of the saccharose that can be extracted industrially (1). Formerly, the extractable saccharose was estimated by the following formulae:

$$SE = 2 \text{ Saccharose} - \text{Brix}, \text{ or } SE = \text{Saccharose} \times \left(2 - \frac{100}{\text{coefficient of purity}}\right)$$

It has, however, been found that, owing to improved manufacturing methods, and to stricter chemical control, the figures given by these formulae are a little too low. Therefore, new formulae have been devised, including that proposed by Dr. ROSE and Dr. PRINSEN GNEERLIGS, viz.,

$$SE = \left(1.4 - \frac{40}{\text{coefficientl of purity}}\right) \times \text{Saccharose}$$

which has been used for obtaining the figures given in this article.

Other useful formulae have also been suggested, such as those of CARP. HAZEWINKEL and Dr. WINTER mentioned by the author. The formula selected depend upon the degree of purity it is desired to attain in the final product (2).

CHARACTERS OF CANE 2725 POJ, — *Stem:* — yellowish-green, later light-yellow, same structure as that of preceding cane.

Internodes like those of preceding cane,

Leaves bluish, very wide, bent.

Tuft numerous shoots, with rapid, strong growth.

	Brix degree corrected	Saccharose Per cent.	Coefficient of purity	Extractable saccharose Per cent.
Base, June 18, 1918.	21.4	20.1	93.8	19.5
Base, June 3, 1419.	21.9	20,8	94.8	20.3
Middle, June 3, 1919.	21.4	20.2	94.5	19.7
Extremities, June 3, 1919	19.5	17.3	88.8	16.4

These two varieties had been planted in the nursery on June 17, 1918, so that they were out a year old at the time of the last analysis the data of which are given above. They are therefore early varieties.

Their susceptibility to root-rot, which cannot be very great, will be definitively determined by the study of large plantations,

The Pasoeroean soils on which these canes thrive are clayey, and this makes it probable, that both the varieties in question will grow on a large

(1) In France it is assumed that 1 part of glucose prevents the crystallisation of 2 parts of saccharose, and that 1 part of ash prevents 4 parts of saccharose from crystallising. Thus the amount of saccharose, glucose, and ash present is determined, and the amount of glucose is multiplied by 2, that of the ash by 3; the products of these 2 operations are added, and the total amount of saccharose subtracted. The figures thus obtained give the refinable saccharose. (*Note by L'Institut Scientifique de Saïgon*).

(2) In order to determine this, the percentage of foreign elements which can be permitted to remain in the mixture can be added to the SE figure. (*Note by L'Institut Scientifique de Saïgon*).

number of soils. It is to be hoped that the results obtained on the very rich soils of Cochin-China will not be inferior to those obtained in Java.

1085 – **Selection and Crossing Experiments with a View to Obtaining New Varieties of Tobacco Resistant to *Phytophthora Nicotianae* de Haan, in the Dutch East Indies.** — D'ANGRENIOND, A. in *Proefstatjon voor Vorstenlandsche Tabak, Mededeeling*, No. XXXVII, pp. 1-29 Semarang, 1919.

The different varieties of tobacco grown in Java are very divergent as regards their resistance to *Phytophthora Nicotianae* de Kaan. Artificial infection experiments carried out on 138 different varieties furnished the following data (the figures in brackets give the percentage of seedlings still alive 30 days after infection).

Timor gebobbeld (84.6) ; Timor glad (40.5) ; Santiago de los Caballeros (94.6); Havana Criollo (82.2) ; Vuelta Abajo (78.4); Cuban Seed-leaf (73.5) ; Connecticut River (82.5) ; Stewart Cuban (89.1) ; Okinawa (85.5) ; Cuban (67.8) ; Satsuma (49.4) ; Cuba (66.9) ; Kanari (0) ; Yo 10 (0) ; Hatano (0) ; Matsukawa (0) ; Bajesi (0) ; Kokubu (0) ; Kanari Satrian (0).

Santiago de los Caballeros, Timor gebobbeld, Stewart Cuban, Okinawa, and Havana Criollo are especially distinguished among the 138 varieties studied for their great and well-marked resistance to *Phytophthora Nicotianae*. None of them, however, owing to the inferior quality of their product, could be used as a substitute for Kanari, or Yo 10, which are great favourites on account of the excellent quality of their leaves, but are unfortunately very susceptible to *Phytophthora*.

Many crosses have been made between the resistant and non-resistant varieties enumerated above. The following are data respecting their descendants in the F_1.

F_1	Percentage of surviving seedlings	F_1	Percentage of survivings seedlings
Kanari × Timor geb. . . .	45%	Hatano × Timor geb. . . .	70%
Kanari × Okinawa	26	Hatano × Okinawa	81
Kanari × Hav. Criollo. . .	25	Hatano × Hav. Criollo . . .	29
Kanari × Vuelta Abajo . .	15	Hatano × Vuelta Abajo . .	41
Kanari × Conn. river . . .	14	Hatano × Conn. river . . .	40

It is interesting to note that the Hatano series of hybrids is more resistant than the Kanari series, although Hatano itself is more subject to the disease than Kanari.

The work is being continued for the purpose of isolating, in the F_2 of Kanari × Timor gebobbeld and Kanari × Santiago de los Caballeros new stable types that combine in the highest proportions the excellence of product distinguishing Kanari, and the *Phytophthora* resistance characterising Timor and Santiago.

1086 – **Studies in the Pollination of the Bartlett Pear in California.** — TUFTS, W. P., in *Agricultural Experiment Station, Berkeley, California, Bulletin* No. 307, pp. 369-390, figs. 8. Berkeley, May, 1919.

In the Sacramento Valley (Davis) and in the Vaca valley (Vacaville), the Bartlett pear is to a certain extent self-sterile, and under foothill conditions as in the Nevada County it is completely self-sterile.

The Bartlett has an exceptionally long flowering period. No cases of inter-sterility have been found to exist between pear varieties, and therefore any variety flowering at the same time as the Bartlett may be used for pollination purposes.

The following varieties can all be employed advantageously to this end: Angouleme, Anjou, Clairgeau, Comice, Dana Hovey, Easter, Howell and Winter Nelis.

Not only did cross-pollination ensure a higher percentage of fruiting buds, but the fruits resulting therefrom did not appear to exhibit the same tendency to fall in June, as those resulting from self-pollination.

1087 – **Pollination Experiments with the Almond in California.** — TUFTS, W. P., in *Agricultural Experiment Station, Berkeley, California, Bulletin* No. 306, pp. 337-336, figs 15. Berkeley, March, 1919.

Report of a series of experiments carried out with a view to solving the following problems :—

1) What varieties of almonds commercially grown in California will prove profitable when planted in solid blocks, *i. e.* without pollenisers? This is a question of self-fertility.

2) What varieties planted in solid blocks will not be profitable? This is a question of self-sterility.

3) Admitting that the almonds at present grown in California will not prove profitable without providing for cross-pollination, which varieties should be planted together? The following points should be considered in selecting varieties :

a) Commercial value of the polleniser.

b) Simultaneous flowering periods of the polleniser and the variety to be pollinated.

c) Ripening periods of each variety.

d) Amount of pollen produced by the polleniser

e) Germination capacity of the pollen produced by the polleniser.

Results may be summarised as follows :

1) Satisfactory artificial germination of almond pollen was secured in 12 % a cane sugar solution.

2) The varieties studied may be divided into early and late flowering as follows : *Early flowering*: — Big White Flat, California, Harriott, I. X. L., Jordan, King, Klondike, Lewelling, Ne Plus Ultra, Nonpareil, Peerless, Princess, Silver Shell. *Late flowering:* — Dickinson, Drake, Eureka, Golden State, Languedoc, Nonpareil, Reams, Sellers, Texas.

3) With some vareties, the first flowers may give a smaller amount of pollen of inferior vitality to that produced by flowers on the same tree later on.

4) Pollinating agents, such as bees etc., are necessary to ensure good setting.

5) The Harriott variety, self-pollinated in 1916, proved, however, self-sterile the following season.

6) All the varieties so far tested have proved self-sterile, at least in certain years. This list in 1917 included : Big White Flat, California, Drake, Golden State, Harriott, I. X. L., Jordan, King, Klondike, Languedoc, Lewelling, Ne Plus Ultra, Nonpareil, Peerless, Princess, Reams, Texas.

7) Certain varieties are inter-sterile : *e. g.* I. V. L., Nonpareil, Languedoc and Texas.

8) California at present seems to be one of the best pollenisers for all the varieties so far tested, which flower contemporaneously.

9) California may be pollinated by Nonpareil and Peerless.

1088 – **Some Variations of the Common Coconut Palm *(Cocos nucifera L).*** — Henry, C. (Directur de the Société Française des Iles Marquises), in L'*Agronomie coloniale, Bulletin mensuel du Jardin Colonial*, New Series, Year V, 1920-1921 ; No. 32, pp. 52-54, figs. 4 + 1 plate. Paris, August, 1921.

The habit of the coconut palm nsually varies very little ; there are always the same large pinnate, more or less erect or drooping leaves, the same annulated trunk, and the same inflorescence in the form of a branch spadix.

The form now in question, however, is very different, it is rather rare and from a morphological standpoint, is worthy of description. Its productive qualities are mediocre, both as regards the number of the nuts and their richness in copra, so it is only interesting as a curiosity. The description of this form is as follows : —

Spadix simple, spicate, from 1 m., to 1.20 m., in length, the flowers occupying about 80 cm., of the total length.

Spathe greenish fawn-coloured, finely ribbed, almost cylindrical, straight, with difficult dehiscence.

Female flowers large, covered with 8 thick bracts from which they emerge when fully open ; they are in groups of 2, 3, and 4 in the upper two-thirds, and are very angular until they open, when they assume the form of

a more or less regular elongated cone, often shaped like a beak. On the lower third of the spadix, they are isolated and filbert shaped.

Male flowers occur either isolated or in the axils of the female blossoms; they are found eclusively on the top 10 cm., of the spadix.

In its entirety, the spadix, before the flowers open, resembles a gigantic ear of maize.

Fruits. — Only a few set (2 or 3 per spadix), and many of the spadices remain sterile. This is perhaps due to the fact that the male flowers open while the spathe is still closed and the female flowers are hidden within their bracts. The fruit is oval, irregular, excentric, 16 cm. in its longest diameter, and 26-28 cm., in height from the peduncle to the extremity of the terminal beak. This beak is sometimes straight and undivided, and sometimes is curved, ending with a kind of gland; the ribs are scarcely visible; the integument is yellowish-fawn, tinged with brown; there is llttle coir.

Nut of average size, 12 cm., in diameter and 14 cm., in height, ovoid, eccentric, terminating in a straight or curved beak 9 cm. long and of the same consistency as the shell; its tip loses itself in the coir.

Kernel not thick.

Met with occasionally in the Marquezas Islands.

The type of coconut palm introduced into these islands, as far as can be judged from some very old specimens still growing there, had fan-shaped leaves, many thick clusters of nuts, which were large, almost round, with little developed beaks, small amount of coir, average-sized internal cavity, thick kernel, pericarp with coloured integument of a pale reddish brown before it became dry. The coconut palms found there now-a-days have fan-shaped leaves that are erect or drooping; very small medium-sized, or very large, round, oval, or very elongated fruits, varying in colour from white to dark-red, after passing through green and yellow. They have either little coir, or a great deal of it, and the thickness of the kernel is very variable.

These variations are doubtless due to the variability of the genus, though some may be regarded as accidental.

As a result of the atrophy of the central shoot, one coconut palm planted on the sea-shore of the island of Ua-Uka, has become distinctly forked; this tree is twenty years old, its anomalous behaviour dates back two years, and both heads continue to bear fruit. Another coconut palm planted at Atwona (island of Hiva-oa) has an extraordinary peculiarity, its bunches of nuts having all been transformed into shoots; the "peduncle" is of normal length, and at the usual junction of the stalks; there is a swelling surrounded by pinnate leaves. The whole aspect of this tree is most curious.

Another tree produces nuts with coir that is easily detached and very white, even in the case of dry fruits. M. AHUNE, President of the Chamber of Agriculture, has informed the author of the existence in the island of Tahiti of an adult coconut palm with entire leaves.

SEEDS

1089 – **Experiments on the Soaking of Seeds.** — BACHELIER P., SCHRIBAUX, PETIT, LINDET, VIGER (President), in the *Comptes rendus de l'Academie d'Agriculture de France*, Vol. VI, No. 29, pp. 712-719. Paris, Oct. 13, 1920.

According to certain authors the yield of cereals can be increased by soaking the seeds in a solution of potassium nitrate or ammonium nitrate, the theory being that the grain is strengthened and nourished during its period of growth.

M. BACHELIER has experimented with seed soaked for 6 hours in pure water, and in 10 % and 20 % solutions of potassium nitrate or ammonium nitrate.

In 1919, soaking barley grains in pure water assisted the plants to spring up during dry weather. Saline solutions had however a harmful effect, which was greater with ammonium nitrate solution than potassium nitrate, and increased as the solution was more concentrated.

The idea of manuring seeds is not new, and M. DUHAMEL-DUMONCEAU in his *Elements d'Agriculture*, 1760, devoted a long chapter to his experiments on this subject, the results of which were always negative.

M. VIGER remarked on the experiments made by the farmers of the Loiret district who have obtained the same results as M. BACHELIER.

There is no doubt, according to M. SCHRIBAUX, that soaking in a very dilute solution is a help to germination, but the effect seems to be due solely to the action of the water. The effects of solutions and pure water have been compared and the latter generally gives the best results.

M. PETIT mentioned his own experiment which dates back 20 years and said that soaking beet seed in pure water gave good results during dry years, but solutions of fertilisers always gave bad results.

Having made grains of barley absorb sugar, in order to see whether germination was accelerated or not, M. LINDET found that the sugar had no effect on germination. The grain contained enough carbohydrates for shoot formation and it was useless to add any fertilisers to aid germination.

In fact, concludes M. VIGER, all the results show that it is simply the coefficient of humidity of the grain which may be advantageous under certain circumstances.

CEREALS AND PULSE CROPS

1090 – **Experiments with Swiss Jura Wheat in the Vosges District.** — SCHRIBAUX AND PERETTE, J., in the *Comptes rendus de l'Academie d'Agriculture de France* Vol. VI, No. 30, pp. 744, and 746-748. Paris. Oct. 20, 1920.

In regions which have severe winters and where Vilmorin and English wheats are killed by the cold, recourse must be had to the native wheats of which Alsatian wheat comes first in order of importance.

In the Swiss Juras where the winter is just as severe as in the east of France, varieties of wheat selected by M. MARTINET, Director of the Experimental Seed Station at Lausanne, are cultivated. In 1918, M. SCHRIBAUX recommended their trial in France. In a report to the Académie d'Agriculture, M. PERETTE Director of the Agricultural Services of the Vosges, describes the first results obtained in his department, and M. SCHRIBAUX has summarised them as follows: —

In a clay loam of Muschelkalk formation, Vuitebœuf wheat was sown after beet, which had been well manured with farmyard manure and superphosphate. To the wheat was added about 100 kg., of nitrate of soda per hectare. The growth of the wheat was remarkable. Earing took place very early, between May 25 and June 1, which was several days in advance of the Bon Fermier variety. The wheat was harvested on July 24, the earliest in the district. The Vuitebœuf variety was very resistant to lodging and to disease. At threshing time it produced 28 quintals of grain per hectare, which is a higher yield than that of the varieties cultivated locally, *i. e.*, Alsatian red wheat and Bon Fermier. According to M. PERETTE, Vuitebœuf, because of its remarkable precocity, will be very useful in countries with short summers and in mountainous regions.

He remarks also that the seeds had been mixed and contained about ¼ of foreign wheats, which yielded a fairly high proportion of bearded ears.

The other varieties tested, Bretonnières and Blanc de Savoie, are as good as Viuteboeuf, and it is anticipated, will give as good a yield as the latter if sown thick enough; Gavillet is not so good. M. PERETTE reserves his opinion regarding the last three varieties when sown on a restricted area.

1091 – **Notes on Experiments in Wheat Cultivation in Southern Italy.** — MANCINI, C., in *Il Coltivatore* Year LXVI, No. 25, pp. 618-620. Casale Monferrato, Sept. 10, 1920.

The area of wheat under cultivation in southern Italy is very great, being about 40 % of the total cultivated area, but the unit production is very low, averaging less than 8 or 9 quintals per hectare, and in some years, *e. g.*, 1919-1920 not more than 5 or 6 quintals per hectare. This inferiority as compared with the other parts of Italy is chiefly due to natural causes, but these could be eliminated to a certain extent.

The most serious factor which influences the production of wheat in southern Italy is the drought in spring and sometimes even in winter which hinders development and grain formation. Irrigation is the chief means for overcoming this difficulty; it is useful in winter and is always necessary in spring. The following experiment made by the author in 1919-1920 is of interest in this connection. A field 10 ares in extent was divided into three plots, the first one being treated with 4 quintals of superphosphate and 1 quintal of calcium cyanamide per hectare. The second was treated in the same way and irrigated twice between April and May. The third was left untouched and served as a control. The yield per hectare was 12, 20 and 7 quintals per hectare, respectively. Therefore, the fertiliser gave an increase of 5 quintals and irrigation 13 quintals per hectare.

Another experiment on a manured plot served to show the efficiency of single or double trenching, in winter or spring. The results were, *without trenching*, 12 quintals of grain per hectare, *with one trenching* 18 *quintals*, and *with two trenchings* 21 quintals per hectare. With the unmanured plot the weight of the grain was 75 kg., per hectolitre and with the second it was 80 kg.

The wheats cultivated in the south of Italy are of the hard or semi-hard type, and are superior to the soft types because, being earlier, they better withstand the scorching due to heat. The author advises the cultivation of hard in place of soft wheats even in Latium, and he cites the case of two farmers of the Roman Campagna, who obtained a unit yield 25 per cent. greater than that of the best soft wheats.

1092 – **Sowing of Wheat on Rice without Ploughing.** — Novelli, N. in *Il Giornale di Risicoltura*, Year X No. 9, pp. 129-131. Vercelli, Sept. 30, 1920.

Because of the great set-back given to the sowing, ripening and harvest of the rice in Northern Italy in 1920, it is necessary to avoid working the soil when the rainy season has already begun, for that would delay the sowing time which would then be carried out under very bad conditions. As a remedy for this, the author recommends that the wheat should be sown on the rice before the latter is harvested. This system is already widely used in the ricefields in the Provinces of Mantua, Verona, and Bologna.

Theoretically, it is more rational to sow after the ground has been well ploughed so as to assist root penetration, but as late ploughing only compresses and stirs up muddy soil, thus injuring the physical and mechanical conditions and the good state of the surface soil when it is not possible to plough in time and on dry soil, it is better to leave the soil as it is, *i. e.*, already well prepared by the previous cultivation of the rice crop, for by this means it can recover its condition more easily, thanks to perfect surface drainage.

The essential condition for the success of wheat in damp, cold soil such as that on which rice has been grown, is that it be sown at the end of September or beginning of October. The only way to sow the wheat whilst the water on the rice fields is diminishing and the ground still muddy, is to sow amongst the standing rice in the furrows. It is better for the seed to fall on muddy ground, as it germinates more quickly and the roots penetrate more easily. The amount of seed to sow is 20-30 kg., more per hectare than the usual quantity.

By the time that the rice has been harvested the wheat is already green, and after the harvest the furrows should be cleaned and the earth heaped up each side, so that proper drainage, may ensue. Phosphatic and nitrogenous fertilisers should be applied as a dressing in large quantities if possible. In winter, the wheat is also better sheltered by rice straw, but the latter, however, should be cut low. In spring, the ground should be harrowed lightly to remove the straw, and, if necessary, more fertiliser is applied.

In the provinces of Mantua and Venice, very productive wheats are obtained in this way ; weeds are scarce and the only cost of preparing the ground is for manure. Open and strong soils, not too lean, are most suited to this type of cultivation.

1093 – **Cultivation of Rice in Southern Rhodesia.** — MUNDY, H. G. (Government Agriculturist and Botanist) in the *Rhodesia Agricultural Journal*, Vol. XVII No. 3, pp. 243-246 - No. 4, pp. 320-344, Figs. 2 Salisbury, June and August 1920.

During dry years prior to the war, production apparently decreased as a result of the poor crops obtained, but with the advent of a wetter cycle, more native rice has lately been grown, and has led to enquiries as to the possibilities of rice becoming better recognised as a European crop. The information conveyed in the reports on native production made by the Native Department is summarised in this article, and deductions drawn therefrom.

Without exception, low lying swampy soil is selected, and when sufficiently retentive of moisture, the strong black soil (Chinyakwe) is preferred, although much rice is grown on the grey sandy loams (Shapa), or on the black granite vleis (Matoro). Adequate moisture is the governing factor, and not fertility. Although sowings are made on virgin soil, broken up six months previously, they are sometimes made to follow "Tsenza" (*Plectranthus* sp.), or early maize and pumpkins are sown thinly in August and intercropped with rice about October. The pit system is gradually being abandoned in favour of the ploughed ridge and furrow, owing to the preferable moisture holding propensities of the latter method. Deep ploughing in early spring is found sufficient where no moisture conservation is necessary. The date of sowing varies according to the moisture retaining capacity of the soil; October appears to be the most favourable month. The crop is harvested from March onwards. Necessary precautions are found essential with varieties which have a tendency to ripen unevenly and have a tendency to shed grain. From 18 to 20 lb., of seed is used per acre, sown either *in situ* or in seed beeds and transplanted. The average yield is about 5 to 6 bags per acre, but the Native Commissioners of Marandellas and Victoria estimate it as high as 15 to 20 bags. Normally, rice is grown for 2 to 4 years on the same land without manuring, after which new pits or lands are made.

The usual methods are followed with regard to threshing and husking. Unhusked rice is attacked very rarely by weevil compared with husked rice. Wood ashes are sometimes mixed with the grain in the native bins, as a preventive measure.

On the whole there is only a small loss through insect pests and fungoid diseases.

A description is given of the varieties fairly widely recognised, but the author cannot vouchsafe for accuracy, owing to the different names given to the same variety.

At present native rice is grown in practically all districts with a rainfall of 25 inches or more, on land with adequate moisture retaining capacity. However, provided the difficulty of uneven ripening could be overcome, there are considerable areas of wet land, especially in granite formation at present only utilised for early grazing, which should certainly grow rice under European methods of farming. That this difficulty is not

unsurmountable, is noticeable in the subsequent article dealing with rice cultivation in other parts of the world.

II. — The chief producing areas are India, China, Burma, Japan, the Southern States of U. S. A., Egypt, Java, the Philippines, Italy, Spain and Brazil. The larger quantity is of the swamp variety, although upland or hill rice is grown under much drier conditions in China, India and the Malay States, to quite a large extent.

Rice in British India. — The bulk is grown under swamp conditions or under irrigation, and when seed is sown broadcast or in drills, 100 to 120 lb., paddy (unhusked rice) per acre is the usual rate, with a possible yield up to 2000 lbs., per acre.

When the transplanting method is followed which is usually the case where terracing and irrigation is practised, the rate of seeding is only about 30 to 90 lb., per acre, with a prospective yield of from 2500 to 3000 lb., per acre. In this case, the seed bed is thoroughly ploughed either dry or inundated. The land into which the seedlings are transplanted is prepared and treated in a similar way.

Rice in the United States. — This is chiefly grown in the States of Louisiana, Texas, Kansas and California. The first commercial crop in California was grown in 1912 (1). By 1914, 16 000 acres were covered, and three years later, 67 000 acres. The ricefields are mostly terraced or contoured with low banks, and irrigation is practised to a large extent.

About 90 lb., of seed is usually sown per acre, and a crop sown in April matures about September ; the yields vary from 2000 to 3500 lbs unhusked rice per acre.

The land is kept flooded until the rice is 12 to 15 inches high, but the final draining of the land is regarded as of special importance to prevent the uneven ripening of the crop which otherwise will occur.

Conclusions. — Comparisons between these countries and Rhodesia, indicate certain similarities in soil types etc. but point to certain advantages in adopting new lines of cultivation in the latter country, such as terracing and levelling to encourage moisture retention, quite apart from irrigation which will not usually be practicable. Also the importance of draining is evident, as it appears elsewhere to be one method of overcoming uneven ripening. This last factor may be due to the thin rate at which the seed is normally sown, compared with elsewhere, and hints may also be taken in this respect.

During the last three years, Southern Rhodesia alone has imported on an average 1 ¼ million lb., of rice, valued at over £10.000, annually ; from India and Burma. The previous difficulties in preparing paddy rice for market, discouraged all efforts towards growing rice except as a native crop, but a complete rice dressing plant at Salisbury has now been established which has altered the situation entirely.

The Department of Agriculture expects to have by the end of August, supplies of seed of several varieties both upland and swamp, available for

(1) See *R.*, December, 1915, No. 1276. (*Ed.*

distribution under the usual terms of co-operative experiments. These supplies will be augmented by issues of seed which Messrs Marck Harris and Co. Salisbury are prepared to make to intending growers. The imported varieties will probably require one or two seasons before they become acclimatised; native varieties should therefore also be tested contemporaneously.

Rice Milling Machinery. — Particulars were supplied by the manufacturers explaining the process employed in husking and cleaning the grain preparatory to being placed on the market in a form suitable for human consumption. The following is a list of the proceedings:— The paddy after threshing, passes: (1) To the shaking sieve for cleansing operations; (2) to the disc rice huller; (3) to the shaking sieve over a blowing fan to eliminate broken rice particles; (4) to the compartment separator underneath the fanner which separates the paddy from the brown or hulled rice, the paddy being returned to the huller for further treatment; (5) to the white rice pearling cone by means of an elevator (the cone consists of a tapered drum covered with a composition of emery which revolves inside the casing covered with wirecloth). The brown inner cuticle is by this means ground off from the rice, thus producing the ordinary white rice as produced in large mills.

If a finer finish on the rice is required, it is taken into a rice polisher. This is of a similar appearance to the above mentioned cone, but the drum is covered with sheepskin instead of emery composition. The rice is then elevated again into a separator and aspirator and graded into three sizes.

Both the white rice pearling cone and the rice polisher are ventilated by means of a suction fan owing to the advisability of keeping rice as cool as possible whilst milling, to keep down the percentage of broken rice.

The mills are made in various sizes ranging from 5 cwt., to 5 cwt., of finished rice per hour.

1094 – **A Variety of Tripolitan Maize Suitable for Arid Climates.** — ZANON, V., in the *Rivista di Agricoltura*, Year XXX, No. 41, pp. 409-510. Parma, Oct. 8, 1920.

The types of Italian maize seeds distributed to the natives by the Agricultural Office of Benghazi produce plants which have a high and luxuriant growth, but do not set seed. On the contrary, the local variety « sboul-el-blet », in spite of the slovenly native methods of farming, always gives a crop and with careful treatment would give excellent yields.

At Derna, experiments in autumn and winter sowing have proved very successful, even without irrigation and the author considers that the variety mentioned would yield good crops in those parts of Italy which suffer most from drought.

The variety possesses the following characteristics:— Height 1 to 1.5 metres with the root-system well developed; in the young shoots the main root develops quickly and grows deep. The ears are always in pairs and situated at the 5th and 6th node, rarely at the 3rd. An abortive ear occurs at the 4th node The ears obtained by the natives are barely

mediocre, but with careful cultivation, the author always obtained very good ears, a large part of which was perfectly yellow, whereas the grain obtained by the natives is largely red. The ears are about 15 to 18 cm., long and 4 to 5 cm., in diameter, and there are from 15 to 22 rows with 28 to 30 grains in each ; the rows are fairly regular, straight, and parallel.

The colour of most of the grains is a bright chrome yellow. Forty mature grains, dried in the sun after ripening weigh 10 grammes; the grains measure 7 × 7 × 5 mm. The aleurone layer occupies $^3/_5$-$^4/_5$ of the transverse section of the grain. There is a high content of sugary material both in the grain (hard or soft) and in the pith. As mentioned above, this variety, cultivated at Derna, has given good results, using no other water but rainwater, whereas the natives employ irrigation.

April and September are the best months for sowing in the irrigated gardens of Bengazi. The period of growth varies from 2 to 4 months, according to the time of sowing. If sown on July 1, ripe ears can be obtained by the end of August, and the grain can be crushed after drying a few days in the sun. The natives generally eat the cobs whilst the grain is still tender.

STARCH CROPS

1095 – **Results of Potato Cultivation Trials made at Carrouge (Vaud, Switzerland) at an Altitude of 720 Metres.** — JORDAN, A., in *La Terre Vaudoise*, Year XII, No. 23, p. 222. Lausanne, June 5, 1920.

Potatoes planted on June 20, 1919, in light soil with a clay sub-soil, and dressed with farmyard manure plus a light application of potash and phosphates, gave the following yields :—

Variety	Growth and remarks	Yield on plots 11 m. × 6 m.		
		Small Kg.	Large Kg.	Total Kg.
No. III (Gratiola) . . .	Strong	1.4	19.1	20.5
No. II (Laurus) . . .	Average (mediocre)	2 6	7.7	10.3
No. I (Rindenberg) .	Very Strong	1.5	15.6	17.1
Ursus	Very Strong, Ravaged by field mice	1,0	13,0	14.0

In spite of late planting the results are good ; No. III is worth recommending, the tubers are very regular and marketable ; No. II is not recommended, as there are many small tubers. Ursus, although last in the above table would have yielded equally as well as, or even better than No. III if it had not been attacked by field mice. Certain plants produced from 10 to 12 tubers, some of which weighed 350 gm. No. I variety is good.

The late planting is very instructive, and shows how late a date planting may be done and how, if the crop has been poor, as in 1919, filling up the empty spaces will ensure a good crop.

1096 – **Cutting Potato Tubers for Planting Purposes.** — MOTTOT, S., in the *Journal d'agriculture pratique*, Year 84, Vol. 23 No. 8, pp. 146-147 + 1 fig. Paris, Feb. 19, 1920.

The scarcity and high prices of potatoes during the last few years have brought into prominence the practice of cutting up of tubers for planting. The use of the peel and the eyes gives a saving in seed, but the result is not good, without taking into account the extreme care required and, consequently, the great cost of labour. As regards cuttings, this practice belongs more properly to gardening.

In cutting it is hardly ever possible to get an exact division of the eyes, as the tops are left the greatest number of best developed eyes; it would thus be more simple to cut off the tops and use them only. This method was described for the first time by M. HARRACA during the war. He advised cutting the tops 1 to 2 cm., thick, but the author believes it necessary to leave them about the size of a hen's egg.

The cutting of the tops of the tubers not only has the advantage of utilising the best developed, youngest and most vigorous sprouts for growth, but ensures the tubers being healthy inside.

It is best to cut the tops some time before planting and place them in cool, well-lit, airy sheds. In this way a layer of dried cells forms over the cut portion, which prevents loss of moisture and enables the sprouts to develop more quickly.

1097 – ***Desmodium Leiocarpum*, a Giant Leguminous Forage Plant in Cuba.** — CALVINO M., in *Estación experimental agronómica, Santiago de las Vegas, Cuba, Boletin* No. 43, p. 24, figs. 7 Havana, Aug., 1920.

FORAGE CROPS
MEADOWS
AND PASTURES

Desmodium leiocarpum G. Don (synonymous with *Meibomia leiocarpa*, *Hedysarum leiocarpum* Spreng., and *H. erectum* Vell) grows wild in several districts of Southern Brazil, and is eaten with such avidity by horses that it is known locally as " marmelada de caballo ". Dr. BARRETTO first drew the attention of the Brazilian farmers to this legume and Dr. J. ROSSI, then Director of the Agricultural Station of the State of Santa Caterina Brazil, introduced it into this State some twenty years ago. On returning to Italy, ROSSI, in conjunction with the author, tried to acclimatise *Desmodium leiocarpum* in 1907, but without success, because the plants were destroyed by cold during the winter. In 1908, the author became Director of the " Estación Agricola central de Mexico ", where he experimented with the plant in 1913, using Brazilian seed. The results were excellent, but the Station was suppressed and the results were completely lost. In 1917, the author took charge of the Estación Experimental agronómica de Cuba, where he conducted similar experiments, using seed from the " Secretaría de Agricultura " of the Brazilian Republic. The results were very satisfactory. *D. leiocarpum* is a perennial, with numerous slender, straight stems 4 to 5 metres high, and bearing large clover-shaped leaves. In temperate climates the stems die during the winter, new shoots being formed in the spring, but in hot countries they last several years. *D. leiocarpum* does not appear to be difficult to suit as regards the soil as it grows in Brazil just the same in soils deficient in lime and

phosphoric acid, where other plants would not grow without the help of fertilisers.

When making new plantations it is better to use prepared seed-beds for the seed, which is very small, and to irrigate morning and evening.

Germination in the field takes place in about 20 days or more ; in irrigated land it requires 5 days, and if the seed has been soaked in water before planting, 4 days. When the young plants are 20 cm., high, they should be replanted 50 cm., apart in rows 1 metre apart. Asexual reproduction is difficult but it is possible by taking cuttings from the lower lignified part of the stem. *D. leiocarpum* is a hardy plant and will live even when abandoned for several years, but benefits greatly from weeding and manuring. In localities where it is necessary to protect the plants during the winter, the plant should be cut close to the ground at the beginning of winter, protection being obtained by ridging with a two-furrow plough.

The theoretical yield is 5 kg., per plant at each cutting and, with 20 000 plants per hectare, 100 000 kg., per cutting, or 300 000 kg., for 3 cuttings per annum ; the actual yield is not so great. The plant should be cut before it becomes woody and used green ; the rest is dried in the sun, made into trusses and put into sheds. It could probably be made into silage.

When the forage, whether green or dried, is slightly woody, it is better to chop it before using. Horses and cattle eat it readily.

According to Rossi, the dry forage contains 8.2 % of water. The composition of the green fodder is as follows :— Water, 70.4 % ; dry matter, 29.6 % ; proteins, 4.1 ; fibre, 5.05 ; pentosans, 3.4 ; soluble carbohydrates, 1 9 ; insoluble carbohydrates 7.95 ; crude fat, 0.85 ; ash, 3.20

The air-dried plant contains 9.8 % of water and its food value equals 313.16 calories ; forage dried at 100° C. has a food value equal to 347.20 calories.

It is thus an excellent fodder and forms a good supplement to a ration of forage gramineae.

In Cuba, as in Mexico, *D leiocarpum* is exempt from really severe diseases and pests. Amongst the insects that attack it, the author found under the leaves some aphids which were soon eaten by the "cotorrida colorada" (*Cycloneda sanguinea*) an insectivorous and carnivorous insect which abounds in Cuba. The plant is attacked at intervals by a cottony *Pseudococcus* and by certain *Chionaspis* the first at the centre, the second at the base of the stems. In May, certain larvae eat the edges of the leaves. A fungus of the genus *Diplodia* cause the death of some young plants.

Several other wild species of *Desmodium* are common in Cuba, and the author has found that their root bacteria can live on the roots of *D. leiocarpum* and form numerous nodules.

The author has also searched for other species which might be of agricultural utility.

D. tortuosum of Florida (Florida beggarweed) is an annual, which

grows less than *D. leiocarpum*. The author has grown it with success in Cuba, where it should be useful as a cover crop for the orchards during the rainy season and as green manure in sandy soil. It will even grow in soils that lack lime.

D. hirtum grows well over a large part of former German East Africa from sea level up to an altitude 2125 ft.; growth is rapid and it chokes all other plants, thus protecting the soil from washing and heat. Reproduction from seed is difficult; the seed should be planted in a nursery and the shoots planted out when 10 cm., high.

D. triflorum is a cosmopolitan type of plant hardly 30 cm., high, but it forms thick bushes. M. DE SORNAY advises it as a substitute for clover and lucerne in those countries which are too hot for these plants. It makes good meadows and is eagerly eaten by cattle. The percentage composition of the fresh fodder is:— Water, 64.6; ash, 2.57; crude fibre, 12.39; carbohydrates, 13.79; sugars, 0.93; fat, 0.92; protein, 4.80; calories (ATWATER), 130.809; starch value, 21.23; nutritive ratio, 1 : 5.7.

The yield is not good, however, as the plant is small. The author mentions, as worthy of the notice of the farmers on the high Mexican plateau, *D. orbiculare*, which is known locally as "engorda cabras" (goat fattener), on account of its good qualities as forage. It grows up to an altitude of 1200 to 2400 metres.

In India, *D. tiliaefolium*, a plant of shrubby growth, produces a fibre used for making string and baskets.

D. leiocarpum also yields long strong fibres which could be used for making rope and sacks.

1098 – **Rice Straw as Fodder.** — See No. 1141 of this *Review*.

1099 – **"Marandi" (*Acanthus ilicifolius*), "tivir" (*Avicennia officinalis*) and "lavi" (*Aeleuropus villosus*) Salt Water Fodder Plants.** — See No. 1142 of this *Review*.

1100 – **Food Value of Willow Leaves.** — See No. 1143 of this *Review*.

1101 – **Meadow Top-Dressing Test in New Zealand.** — SCHWASS, C. H., (Fields Instructor-Wanganui), in *The New Zealand Journal of Agriculture*, Vol. XX, No. 6, pp. 369-370, Wellington, 21 June, 1920.

In 1917 an experiment was commenced at Marton for the purpose of ascertaining the respective values of certain top dressing on the typical heavy land in that district. An area of 6 acres of meadow was divided into 6 plots of 1 acre each and top dressed in October as follows: 1) Control, no manure; 2) carbonate of lime, 1 ton; 3) carbonate of lime 1 ton superphosphate, 3 cwt sulphate of potash, ½ cwt blood, ½ cwt; 4) carbonate of lime 1 ton superphosphate, 3 cwt sulphate of potash ½ cwt; 5) carbonate of lime, 1 ton superphosphate, 3 cwt; 6) powdered clay (Papa rock), 2 tons. The whole area was closed up for hay in each of the three seasons.

From the accompanying Table it will be seen that all areas treated produced more feed than the untreated area. During the whole time, when the whole of the area was grazed with sheep and horses, they showed a preference for plots 3, 4, and 5. These were always eaten more closely, they also showed a much closer sward, and clovers were more prominent. The areas top dressed with lime and papa rock respectively, displayed a greener appearance than the unmanured area and also produced slightly more clovers. The pasture on the unmanured plot remained coarse and with scarcely any clovers. Prior to the test, it may be noted that the field had passed through the following phases; oat cropping; grass mixture, including more than the average amount of clover, but unmanured; and paddock for horses and cows with a few sheep for butcher's meat 1912-16. During this last phase the field was top dressed in 1913 with basic slag bonedust and GEAR grass manure 1 ½ cwt., to 2 cwt., per acre.

Tap dressing results, at Marton 1917-19.

Plot No.	Total Weight for 3 years per acre	Net Increased Return for 3 years over "No. Manure Plot"

FIBRE CROPS

1102 – **Flax Cultivation in North Africa.** — I. DUCELLIER, L., (Professeur á l'Ecole d'Agri. culture de Maison-Carréé, Algiers), in the *Bulletin des Matières Grasses de l'Institut Colonial de Marseille*, 1920, No. 4, pp. 153-172. Marseilles, 1920. — II. Commandant TRIOL (Agent général de Culture de la Société Tunisienne des Lineries Feuillette), La culture du lin en Tunisie, *Ibid.*, pp. 173-178.

I. — In North Africa only one variety of flax is cultivated; it more or less resembles the Italian variety, having large seeds, short, thick stems, with a large amount of tow, which is coarser than that produced by the Riga type. The Riga flax is distinguished by its long, slightly branched stems, which yield a better tow; it is widely cultivated in Russia. Various trials of this flax in Algeria have shown that it might be grown there with profit as it does not degenerate and keeps its good qualities whilst ripening earlier than the other varieties.

The author has made trials at Maison-Carrée with several varieties of flax, such as the Zeeland, Pskoff, white flower (North America), yellow seed, perennial flax (Siberia, Sweden), etc. These varieties did not do as well as the Riga, Italian or Algerian flax.

The author advises the use of line selection for the Riga and Algerian flax in North Africa He thinks that for textile flaxes, a microscopic

examination of the layer of fibres would be useful, as it would then be possible to find the correlated characters (inflorescence, capsules, stems, leaves, etc.) which would greatly help the plant breeder to discover, in the field, those individuals that yield most fibre. Practical industrial examination should be used to confirm the anatomical examination. The author deals with the soil and manuring, the preparation of the soil, the crop rotation (in North Africa, flax follows the Alexandrian clover, beans, mangolds, probably also vetchling and well manured chick-pea ; it has been long known that flax cannot be grown again for 6 or 7 years on some soils, but the reason is not properly understood), the choice of seed, sowing, upkeep of crop, harvesting of stems and grain, retting, yield, and cost of cultivation. He concludes with the following remarks :—

The cultivation of flax will be all the more profitable if more care is taken, as the crop can give very high yields. The attention of the farmer should be drawn chiefly to the choice of the variety and the seed, as well as the preparation of the ground.

The exploitation of flax, in addition, is facilitated as far as possible by the improvement of industrial retting.

The grower who deliwers the beaten stalks to the retting mill, will not have to perform the different operations necessary in preparing tow, as these are lengthy and expensive if done on the farm. The crop, thus freed from retting, presents very similar conditions to cereal crops.

It must remembered that proper flax cultivation will enable the cultivators to guard against fluctuations in market prices.

The importance of this industry is greatly enhanced by the demand for its by-products, such as tow, oil, cake and paper pulp, and should become an important source of revenue to North Africa, where the soil is well suited to the crop.

The chances of success appear all the more certain as there will be unlimited openings for a long time yet in the world's markets.

II. — At the Conference held in July, 1920, in the agricultural centres of Materu, Medjer-el-Bab, Béja, and Souk-el-Kemis, questions relating to commerce, the contract between the producers and the Société des Lineries Feuillette, and the cultivation of the flax (time of sowing, seeding, weeding, harvest, tedding and trussing) were discussed.

1103 - **New Zealand Flax *(Phormium tenax)*.** — *The Bulletin of Miscellaneous Information, Royal Botanic Gardens, Kew*, Vol 3, 169-177, 8 plates. London, 1919.

The possibility of growing New Zealand Flax as a commercial undertaking in the British Isles has for some years been a matter of interest and experiment in Scotland and Ireland. The variety with drooping leaves usually grown in gardens is not the form which gives the best yields of fibre, and attempts have also been made to grow the New Zealand flax in places for which it is not suited and the growth is so slow that as a commercial undertaking there could be no possibility of success.

To overcome the first difficulty a consignment of the best fibre yielding varieties of *Phormium* were sent over from New Zealand in 1914-1915

and 1918 and were put under trial in Ireland, Co. Kerry under conditions most likely to be favourable to their growth. Already evidence goes far to show that the possibility of growing *Phormium tenax* in S. W. Ireland as a commercial undertaking is an established fact. Reports from this trial station state that it is difficult yet to estimate the yield of fibre per acre but it will be over 1 ton per year and possibly 2 tons. Once established the plant yields crops for an indefinite number of years.

Experimental plantings should be made on boggy and poor moorland soil. The growth of th se plants in such situations has proved encouraging. The crop can be harvested at any time of year, and the work can be done in any sort of weather. Provided the crop is properly fenced and strong healthy stock planted and kept free from heavy grass just round each plant for the first year, the growth of a limited area should present no difficulties. Fife-sixths of the plants cultivated are of the variety known as the Powerscourt (*Phormium tenax*). This report by Lord VENTRY is compared with reports from other quarters in Scotland. The general opinion hints that although the *Phormium* will grow in almost any soil, it do s best where there is moisture present and also that home grown seed does better than imported seed. Advice is given in one case to cut the outside leaves of each crown every year to give a more regular fibre both as regards length and strength. Another states that the plant grows luxuriantly in cultivated peat soil, well drained.

At present the main purpose for which this fibre is used is for making binder twine and high grade string and cord.

1104 – **The Mechanical Properties of Philippine Bast-Fibre Ropes** — KING, A. E. (Division of General Inorganic and Physical Chemistry, Bureau of Science, Manila), in *The Philippine Journal of Science*, Vol. XIV. No, 6, pp. 561-655, Pl. 5. Fg. 2. Manila, June, 1919.

There are numerous uncultivated species of plants in the Philippine Islands, chiefly belonging to the families Sterculiaceae, Tiliaceae, Malvaceae, and Moraceae which produce fibres derived from the tough bast found in the inner portion of the bark of the stems and of the branches. At present they have no commercial significance in the Philippines, with perhaps the exception of *Abroma fastuosa*, but are used locally for the manufacture of cordage sufficiently resistant and durable for agricultural and animal husbandry purposes.

Lists have been published of the fibre plants including many yield basts, with botanical descriptions and the distribution of species, but no definite data concerning the relative strengths are given. No information has been given as to the approximate size of the cords studied, their weight per unit length, their elongation, and the manner of testing.

The present investigation was primarily undertaken for the purpose of securing quantitative results on the mechanical properties of bast ropes. Thirty-eight coils of rope were secured from material authentically identified in the Bureau of Science in 1917 (32 from bast plant series, and 7 from non-bast species). In addition, ropes from two standard cordage

fibres namely : Abacá (Manila hemp) and Maguey were used for the purpose of comparison.

The species from which the fibres listed were obtained are as follows :

(1) Bast fibres.

STERCULIACEAE : *Abroma fastuosa* — *Commersonia bartramia* (Linn.) — *Helicteres hirsuta* — *Kleinhovia hospita* — *Pterocymbium tinctorium* (Blanco) — *Pterospermum diversifolium* — *Sterculia crassiramea* — *S. foetida* — *S. oblongata* — *S. stipularis.*

MALVACEAE : *Bombycidendron Vidalianum* — *Malachra fasciata* — *Sida acuta* — *Thespesia Lampas* (Cav.) — *Urena lobata.*

TILIACEAE : *Columbia Blancoi* — *Corchorus olitorius* — *Grewia bilamellata* — *G. eriocarpa* — *G. multiflora.*

MORACEAE : *Alleanthus glaber* — *Artocarpus communis* — *Ficus Benjamina* — *F. Forstenii* — *F. pachyphylla* — *F. palawanensis* —

BORAGINACEAE : *Cordia cumingiana* and *C. Myxa.*

GNETACEAE : *Gnetum* sp.

BOMBACEAE : *Bombax Ceiba.*

ULMACEAE : *Trema orientalis.*

ANONACEAE : *Goniothalamus Amuyon.*

(2) Non bast fibres.

GRAMINEAE : *Dendrocalamus Merrillianus.*

MENISPERMACEAE : *Anamirta Cocculus.*

PALMAE : *Cocos nucifera* — (*Corypha elata*).

ZINGIBERACEAE : *Amomum* sp.

(3) Standard cordage fibres.

AMARYLLIDACEAE : *Agave cantala.*

MUSACEAE : *Musa textilis.*

Preparation processes may be classified as (1) plainstripping and (2) " water retting ". The two methods yield very different products. One series of experiments was conducted on test pieces in an open air-dry condition and the other on specimens that had been immersed in fresh tap water for 24 hours. A primitive wooden rope laying apparatus is described and illustrated.

Tables are given showing the tensile strengths per unit area of dry and wet tests, and also of breaking length of the ropes tested (that length which when suspended at one end will cause the specimen to break of its own weight). Ropes made of the strongest and lightest fibre gave the highest breaking length. The elongation of bast fibre ropes is generally less than that of most standard cordage fibres. The minimum and maximum averages for dry and wet specimens are 6 and 16 % and 9 and 25 % respectively.

The final summary Table gives all the species with the averages of tensile strength tests, breaking length, weight per unit length, elongation, girth, diameter, etc. The following have here been selected to indicate the species which gave the most successful results :—

I. *Gnetum* sp. —The Gnetum fibre is the most tenacious and has the highest breaking length 8.450 m., and is exceptionally pliable and compares favourably with two high grades of abacá rope, and a high grade machine laid maguey rope. It heads the list even after wetting for

24 hours, and shows augmented tenacity, 31 % strength. Results show in the other cases that wetting generally causes a slight decrease in tensile strength of most bast ropes. Gnetum is both durable and reliable, and is therefore preferred for making wild hog traps, and for trawl fishing and mounting seines.

II. *Abroma fastuosa*. — This has a high uniform strength which compares favourably with machine made abacá rope, and is only second to *Gnetum* sp. in breaking length, but this fibre is unsuitable for use in the wetted condition. When dry it is much valued.

COMPARISON TABLE.

	Mean breaking length	Average weight per unit length	Average elongation at the instant of rupture	
			Dry	Wet
Gnetum sp	8.450 m.	19.7 gr per m.	10 %	12 %
Abroma fastuosa (crude strips)	5.770 m.	83.7 » » »	12 % gauge length	13 % gauge length
Abroma fastuosa (retted bast)	7.740 m.	20.2 » » »	no test	no test

Full details are given with regard to the description of each species by the author, and Tables are made giving records of each individual test.

In connection with the fabrication, it may be mentioned that nearly all the bast fibre ropes are laid with three strands with the exception of one case which had only two. The so-called " diameter ' of the test specimens given, was calculated upon the assumption that the girth measurement of the rope is a true circle (1).

Results show that the maximum tensile strength of fibres is obtained when they are tested in their untwisted condition. Experiments by RÉAMUR show that vegetable fibres lose anywhere from 14 to 39 % original strength after being twisted into shape

1105 – ***Desmodium leiocarpum*** **and** ***D. tilaefolium*** **as Fibre Plants.**— See No. 1907 of this *Review*.

PLANTS YIELDING OILS, DYES, TANNINS, ETC.

1106 – **Experiments with Peanuts in Mesopotamia** — *The Journal of the Royal Society of Arts*, Vol. LXVIII, No. 3507, pp. 194, London, Feb. 6, 1920.

An interesting account of a successful experiment carried out at Fellujah, on the R. Euphrates, about 38 miles west of Baghdad, has been furnished by the United States Consul at Baghdad. It should be noted that except for a little sesamum and linseed, practically no oil-seed had previously been grown in Mesopotamia.

One-tenth of an acre was sown in June and the crop lifted in November and although the cultivator was inexperienced, the crop when first lifted, gave 2550 lb. of nuts, which when dried gave 1800 lb., per acre. Peanuts are already in considerable demand, large quantities having been

(1, See *Philippine Journal of Science*. Vol. 13 (1918), pp. 285-339. (*Ed.*)

imported from India. At present the nut is consumed in a parched state or is used for making sweetmeats. Later, when the production exceeds the local demand, the surplus will find a ready export as an oil-seed. The variety grown is a tight-husked variety, with a bright red skin, known as the small Japanese. It has the advantage of being quick growing, requiring comparatively little water, and being easy to dig.

Local merchants are much interested in this entirely new production. Demonstration plots at various centres were to be arranged for this year by the Agricultural Department and it should be possible to establish this crop on a commercial scale in a short time.

1107 - **Oil and Oil Cake from Tobacco Seed.** — PARIS, T., in *Bollettino tecnico del R. Istituto Scientifico sperimentale del tabacco. Roma-Scafati* (Salerno), Year XVII, No. 1, pp. 101-151. Scafati, Jan.-March, 1920.

The tobaccos which are not topped and are used for cigarette making are chiefly the Levantine varieties Xanti-yaka and Herzegovina, and to a lesser extent the Porsucian, Ayassalouc and Samsoun varieties. In Italy they are widely grown in the province of Lecce and they are now being tested in the provinces of Teramo, Chieti, Catania and Trapani.

Each Levantine plant yields, on an average, 2.5 gm., of seed, but others, like the " Brasile leccese " produce about 40 gm. About 140 million plants of Levantine tobacco are grown in Italy at the present time, and yield from 2000 to 2500 quintals of tobacco seed per annum, even when losses are allowed for. The composition of the seed is given in the following table.

	Per cent.
Water	9.17
Crude protein	21.87
Crude fat	37.68
Starch and sugar	0.05
Pentosans	2.90
Cellulose	7.15
Crude ash	3.84

Composition of the ash: —

Sulphuric anhydride	1.97
Phosphoric anhydride	22.12
Sodium oxide	3.48
Potassium oxide	28.05
Calcium oxide	9.54
Magnesium oxide	14.63

The seed can therefore be used as a source of oil.

M. D. D'AMATI, of Cerignola, during experiments made by authority of the Ministry of Finance, obtained 30 % of oil from the seed, using hydraulic presses working at a pressure of 350 atmospheres; the residue still contains 3 to 4 % more which can be extracted by means of solvents.

The oil-cake is the colour of tobacco, hard, compact, and not easily

broken. The following tables give the composition, and coefficient of digestibility of this cake.

Composition.

Water	11.83 %
Crude protein	28.63 »
Crude fat	1.64 »
N–free extract	31.41 »
Cellulose	19.90 »
Crude ash	6.59 »

Coefficients of Digestibility.

Protein 65 %.
Crude fat. 80 %.
N–free extract 75 %.
Cellulose 45 %.

The nutritive ratio is very narrow (1 : 80), but this can be corrected by the addition of bran or other starchy materials, by avoiding the extraction of too much oil.

An annual production from 2500 quintals of seed would yield 800 quintals of oil and 1 600 to 1 700 quintals of oil-cake. The cake does not contain nicotine and can be used as a cattle food ; it is very rich in nitrogen, and would constitute an excellent fertiliser.

The oil is clear yellow in colour, without smell or strange taste ; it is excellent for burning, for making soap, etc. The author considers that it is can be used for human consumption, as it contains no harmful substances. It is semi-drying, absorbing 5.16 % oxygen in 2 days and 6.21 % in 8 days (determined by the Livache method).

1108 – **Production of Henna in Morocco.** — See No. 1115 of this *Review*.

1109 – **Vitality of Beet Seed in the Soil.** — Schribaux in the *Comptes Rendus de l'Académie d'Agriculture de France*, Vol. VI, No. 33, pp. 799-801. Paris, Nov. 10, 1910.

SUGAR CROPS

In 1920, the anthor harvested beet at Montedour (Eure-et-Loire) from fields which had not grown beets for 3 and 8 years. The explanation was the germiuation of the hard seed, always capricious, which took place over several years and in various seasons.

The appearance of roots in the different parts of the rotation in a beet farm was thus quite natural. The surprising thing in this particular case was the lateness in germination of a considerable number of seeds ; in certain plots the number was about 1 per cent., on certain parts of the oat stubble as many as 50 per sq. metre (probably at places where the seed-plants has been heaped).

They appeared more frequently on certain patches, either because the soil was more clayey there, or because they preferred the headlands, etc. ; this shows how much the physical condition of the soil distinctly influenced the evolution of hard seeds. These facts are instructive for the producers of beets with rich seeds. In order to avoid mixtures that might harm their selection, they should avoid as much as possible, growing seed beets on the same piece of land, even at very long intervals. To

avoid this, they should try to produce varieties that do not yield hard seeds.

1110 – **Seed Production by Cultivated Beets during the First Year.** — MUNERATI, D., in *L'Italia agricola*. Year 57, No. 7, pp. 200-204 + 4 figs. Piacenza, July 15, 1920.

A critical review of Dr. CASSEL'S article on the same subject (1) based on the results of methodical studies carried out by the author since 1910 at the R. Stazione sperimentale di Biecoltura at Rovigo (2).

ANNUAL AND BIENNIAL QUALITIES OF WILD AND CULTIVATED TYPES. — Annual, biennal and perennial types of wild and cultivated beets occur. With the help of continuous selection, cultivated beet has gradually acquired the stable equilibrium of a biennal plant. However, in the wild state there is a *predominance* of types which flower and fructify in the first year, and whose roots retain sufficient reserve for the production of seedbearing cyms during 2 or more successive years.

It is easy to displace this equilibrium, *i. e.*, to obtain types mainly annual and biennial both in wild and cultivated plants by starting from types with opposite characteristics. The equilibrium may be only prevalently (and not absolutely) annual or biennial, for it is not possible to fix the annual or biennial character.

DE VRIES calls these types of plants " unfixable ", for continuous selection fails to eradicate the tendency of the biennials to seed during the first year and vice versa. Under different conditions, the same seed may produce a high proportion of annual plants that are mostly biennial. The author considers that the opinion expressed by Dr. CASSEL and many other authors, viz., that the first-year seeding of the beet constitutes a return to the primitive or wild type, that is, an atavic return, is therefore unjustifiable.

The conflicting results of experimentors who have traced the progeny of annuals derived from biennial parents should probably be attributed to the diverse nature of the subjects primarily used in examining the transmissibility of the tendency to seed during the first year.

By isolating plants in flower and studying each descendant separately a distinctly different behaviour can be observed in the descendants according to their parentage.

As a rule:—

(*a*) Beets which seed early tend more easily to produce annuals (these are nearly always characterised by the absence or small number of leaves at the base of, and along, the cymes, and by small thin roots more or less woody tissue).

(*b*) The tendency to produce annuals is only exceptionally transmitted to any great extent by beets that seed late (leaves are normally present in abundance along the cymes and at their base, the roots do not diverge from the normal weight and their tissues are either slightly or not at all ligneous).

(*c*) Beets which have descended from the so-called " rosettes " or

(1) See *R.*, April, 1920, No. 412. — See also *R.*, Jan., 1919, No. 9. (*Ed.*)
(2) See *R.*, May 1917. No. 4275 R. June 1918. No. 645 (*Ed.*)

" annuelles manquées " type have very little or no tendency to became annuals.

A fact which has not yet been explained, is that in every case and under the same conditions, beets that seed in certain years yield progeny in which the tendency to transmit the character is more pronounced than in the progeny of similar plants which seeded in other years.

IS THE ANNUAL TENDENCY A SIGN OF DEGENERATION DUE TO DEFECTIVE SELECTION ? — Dr. CASSEL replies in the affirmative, but the author remarks that it is very easy to obtain beets that tend to seed in the first year, both from beets rich in sugar, that is, very much selected beets and from very poor types.

THE INFLUENCE OF SOIL AND SEASON ON SEEDING. — All the workers are agreed that plants from the same seed show different tendencies to " rogue " according to the cultural conditions under which they have been placed. Early sowing has a particularly marked influence on premature seeding.

The influence of the soil on early flowering has been recognised by most workers, and some experiments made by the author have cleared up certain doubtful points on this subject.

(1) In 1916, comparative sowings made on the same day and with the same seed gave very different percentages of early flowering on land manured with different fertilisers ; these varied from 1 to 2 % on non-manured sandy soil to more than 50 % in open soil that had been heavily manured.

(2) The remarkable tendency to rogue, of beets in the 2nd or 3rd generation derived from annual parents is shown even though sowing is late, and when not even arrested growth or other causes can provide an explanation.

In 1918, the author obtained more than 90 % of annuals from seeds sown on April 26 (*i. e.*, later than in the Rovigo district), and which showed a tendency to behave like annuals in 1919, although in smaller numbers and despite sowing effected in July.

It is a recognised fact that beets may not seed even in the second year and this is why it is questioned whether seeds from beets that have flowered in the third year may give progeny less liable to rogue in the first year, and some workers have concluded, from their own experimental results that this is so ; but Prof. MUNERATI is unable to agree with them on this point, judging from his own observations.

1111 – **Isolation of Sugar Beet for Seeding Purposes.** — VILMORIN, J., in *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VI, pp. 365-369. Paris, April, 14 1910.

The author first explains that in his laboratory at Verrières, the richest or first-class roots are examined one by one in respect of their progeny, the lines so obtained serving as a basis for future selected seed-bearers ; then he describes the method used for isolating the roots.

Each beet is surrounded by a galvanised iron sheet half buried in the soil and to which is fixed a cloth impermeable to pollen. The whole

is supported by a strong stake stuck in by the root and carrying wooden hoops to support the cloth. The plant is thus enclosed in a kind of tent with an opening that can be closed if desired ; pollination is assisted by shaking the central stake.

The operation is usually performed on half-roots, the other half being left to flower in the open air. If this other half is considered to be of special value it is isolated by distance (" Raumlich-isoliering " in the German).

In spite of the bad conditions under which the plant grows if experimented with in this way, a sufficient number of seeds is obtained to permit of judging purity of the plants isolated. The author confirms the existence of self-sterile plants, and gives Tables showing the weights of the seeds obtained from them. No cases of degeneration were observed with these isolated plants. The sugar-beet, however, has recessive characters, except as regards the weight of the seeds.

The author confirms this by quoting, as an example of perfect, recessive fixation, certain strains of mangolds with red leaves and green petioles which never produce plants with red leaves and petioles. Therefore it must be admitted that abnormal characters such as red leaves and yellow skin are due to defective isolation.

1112 – **The Effect of Salinity on the Growth and Composition of Sugar Cane Varieties.** — Row, K. K., in *The Agricultural Journal of India*, Vol. XIV, Pt. 4, pp. 486-493. pl. 3, charts 5. Calcutta, 1919.

Soft, thick, juicy varieties of sugar cane do not come up at all in saline land, whilst, thin hard and less juicy varieties come up fairly well. The former may however succeed better under less saline conditions, and this difference is traced to be due chiefly to sodium chloride.

The effect of saline irrigation is to give an impure juice containing large amounts of chlorine and potash and a determination of chlorine alone, which is comparatively easy, will give an idea of the approximate quantity of the potash.

As the usual method of determining chlorine by evaporating the juice, igniting the same, and determining the chlorine in the water extract is not quite feasible in a field laboratory, the author proposes a new method of directly determining chlorine in the juice by lime water and alumina cream ; 50 c.c. of the sugar cane juice is measured out into a 100 c.c. measuring flask, neutralised with pure lime water, 25 c.c. of alumina cream added and the whole then made up to 100 c.c. with distilled water. This is then transferred to a beaker and kept covered on a sand bath for some time till albuminoids etc., in the juice begin to coagulate and settle down. On filtration the filtrate is found to be clear, and ready for titration. For impure juices, a small quantity of bone char may be added to ensure a clear filtrate ; 25 c.c. of this filtrate (equivalent to 12 ½ c.c. of the original juice) are taken and titrated against decinormal silver nitrate solution : though this method gives slightly higher percentages than that obtained by the ignition method, the results give a correct idea of the relative quantity of chlorine in the juice.

The chlorine content of a variety depends upon: *a*) Conditions of soil, water etc. under which it is grown; *b*) the nature of the variety itself. The effect of large quantities of chlorine in any juice is to lower the sucrose purity, and glucose contents of that juice. A high percentage of soluble salts in the juices of canes grown under saline conditions is usually associated with a low glucose content and interferes with the crystallisation of sucrose.

1113 – **Extended Cultivation in Java and Introduction inte Indo-China of Two New Varieties of Sugar Cane.** — See No. 1084 of this *Review*.

STIMULANT, AROMATIC, NARCOTIC AND MEDICINAL PLANTS

1114 – **Cocoa Production in the British Empire and other Countries.** — *The Bulletin of the Imperial Institute*, Vol. XVII, No. 1, pp. 40-95. London, Jan.-March, 1919.

In this article a comprehensive account is given of the present production of cocoa within the Empire, but an account is also given with regard to production in other countries.

Among the countries of greatest export Trinidad may be taken, with Venezuela, as an old cocoa producing country which has steadily been increasing its output during recent years, and the Gold Coast affords the most striking example of quick development of cocoa cultivation in any country where it is grown. The Table shows the production of raw cocoa in the chief producing countries in the years 1912 to 1917, as far as figures are available.

The relative importance of cocoa growing in some of the chief countries of production is indicated to some extent by the following figures, showing the exports of cocoa in cwt., per square mile:

San Thomé	1 487.9
Grenada	785.7
Trinidad	230.5
San Domingo	21.1
Gold Coast (1)	12.6
Ecuador	6.6
Venezuela	0.8
Brazil	0.2

(1) Colony and Dependencies.

To the first three of these countries Fernando Po should be added as an island where cocoa plantations absorb a preponderating share of the land used for agricultural purposes.

Only three species of *Theobroma* need be recognised as constituting raw cocoa as exported:— namely: *Theobroma Cacao*, *T. pentagona*, and *T. sphaerocarpa*. The first is that in most common use, and has split up in cultivation into some well marked varieties which are grouped as follows: "Forastero", "Criollo", and "Calabacillo".

According to VAN HALL, 1914, "Criollo" cocoa is grown only in Venezuela, Ceylon, Java, Samoa, Madagascar and Nicaragua, and "Forastero" is also found in those countries but alone in Ecuador, San Thomé, Trini-

dad, West Indies, Gold Coast, Surinam. etc. The cocoa in Trinidad has, however, been classed by HART (1911) as Trinidad " Criollo ".

T. pentagona is a native of Central America, and is grown on a commercial scale only in Nicaragua, Mexico, and Guatemala. It gives satisfactory stocks for *T. Cacao*.

T. sphaerocarpa is said to be common in cocoa plantations in San Thomé.

Details are given with regard to cocoa production in individual British Colonies and Protectorates, especially the Gold Coast where reference is made to the fact that the natives do not pay sufficient attention to the combating of pests (*Sahlbergella singularis*, *S. theobroma* and a *Helopeltis* sp., etc.) and also to diseases that are so likely to increase to a damaging degree.

Amongst those Possessions which have attained importance in respect to cocoa production, the West Indies and Ceylon appear to offer the best prospects for further extension of plantations under European control, and the Gold Coast and Southern Provinces of Nigeria under native farmers, but the introduction of better cultural and manufacturing methods is first necessary in respect to the native plantations.

A Table gives the quantities of raw cocoa consumed in various countries from 1911-1913, United States, and Germany taking the head of the list. Further Tables give details of the imports and exports connected with the cocoa trade of the United Kingdom, and points of information are given indicating extension prospects in the future.

1115 – **The Aromatic Plants of Morocco.** — I. GATTEFOSSE J., La Coriandre, le carvil, le cumin et leur culture au Maroc, in *La Parfumerie Moderne*, Year XIII, No. 1, pp. 2-5. Lyons, 1920. — II. Le henné au Maroc. *Ibid.*, p. 3. — III. Les plantes à parfums au Maroc, *Ibid.*, p 12 — IV. DE LORGUES, J., Les plantes aromatiques du Maroc. *Ibid.*, pp. 17-21. — V. Statistiques. *Ibid.*, p. 22.

At present, there is no European industry of the distillation of perfume plants in Morocco. The natives, however, use large quantities of scents, which they make with primitive apparatus, employing simple methods. It is certain, however, that the good, irrigable soils, which occur in almost all the pacified regions of Morocco, and especially in the district of Marrakech, would be most suitable for the systematic and intensive cultivation of flowers. The aromatic or scented plants of the country are not limited to the cultivated varieties, and many wild flowers of which but little is known are well worth the attention of those engaged in the perfume industry. The following is a summary of the chief aromatic plants of Morocco, arranged according to their families.

RANUNCULACEAE :— *Nigella sativa* L. is grown on a very limited area in Morocco ; in 1915, however, 397 kg., of the seeds of this plant was exported. *Nigella damascena* L., *N. arvensis* L., *N. hispanica* L. var. *intermedia* and *N. sativa* L. grow wild in the country.

CRUCIFERAE :— *Nasturtium officinale* L. (water-cress) is also grown on a very small scale. In 1914, 1568 kg., of seed was exported, but the next year the amount fell to 393 kg. *Cochlearia armoriaca* L. (horse-radish)

is also grown in Morocco, its seeds being exported for use as a condiment, but during the war there has been little demand for them. The export in 1913 was 12 329 kg., but fell to 5973 kg., in 1915. The aromatic root is rised in perfumery.

CAPPARIDACEAE:—*Capparus spinosa* L. (caper) grows wild on the Moroccan coast, especially in the South. Its aromatic buds, or capers, are gathered regularly. Before the war, the export trade was chiefly directed to Germany, but now the chief buyers of capers are the English and French. In 1915, Safi exported 2600 kg., of capers to England and France, as against 3339 kg., to Germany on 1913.

GERANIACEAE:—*Pelargonium Radula* L'Hér. var. *rosodora* (pink geranium) and another commoner kind that is not yet exactly determined, grow plentifully in the gardens of Morocco. *P. radula* var. *rosodora* from Algeria which yields a much prized scent, is largely cultivated throughout east Morocco. The finest crops are now grown at Oujda and the plain of Triffa. The "hamri" and "tirs" soils of the west coast of Morocco seem to suit this geranium equally well. Large areas were planted under it at Casablanca and Marrakech in 1919.

RUTACEAE:—*Citrus* sp. There is a primitive native distilling industry of *Aurantiaceæ* centred at Fez and Marrakech. In the neighbourhood of Fez, over 10 000 Seville orange trees are to be seen, but at Rabat, the sweet orange-tree predominates, whilst the mandarin is the favourite at Marrakech, and sweet and acid lemons trees are plentiful in the South. The weight of fresh flowers yielded by a Seville orange-tree (the average of 89 trees in the Marrakech Experiment Garden) was 6.830 kg., in 1915, and 2.573 kg., in 1916, which shows a marked seasonal variation. The Service des Domaines and that of the *Habous* (property of Religious Communities) possess plantations of *Auranticaceæ*, where the flower crop is sold in the trees by public auction. The natives usually distill these blossoms (the flowers of the lemon-tree, orange, Seville orange, and limes, etc.) mixed together by primitive methods that produce a scent that is much used by them. However, there always remains a certain quantity of orange-flower water for export, chiefly through the ports of the Spanish zone; the amount has been increasing of late years, and has risen from 328 kg., in 1913 to 1187 kg. in 1915. The price of orange-flower water is about 1 franc per litre. Extract of neroli is not made by the Arabs as they are too badly provided with apparatus.

ANACARDIACEAE:— *Pistacia vera* L. (or the pistachio) is a shrub sometimes cultivated. *Pistacia atlantica* Desf. is a larger plant than the true pistachio; it has aromatic fruits, and is widely grown in Morocco and Algeria.

ROSACEAE:— *Rosa* sp., The scent rose of Morocco appears to be a variety of *Rosa moschata* L. Roses are only cultivated on a large scale in Maghzen Morocco, in the neighbourhoud of Marrakech, though they are grown to some extent near Fez and Tetouan. At Marrakech, all the gardens are full of roses. South of the Atlas Mountains, the only roses known are those of Sous and of Taroudant, a town which exports many

dried rose-buds to Marrakech. In the gardens of Marrakech the roses are not planted thickly, but are grown on the borders of plots or in spaces between the trees bordering the walks. In spite of the rare occurrence of spring frosts, the rose-crop is poor, owing to lack of care in cultivation. One bush bears an average of 500 to 700 flowers, weighing, when fresh, from 1 kg., to 1.5 kg. The real centre of the dried-rose industry is the region, still almost unknown, lying between the Upper Atlas in the north, and Djebel Sarro in the south, and perhaps to some extent, the neighbourhood of Tamghrouth and of Tafilalet ; these roses are exported by way of Safi and Mazagan to France and Spain. Much is said of the roses of Tafilalet, but none of the varieties on the market of Marrakech seem to come from that region. The roses most prized in Marrakech are from the oases of Skouras and Daddès where the population is extremely dense. On the Marrakech market, the so-called " Entifa " and " Glaoua " dried roses are also sold ; these appear to be produced in the Atlas Mountains themselves, but according to an official report, they are less in request. Safi and Mazagan exported 25 329 kg., of dried roses in 1913, 8536 kg., in 1914, and 18 541 in 1915. At the present time, these flowers are also exported from Casablanca and Mogador : they go, not only to France and Spain, but also to the United States and Tunisia. The following table shows the distribution of this trade during the war, in 1916 and 1917.

	Casablanca	Mazagan	Safi	Mogador
1916	2 702 kg.	9 767 kg.	12 453 kg.	3 039 kg.
	3 836 fr.	12 001 fr.	22 380 fr.	3 039 fr.
1917	2 015 kg.	3 788 kg.	6 519 kg.	589 kg.
	7 999 fr.	5 588 fr.	8 141 fr.	913 fr.

The flowering season lasts from the beginning of April to the end of May. The women employed in gathering the roses are paid from 0.50 fr., to 0.75 fr. per day, the men being paid from 2.50 fr., to 3 fr. The flowers are sold by the " retal khodari " of 0.864 kg. In 1916, the price varied from 1.40 fr. retail, to 0.80 fr. wholesale. Distillation is carried out on the spot, by a very primitive process ; in Marrakech, about ten small traders distil some 10 000 kg., of fresh roses monthly, obtaining approximately 5000 kg., of rose-water. As a rule, however, the natives of the middle and leisured classes make their womenfolk distill the rose-water they use so largely from the flowers of their own gardens. The great demand for this scent has a considerable influence on the price of fresh roses, but the fact that the scent is sold on the spot would greatly reduce the cost price of rose essence, if it were made commercially.

Marrakech also supplies the coast-dwellers with small quantities of rose-water at prices that vary according to the quality, but usually about 2.20 fr. per litre

The dried roses (entire floral buds) from Sous and Drâa arrive daily at Marrakech from May until the end of June. The Daddès roses are the most in request, and fetch the highest prices; after them come the Skouras roses. It is estimated that 40 to 80 metric tons of roses, of the value of 200 000 fr., leave Marrakech annually. The transactions are carried out at the Mellah, in the "fondouk" of the druggist's shop, always an important place in Arab countries. Formerly, the "quantar attari" (54 kg.) was worth 8 to 12 fr., but in 1915 the price started at 20 fr. and rose to 35 fr. at the end of the season. In 1916-1917, the high prices kept up and even increased by 25 to 100 fr., between 160 and 175 fr. were paid for 65 kg., during the 1918 season. The principal market for roses is, however, Morocco itself, for only some 30 tons were exported.

It seems that the rose-bushes now found at Marrakech and Taroudant, etc. would yield larger crops with better cultural care and the gradual replacing of plants past bearing. On the other hand, all the regions of Morocco contain soils suited to new plantations, which could be managed by competent natives. Thus it would appear that no practical difficulties stand in the way of extending the cultivation of roses.

LYTHRACEAE: *Lawsonia alba* Lamk. (= *L. inermis* L.) is the plant known as henna; it is chiefly grown in the neighbourhood of desert zones, and is greatly used by the Arabs. Its fragrant flowers could also be employed in making perfumes, and it is one of the most important dye-plants of Morocco. In 1917, according to the Terbib statistics, the henna crop covered 161.35 hectares, which were distributed as follows: —

Regioni	European	Native
	hectares	hectares
Fez	—	0.13
Rabat	—	26.50
Casablanca	2.0	7.23
Doukkala	0.12	135.37
Total	**2.12**	**169.23**

Morocco produces less henna than it consumes, as can be seen from the Customs statistics:

	1913	1914	1915
	kg.	kg.	kg.
Import	48 996	85 392	99 634
Export	900	1 875	925

These figures show the desirablity of increasing the production of henna in Morocco. Systematic cultivation trials of the plant have just been

begun at the Fez Experiment Farm and at the Experiment Station at Marakech.

Henna is chiefly grown at Azemmour, Sidi-Ali, and Mazagan, and on a few plantations in the interior of the Doukkala, but these are of minor importance. Henna is an irrigated crop, and therefore the plantations are situated near wells, or " sanias " (areas that can be irrigated from the same well). The area of a sania under henna varies from a few areas to about 1 hectare. The natives only cultivate this plant on clay or sandy loams ; light, sandy soils do not suit it and when grown on such soils, the yield is lower, and the plantations last but a short time, 5 or 6 years, whereas on shallow, calcareous soils they grow for 10 years on an average. Water containing much salt is very injurious to henna. It is usually grown with a catch-crop. The land-owner provides the " sania " and furnishes the animals required to work the " noria " during the growth period. At Mazagan, the yield is estimated at 600 to 900 kg., per hectare.

The prices vary according to the seasons and the quality, the average price of a quintal of leaves being from 200 to 220 fr. The chief market of the Sidi-Ali region is Souk-el-Tnine of the Chiadma Chtouka. The wholesale buyers afterwards supply the different centres of the coast, going as far as Rabat, and even Tetouan, whither the henna is carried by coasting-vessels.

Umbelliferae : — Different varieties of *Foeniculum* (fennel) are found wild, as well as cultivated in the gardens surrounding the towns ; amongst them are *Foen. piperitum* Sweet *Foen. dulce* Mill, and *Foen. Clarryi*, the last named species having a very characteristic and disagreeable odour. Varieties of *Anethum* (dill-seed), are also grown for use as condiments and give rise, like the fennels, to a certain amount of local trade.

The cultivation of *Carum Carvi* L. (caraway) was practised successfully as early as the twelfth century ; it is localised in the region of Meknès, where in 1917, the harvest reached 15 tons. In the vicinity of Meknès, where the caraway is grown on rich, deep, irrigated soil, the seeds are sown in seed-beds in October. When the seedlings are 20 to 30 cm., high, they are planted out, care being taken to raise each with some soil adhering to its rootlets. The caraway is a plant needing repeated irrigation followed by hoeing. The crop is harvested at the end of June, the stalks being cut with a sickle ; they are left some days on the field to dry, and then collected into a heap on a threshing-floor, where the fruits are threshed out, winnowed by a current of air, and put into a sack. As the fruits fall as soon as they are ripe, the state of the crop has to be most carefully watched. This crop is best sown in lines 30 cm., apart, and should be thinned out, leaving one plant to every 15 or 20 cm., to facilitate tillage operations in general. The price of the fruits (seed) rose considerably in 1917, reaching 100 fr., per quintal on the coast markets as against 65 fr., which was the average price the preceding year. In 1914, 10 kg., of caraway seeds was exported, 100 kg., in 1915, and over 10 tons of the 1919 crop have already been exported. This ancient Arab crop is finding a wider market and exportation and once started, will continue to increase steadily and extend.

Cumin (*Cuminum Cyminum L.*) is a crop of considerable importance in Morocco, both on account of its market value and the area of ground it covers. It has long been grown as the Arabs cultivated cumin in Morocco and Algeria in the thirteenth century. According to the statistics of Terbid, 5391.90 hectares were ander cumin in 1917; of these, 23.22 hectares were in south Chaoiua and the rest were in the Marrakech region, which is the centre of the industry.

In the southern regions of Morocco, cumin is sown broadcast in the spring. It needs a light, warm soil, and is harvested in May and June. When taken to the market, it is passed through a winnowing machine and afterwards cleaned by hand by women, the cumin being freed from 12 to 15 % of impurities before being put in 50 kg., sacks for export. Before the war, it was sent to Marseilles, London, Hamburg, and America, and the average price varied, from 80 to 100 fr. Since 1914 the trade has begun to extend to Egypt, and Tunisia, and the price has risen considerably being 145 fr., per 100 kg., on the markets of the Southern ports, and 110 fr., at Marrakech. Most of the cumin is exported from the port of Sarfi ; it pays dues to the amount of 3.96 fr., per quintal. The export from the ports of the Protectorate alone is as follows :

Year	Kg.
1912	1 260 500
1913	515 189
1914	544 935
1915	1.557 280
1916	1.127 271

Owing to the high market prices the cultivation of cumin is increasing and it is certain that in some districts of South Morocco where suitable soils are not lacking, this plant would yield very paying crops in many places.

Coriander (*Coriandum sativum L*). is grown in Morocco: (1) On a large scale by European cultivators in Chaouia (2) on small scale by small native landowners, who cultivate it chiefly as a matter of tradition. Since it has become an article of export, small scale cultivation is tending to change, the Arabs having become more inclined to specialise and to devote themselves to a single crop. Fields of coriander are met with in the districts of Marrakech, Safi, Mazagan, Fez, and Casablanca. In 1917, there were 2592.42 hectares under coriander in Morocco including 2580.68 hectares in Chaouia. Therefore at present the latter district alone can be regarded as producing coriander. The industry has extended rapidly ; whereas only 707.68 hectares were under coriander in 1915, there were 1019.93 hectares under the plant in 1916.

It is sown in the autumn on clean ground, with a warm exposure ; the soil must be deep and light. When the seedlings come up, they must be weeded out, so as tol eave a space of 15 cm., between each plant. Repeated hoeing is necessary. The plants attain an average height of 30 cm.

Nearly the whole crop (especially in August) is exported from Casablanca. The total exportation for the whole of Morocco was :

Year	Kg.
1912	1 795 621
1913	1 484 388
1914	1 861 133
1915	2 793 517
1916	2 920 290

The export tax on coriander is 4.93 fr., per quintal, and the present price at Casablanca is 115 fr., per 100 kg., which represents a considerable advance on the pre-war prices, which were about 25 fr., per 100 kg. The cultivation of coriander is also increasing in Morocco where the conditions are favourable to the production of good yields.

It is also grown in Tripolitania, Fezzan, and Cyrenaica as well as in Algeria and Tunisia, but it does not do so satisfactorily there as in Chaouia.

Dorema ammoniacum:— This umbelliferous plant exudes a substance known as ammoniacal gum, which is used especially in Asia, for fumigating, making depilatory paste, and in pharmacy (diachylon). From 100 to 800 quintals are exported annually from Casablanca, Mogador, and Safi, at an average price of 60 fr., per quintal.

The use of the various aromatic Umbelliferae of Morocco and Algeria Tunisia would entail considerable study, for in these countries the numerous representatives of the family are widely distributed. From such study, much benefit would accrue to therepeutics, and to the perfume, drug, and food preserves industries.

COMPOSITAE:— *Santolina rosmarinifolia* L. seems very plentiful on the high plateaux of East Morocco and the Northern slopes of the Middle Atlas. It is a very important perfume plant.

Artemisia Herb-alba Asso., *A glutinosa* J. Gay, *A. Absinthium* L., *A. Camphorata* L. and *A. odoratissima* Desh. all deserve attention from distillers, for they grow thickly and cover extensive areas.

OLEACEAE:— *Jasminum* sp. The sweet jasmine and some other ornamental varieties much prized by the Arabs and Asiatics, are plentiful in all the gardens.

LABIATAE: *Lavandula multifida* L. :— This lavender grows most extensively in the interior of the country, but also covers a zone lying along the ocean coast: it forms associations with other varieties such as *L.dentata* L. on the actual coast, *L. pedunculata* L. in S. Spain, and *L. abrotanoides* Cav. in the South (this plant is common in Teneriffe). The chief thick associations of lavender which could be easily exploited are said to be in Haha-Chiadma (in the neighbourhood of Mogador).

Mentha sp. :—Mint is a very common plant in Morocco, where numerous scented varieties are reported to be cultivated or to occur wild. In 1919, large plantations of mint were made. Among the strongly-scented North-African varieties the chief are *M. rotundifolia* L., *M. aquatica* L., *M. Durandoana* Malinv. with an agreeable lemon scent, and

the common *M. Pulegium* L. ; *M. piperita* L. is cultivated in Arab gardens in Algeria.

Thymus sp. :—The different varieties of thyme could certainly be turned to account, as they are most abundant. Enormous associations of this plant are found in the Haka-Chiadma.

Origanum glandulosum Desf. :—This plant covers large areas in the Gharb, and forms the object of a considerable export trade through Tangier and Larache ; the exports were as follows :

Year	Kg.
1912	27 574
1913	11 659
1914	10 144
1915	32 406

The Moors cultivate the true marjoram (*Origanum Majorana* L.), and use the flowers and leaves to scent their tea.

Rosemary is stated to be very plentiful in North Morocco, and to be exploited industrially by large firms. Here, as in Algiers and Tunis, *Rosmarinus officinalis* L. and *R. laxiflorus* De Noé (a variety with white flowers and recumbent staiks) should be met with.

Little is known of the Moroccan sages ; *Salvia Aucheri* Boiss., *S. aegyptiaca* L., *S. phlomoides* Asso, *S. algeriensis* Desf., *S. lanigera* Poiret, *S. maurorum* Ball., *S. bicolor* Desf., *S. argentea* L. have been found or could be found in different parts of Morocco.

IRIDACEAE :—The saffron (*Crocus sativus* L.) is grown in Morocco as a dye-plant, but can also be used to furnish an aromatic essence employed as a condiment.

The following quantities of iris root (*Iris florentina* L.) were shipped from the ports of Mazagan and Safi :—

Year	Kg.
1913	73 672
1914	15 879
1915	21 281

CONIFERAE :—*Juniperus phoenicea* L. (Sabine) is much used in perfumery, and is very common in the Mountains (Uppe and Middle Atlas). In the Haha-Chiadma it forms large stands together with the iron-wood tree and *Thuja*. The yew and fir occur more rarely.

Juniperus oxycedrus L. and *J. communis* L. are very plentiful in the mountainous parts of Morocco, and could be exploited on a large scale.

Thuya articulata Wahl. occurs to a small extent everywhere. The chief stands of *Thuya* are in the valleys of Korifla (Rabat) and Mdakra. The variety furnishing sandarac resin is the only kind that is regularly exploited in the Haha-Chiadma and on the slopes of the Atlas to the south of Mogador ; it is no longer exploited in the Zaers and the North of Chaouia. In the northern zone there are 50 000 to 60 000 hectares of *Thuja*

which are still untonched. It is estimated that there are 100 000 hectares under *Thuya* in the Haha-Chiadmas, and the tree also extends further south on the other side of the Sous.

Before ending this very incomplete list, mention should be made of the following plants (as given by various writers), which are aromatic or have scented flowers, and are much grown in the gardens of Morocco in the regions suitable to them :—Bitter almonds, violets, ixias, narcissi, gladioli, peonies, agapanthi, laurels, tumeric, pepper-plants, carnations, nutmeg trees, cinnamon, and aniseed.

1116 – **Manuring Lavender.** — SCHRIBAUX, *in Comptes rendus de l'Académie d'Agriculture de France*, vol. VI. No. 32, pp. 777-778 (Meeting on November 3, 1920); FONDARD L., *Ibid.*, pp. 778-793. Paris 1920.

The growing importance of the lavender crop in the Lower Alps (1) has led M. FONDARD, Director of the Agricultural Services of that Department, to ascertain the best conditions under which the plant can be cultivated. In 1919-1920 , he made a special study of the action of superphosphate and sodium nitrate. The following are the results he obtained the first year at Gréoux (Basses-Alpes) :—

Treatment of plot (1481 bushes planted 1.50 m. apart)	Yield of Flowers kg.	Yield of Flowers Index of production	Yeld in Essential oil kg.	Yeld in Essential oil Index of production
Control plot without fertiliser	87.500	100	0.533	100
28 kg. of superphosphate	94.300	108	0.618	116
12 kg sodium nitrate	180.700	206	1.200	225
28 kg. superphosphate + 12 kg. sodium nitrate	188.500	215.4	1.280	240

All the fertilisers had increased the yield and the content of essential oil ; but nitrogen, which more than doubled the yield, was clearly more efficacious than phosphoric acid and the complete fertiliser proved superior to the fertilisers used separately. It was remarkable that the quantity and quality of the crop had increased *pari passu*.

The experiments carried out in 1920, at Moustiers (Basses-Alpes) confirmed those of the preceding year. The application of 300 kg., of superphosphate and 150 kg., of nitrate of soda per hectare increased the yield of essential oil by 11.33 kg., per hectare, which represents, at the rate of 250 to 300 fr. per kg., an increase in the return amounting to between 2000 and 3000 fr., per hectare.

It only remained to determine the effect of the fertiliser upon the quality of the essential oil. It is claimed that wild perfume plants produce better essental oils than cultivated ones, and it is well known that in the case of certain plants such as mint, the composition of the essential

(1) Cf. L. FONDARD, *Culture de la lavande*. Antibes, La Petite agricole, 1920, pp. 50. (*Ed.*)

oil is influenced deleteriously from the application of fertilisers. This is, however, not the case with lavender. It was found that plants grown in 1916 in the lavender-fields of Gréoux, on garden soil rich in humus, and well irrigated, produced essential oil containing 48.02° of esters, whereas that yielded by wild lavender gathered from neighbouring plots only contained 34°. Similar results were obtained in the Moustier lavender fields: the essential oil from plants that had received no fertiliser contained 38.22° of esters, while the ester content in the case of bushes that had received superphosphate and sodium nitrate was as much as 43.61°. Therefore, the application of fertilisers improves the quantity and quality of the oil of lavender produced.

It has further been ascertained that plants grown on a field with a southern exposure yield from ⅓ to ¼ more essential oil than those gathered on land facing north. The composition of the essential oil is also influenced in the same maner. The oil contained 44.59° of esters when the field had a southern aspect, as against 41.16° with a northern exposure.

These results prove that lavender requires abundant sunshine and also that it gains when cultivated intensively and produces finer essential oil than when it grow wild.

M. SCHRIBAUX advocates the systematic study of the various factors governing lavender production, and especially those connected with selection. As lavender is propagated by cuttings, it would be easy to obtain, in a short space of time, by means of artificial pollinisation, improved races that would be greatly superior to those now cultivated.

1117 – **Results of Qualitative Tests of the Light Yellow Tobacco Produced in Tripoli.** — SAILER, A., in the *Bollettino tecnico pubblicato dall'Istituto scientifico sperimentale del tabacco*, Year XVII, No. 1, pp. 116-145. Scafati, Jan.-Feb. 1920.

The " R. Istituto sperimentale agrario " of Tripoli has studied the behaviour of several kinds of tobacco in that country.

The types were divided into 2 series; the first, grown in the Savari garden (Tripoli) was composed of 8 types, viz., Giant Herzegovina, Haya Solouc, Porsucian, Xanti Yaka, Samsoun 1st crop, Samsoun 2nd crop, Bright Virginia and Java (Brandjar Ardio); the second series consisted only of Samsoun which is cultivated in the oases by natives authorised by the Monopoly Department.

Each type of the first series was divided into three classes: — (*a*) The first and second classes kept together but divided into leaves from topped and non-topped plots; and (*b*) the rejects without any indication of origin. Altogether there were 25 specimens. The non-topped Herzegovina Giant was divided into big and small.

In the second series, the product was divided into 4 qualities, each topped and non-topped, making 8 samples in all.

In the first series, the leaves being cut uniformly and made into cigarettes of uniform thickness, the following results were obtained: — None of the varieties cultivated retained the original properties (aroma,

strength, combustibility) except Giant Herzegovina, which only loses its aroma when the leaves are excessively developed. Java lost all its organoleptic and intrinsic qualities, but bright Virginia gave a product which should be seriously considered, although it differs from the original type.

All the samples had a " hay " taste and aroma, due to incomplete fermentation in too small masses.

Topping was found to impair the combustibility owing to the accumulation of salts in the leaves.

The second series grown in soil that was well fertilized and irrigated, gave a well developed product with a pleasant aroma, but still quite different from the original characters, i. e. unpleasant, bitter tas e and poor burning qualities. Blends agreable to the native taste were also studied, and the mixtures of the Italian State factories were made use of. These were in 1914, 30 % original Samsoun. and in 1916, 20 % of original Samsoun, also the Samsoun was replaced by that obtained in the Colony. The Samsoun cultivated in gardens slightly diminished the quality of the first grade scaferlati tobaccos, but within possible industrial industrial limits, whereas Samsoun from the oasis killed the burning qualities of the blend and made it unpleasant and bitter.

It was with the idea of blending other tobaccos with the original Samsoun that use was made of certain of the other varieties grown in the colony (garden). that had suitable qualities ; Giant Hergegovina and bright Virginia were used. In 1914 bright Virginia 40 % was mixed with an increased amount of Bulgarian (12-15 %) ; a satisfactory result was obtained which is duplicated if Herzegovina takes the place of Virginia, and better result is obtained by making up the above 40 % with 20 % Virginia + 20 % Herzegovina.

The weight of tobacco obtained per hectare was : Samsoun 1150 kg. ; Samsoun (second crop) 1530 kg., Herzegovina, 3340 kg. ; Virginia, 2800 kg. ; Xanti, 900 kg. ; Aya, 1040 kg. ; and Porsucian, 920 kg.

The higher yields of tobacco obtained from native cultivation of Fezzania (3000 kg.) and Trablus (2000 kg. per hectare), show that the attempt to obtain a high unit yield from Samsoun has profoundly altered the characteristics of the original type.

The Agricultural Bureau has also experimented with tobaccos giving a high yield such as Giant Herzegovina and the bright Virginia, and if larger yields can be obtained it is hoped that the natives will be encouraged to cultivate the two types.

The author has added to his paper a table showing the results of the 1915 season.

VARIOUS CROPS

1118 – ***Desmodium tortuosum*** and ***D. hirsutum*** as Cover Crops. — See No. 1097 of this *Review*.

HORTICULTURE

1119 – **Pine Apple Growing in Cuba.** — Muños Ginarte B., in the *Estación experimental agronómica, Santiago de las Vegas, Cuba, Boletín*, No. 45, pp. 43 16 photogr. Havana, Sept. 1919.

Importance of the pine-apple crop. — In Cuba the cultivation of pine-apples is stationary whereas the demand for local consumption, export

and the preparation of preserves is increasing continuously. The bulletin under consideration urges the growers to devote more ground to this fruit so that it becomes accessible to people of modest means. At present the fruit is not consumed so widely as was formerly the case.

Pine-apples are cultivated in the British and French colonies in Africa, in Ceylon, Siam, Cochin-China, Japan, Australia, Malaya, Melanesia, Polinesia, South America, Central America and Florida,. The region best suited to the crop is the Antilles.

VARIETIES. — Many varieties are cultivated in Florida and the Antilles. In Florida WEBBER has described 25 varieties, the chief of which are red Spanish, Reine d'Espagne, black Jamaica, Grande Trinidad, Enville City, Abbaka, Cayenne, smooth Cayenne, Puerto Rico, and sugarloaf.

In Cuba there are two definite varieties, viz. " piña morada de Cuba " and " piña blanca " or piña de la tierra, " both having spiny leaves.

The " piña morada " has dark, thin narrow leaves, with thorns thinner than those of the " blanca " variety. It has been grown in Cuba since time immemorial, and is the most cultivated variety there not only because of its superior table qualities but because it is more hardy and travels well. The fruit is cylindrical, somewhat swollen in the centre, violet in colour before ripe and pale red when ripe. The flesh is bitter-sweet and light yellow in colour. There are many buds at the base of the fruit and there is a large regular crown (bud) on the top. In some places the fruit is harvested whilst quite sweet and in others somewhat acid with the result that it has been erronously considered that the fruit belonged to two different varieties. The fruits weigh from 2. 6 to 6.9 lb., and will keep about 3 weeks; they can be made into jam.

The " blanca " variety has larger leaves of a clear green colour and with sharp thorns. The fruit is conical, the base being greater than the length. It remains green until fully ripe, and has a white, jucy, slightly acid flesh.

This is the variety preferred for table use, which accounts for its high price The fruit, however, cannot be exported as it rots and ferments very rapidly. Antiseptics such as sulphur dioxide and alkaline sulphites and also protective envelopes have been used in attempts to preserve the fruit for exportation, but with little success.

In Trinidad an intermediate variety between the " morada " and the " blanca " is cultivated. Varieties have been introduced into Cuba from Florida but have not given satisfactory results.

SOILS. — There are 4 well defined of types of soils in Cuba:—

(1) *Coloured soils* (" *colorâti* ") abundant in the provinces of Havana, Matanzas, and certain regions in the north and east of the province of Pinar del Río. The colour is due to the high content of limonite (iron ore); the soil contains 45 to 60% of sand and 20 to 35% of clay, and is of average consistency, well adapted to the cultivation of pine-apples, especially if the sand is present in large grains, which allows of sufficient aeration for the roots. The plants live from 5 to 10 years but would last longer if fertilisers were used.

(2) *Sandy soils* in Pinar del Río and other districts.. They contain from 65 to 90 % of sand (grains of all sizes) and 8 to 20 % of clay. When the sand grains are large, the soil is well suited to the pine-apple which, however, does not do well in the " polvillo " (dusty soils) because they contain up to 55 % of fine sand which clokes the roots. This is why the Cuban savannas (plains) are so sterile.

(3) *Black soils* are found all over the island. The colour is due to richness in organic matter and humus. They contain from 30 to 50 % clay, and are of volcanic, calcareous, or granitic origin ; they are of very a close texture and not suitable for pine-apple cultivation.

(4) *Calcareous soils* are not very widespread in the island, although calcareous rocks are common, the reason being that the rocks contain a large proportion of other elements. These soils are not suitable for the pine-apple, because there is not sufficient aeration and they do not absorb sufficient heat.

Preparation of the ground and methods of planting. — All stones, clods and roots are first removed by repeated ploughing followed by harrowing, and the ridges are made of a height that allows the soil to retain as much moisture as possible. In dry soils, i. e., where the water table is about 2 feet deep, and where the slope assists drainage, wide flat beds are used. Planting may be in simple lines, double lines and in groups of 3, 4, 5 or 6 lines well divided. The first two methods are the most usual.

When planted in single lines the pine-apples are placed at intervals of 1 to 2 ft., on top of the ridge, with 1 to 6 ft., between the lines. This works out at about 14 000 to 15 000 plants per hectare. When double lines are used the plants are in squares 1 to 2 feet apart, 6 to 10 inches from each side of the ridge, the ridges being 3 ft. apart. This method, while utilising the soil better than the other has the same advantages, i. e. the plants grow well and cultivation and harvesting is easy. In plantations where there are 3 to 6 lines per furrow, planting is done in squares 15 inches to 2 ft., apart there being a distance of 5 to 9 in. from the ridges which are nearly 6 ft. apart. The disandvantage of this method is that the centre lines are not so productive as the outside ones.

The plots are 30 to 50 ft., wide, the lines about 17 inches apart and a about 8 ft., wide is left every 195 ft.

Propagation. — The shoots growing in the axils of the leaves of the female plant are used, as well as those growing below the insertion of the fruit and forming the crown. The former shoots bear fruit 1 year after they are planted, and the latter after 18 to 20 months ; plants growing from both are equally productive. The shoots forming on the fruit, and which are also part of the corona, could likewise be used for propagation, were it not that they are always removed with the fruit.

Shoots ready for planting are sold at 4 or 5 *pesos* (20 to 25 fr. at par) per thousand. When planting, care must be taken not to allow any soil to get into the axil of the leaves, or the shoot will die. It takes 8 days for 3 men to plant 1 hectare; one waters the place where the shoot is to be

planted, another digs the hole and the third puts in the shoot, fills up the hole with earth and stamps it down.

Shoots from the roots or from the axils of the leaves are planted in spring and those from the crown in August and September. The latter type of shoots are the best to use, as the others are liable to be injured in separating them from the parent plant and the work is more costly and slower. Further, they are only found in abundance on old plants that are falling off. Another disadvantage is that the plants growing from root or leaf-axil shoots bear smaller fruits than the crown shoots and those produced by the same plants the next year.

In order to turn to account the vacant spaces in new plantations, bananas, beans etc., can be grown as catch-crops.

It is useless to sow pine-apples, for the seedlings only bear fruit the third year; further, very few of the fruits contain seeds. Prof. CALVINO and the author have, however, used seeds in the work of improving the varieties now cultivated.

Shoots failing to strike, which hardly ever exceed a proportion of 10 %, are replaced 15 to 20 days after they were planted.

CULTURAL OPERATIONS. — These consist in keeping the ground very clean; the plants are usually hoed twice, once when it is necessary to remove the supernumerary shoots (only 2 or 3 are left to replace the parent-plant) and again when the fruits are formed. The suckers that may have grown on the central fruit-bearing axis are cut away at the same time and props are put to the larger pine-apples, which by their weight tend to cause the stem to bend over right down to the ground.

MANURING. — In Cuba, a great mistake is made in not manuring the pine-apple crop, for with a fertiliser, larger fruit can be obtained. On the other hand, as the exporters pay the same price for all pine-apples, no matter what their size may be, there is no encouragement offered to the producer to grow finer fruit.

The author recommends a fertiliser containing 5 % nitrogen 4 % phosphoric acid, and 10 % potash, such as, for instance, a mixture consisting of 41.6 parts of dried blood (10 to 14 % nitrogen) + 8.8 parts of double superphosphate (40 to 45 % phosphoric acid, 20 parts potassium sulphate, 50 % potash) + 29.6 parts of inert material (sand, soil, etc.).

The fertilisers sould be applied as soon as the ridges are made and before planting. A good result is obtained by spreading over the shoot which has just been planted, sufficient dried blood or ground cotton cake ot fill up the interstices between the leaves; in this way, the plant is manured, and the soil prevented from lodging. No fertiliser should be spread before the shoots have taken root, that is to say, about 2 or 3 months after they are planted. The author advises 3 top-dressings with fertiliser; the first, applied 2 to 3 months after planting, should consist of nitrogen 2 kg., phosphoric acid 1 kg., potash 4 kg. (this is enough for 1000 plants); the second, used 6 months after planting, should contain, for 1000 plants, nitrogen 1.5 kg., phosphoric acid 1.5 kg., potash 3 kg., and the third (also for 1000 plants) should be composed of nitrogen 1 kg., phosphoric acid

1.5 kg. and potash 5 kg. and be spread in October or November, 2 month after the plants have flowered. After the flowers-stem has formed, fertilisers are injurious, for they tend to produce malformation of the fruit. It may be noted that in the successive application of fertilisers, the amount of nitrogen is decreased, in order to prevent the fruit becoming soft, and hence keeping and carrying badly; the amount of potash, which has the contrary effect, is increased. After gathering the crop, the shoots which are to produce new plants are manured with a fertiliser composed (for 1000 plants) of 3 kg., nitrogen, 2 kg., phosphoric acid, and 4 kg., potash.

HARVEST. — The pine-apples are known as 18, 24, 30, 36, 42, or 48, according to the number required to fill a small case called a "huacal," which is 92 cm. long, 26.5 m., wide and 30 cm., high. It is generally estimated that 90 % of the Cuban variety of pine-apple, known as "Morada," bear fruits; of these 60 to 70 % are 24 to the "huacal" or larger, and the remainder are of different sizes. The second year after planting, 85 % of the pine-apples bear fruit, but only 50 % the third year. After the third season, it is advisable to make a new plantation, growing another kind of crop in the pine-apple field. One man with 2 assistants, carrying alternately the fruits (neatly cut a little below their base) in baskets to a little cart, can gather 300 dozen pine-apples in a 10-hours day, which means that such a gang can clear one hectare in 4 days.

The pine-apples, are taken to the packing-rooms, where they are allowed to cool at least for one night and are dried, if they have been cut in wet weather. They are then graded according to size, wrapped in paper, and packed. A good packer can fill 400 cases in one day.

CULTURAL EXPENSES. — The author gives the following figures as being most representative (1 peso equals 5 francs at par):—

I. — *Expenses and Profits per hectare of pine-apples grown for local consumption.*

EXPENSES.

Ploughing four times	230.00
Ridging	92.50
Purchase of 15 000 shoots at 25 fr. pr 1000	375.00
Planting	200.00
Establishment expenses	**897.50**
Interest at 1 1/2 % per month on 897.50 fr, for 18 months	242.10
Working expenses, hoeing, etc.	550.00
Rent of ground for 18 months	112.50
Interest on this outlay for 18 months: 662.50 fr. at 1 1/2 % per month	178.00
Expenses at end of first year	**1.980.10** fr

RETURNS.

From 15 000 plants, 90 % of which bore fruit, were obtained 13 500 pine-apples selling at 1.50 fr. the dozen	**1 687.50** fr
Deficit	**292.60** fr

EXPENSES.

Cultural operations	305.00 fr
Rent of ground for 1 year	75.00
Interest on 305 fr	30.00
Total expenses	**410.00** fr

RETURNS.

From 15 000 plants, 85 % of which bore fruit, were obtained 12 750 pine-apples fetching 1.50 fr the dozen	**1 593.00** fr
Profits realised after deducting expenses of 2nd year	**1 183.00** fr
Profits realised after deducting first years deficit together with the interest thereon viz., 344.50 fr.	**838.20** fr

From this calculation, it would appear that no profits are realized until after the second year, but certain returns have been omitted, such as the sale of shoots, etc. From this source, according to the books of a cultivator and exporter, a profit of 920 *pesos* per *caballería* (13.41 hectares) or 344 fr. at par per hectare is realised from the first year.

II. — *Expenses and Profits of an Exporter.*
(per hectare of pine-apples producing 13 5000 fruits).

EXPENSES.

Cost of 1125 dozen pine-apples at 1.50 fr per doz.	1 687.50
Cutting the pine-apples	60.00
Three men with baskets	162.00
Motor transport of 1125 doz. pine-apples	337.50
Making and nailing down 490 cases	171.50
Packing (4 men)	60.00
Transport to steamer, at 0.50 fr. per case	245.00
Supervision expenses	50 00
Total expenses	**2 773.50**

RECEIPTS

490 cases at 7.50 fr.	**3 675.00** fr
Profits	**901.50** fr

In the region of Artemisia, the sale price of a case of pine-apples was: 7.50 fr. in 1917, 12.50 fr. in 1918 and 17.50 fr. in 1919.

DISEASE AND PESTS. — The pine-apple is subject to few diseases or pests, amongst which the following may be mentioned: —

(1) " Espiga larga " (lit. wide head): — The plant produces no central leaves and generally no fruit, or else produces a fruit of inferior quality. This disease is attributed to an insufficient amount of fertiliser, especially phosphatic. As a remedy, it is advised to use organic fertilisers with a nitrogen and phosphorus basis, such as dried blood, tankage, and bone-powder. The plants should also be carefully cultivated.

(2) " Marchitez' or wilting : — The roots assume an abnormal shape, the leaves change in colour from green to red then to yellow and afterwards become dark and wilt. As yet, little is known as to the cause of this disease, but it seems to be due to the bad condition of the soil, and want of proper rotation of crop. If the disease appears, the only course is to root up and burn all infected plants, to spread lime over the land, to leave the soil exposed to the sun for some weeks, and to aerate the soil again. When this has been done, new shoots may be planted to replace those that have been removed.

(3) " Hormiga brava " (*Solenopsis geminata* Fabr.) and its associate " queresa " (*Pseudococcus atri* Risso) make their nest in all parts of the pine-apple field and when they happen to place them under the roots of the plant they cause a great deal of injury The best means of controlling these pests is to water the nests with the following mixture : —

Kerosene or refined paraffin	7.6 litres
Crude carbolic acid	0.5 »
Caustic potash soap	225. grammes
Water	3.8 litres

The soap is dissolved in hot water and the carbolic acid added ; the mixture is then poured (stirring all the time), into the vessel containing the paraffin ; this concentrated solution must be diluted with 18 volumes of water just before use.

INDUSTRIAL PRODUCTS OBTAINED FROM THE PINE-APPLE PLANT. — The sap of the pine-apple contains 12.43 % of crystallising sugar and 3.21 % of glucose. The peel of the fruit, when macerated in water, yields an astringent juice which fermented with sugar, furnishes " garapigña " or " chicha, " a diuretic beverage that is also said to be a vermifuge. The crushed leaves yield a sap that can be used for bleaching plant fibres (flax, hemp, etc.), and when diluted, forms a lye.

Amòngst the products of the pine-apple he mentions :— *Preserved pine-apples* (plain ; in brandy ; in pine-apple syrup ; jam) ; *beverages* (pine-apple wine and cider ; cream) ; textile fibres (fibres obtained from the leaves).

1120 – **Commercial Dutch Bulb Culture in the United States.** — GRIFFITHS, D. and JUNEMANN, H. E., in the *United States Department of Agriculture, Bulletin*, No. 797 pp. 1-50, Washington, Nov. 22, 1919.

It has been found that stocks succeed under a great diversity of conditions. Thus far, commercial production of Dutch bulbs has been confined mainly to the Atlantic and Pacific Coasts, but recent successes in interior Eastern United States, and Illinois and Michigan seem to prove sufficiently that there is abundant territory adapted to increased production. Bulb cultivation is associated with sandy soils, but in Washington, better tulips and narcissi were produced on silty rather than lighter sandy soils, and they flower well on almost any soil.

Dutch methods have been employed in the greater part of the work, but it is hinted that variations in practice will be inevitable as an industry in bulb production is developed in this country. All details of methods now employed are given, and list of the varieties suitable for cultivation.

1121 – **The Effect of the Position of the Graft in Trees.** — FLORES, G. N., in *Il Coltivatore*, Year 66, pp. 403-465. Casale Monferrato, June, 1920. FRUIT GROWING

A wild plant, or one growing on its own roots, differs from a grafted plant in having more compact tissues with less water, less sugar and more acid. It is to these differences, as is well known, that the tissues owe their longer life and their vigour and resistance to adverse conditions. According as the graft is made at a greater or lesser height (on the branches, trunk, or root-stock, the amount of sap elaborated and therefore put at the disposal of the scion is greater or less, so that the influence of the stock upon the scion is stronger, or weaker.

When grafting is done on the branches, the abundant supply of materials produced by the stock gives to the scion (on account of their greater acidity) superior resistance to parasites, and further, produce in the most easily-affected parts, such as the stems, variations which may take the form of a larger yield of fruit than that of the plant from which the scion was taken. The fruit is, however, often smaller and less sweet when completely mature, and frequently ripen later.

On the other hand, if the scion is grafted on the trunk the wild stock has less effect upon it. The scion will bear fruit similar to that of the parent tree, or even of better quality, but it will be much less vigorous and resistant, and not so long-lived as in the preceding case.

The biological explanation of these differences has been confirmed, in certain districts, by agricultural practice. In this connection, it will suffice to describe the measures adopted in Sicily for the control of gummosis of citrus trees, a disease that first appeared there about 1865 (the attack being very severe for several years), and also those advocated by M. INZENGA, which were carried out in that island for the control of " male della cagna, " or root rot, of citrus trees. The latter were no longer propagated by cuttings and layering as before, but recourse was had to grafting upon a bitter orange tree growing on its own roots, or even to grafting on the shaddock. Shield or crown grafting was adopted, but the grafts were made as high up the trunk as possible, and the effects were immediate and lasting. In the Province of Messina, especially, another method is usually adopted in order to render the stock stronger and the foliage of the sweet-orange graft more luxuriant: — A shoot is allowed to grow on the stock, which is a bitter-orange ; this shoot like the stock, elaborates a sap with the qualities mentioned above, some of which passes into the trunk supporting it. This sap rises from the branches into the leaves, is distributed among them, carrying with it a large quantity of acids which give vigour to the tree, and also protect it from plant parasites, for the latter grow best in an alkaline sap, or one poor in plant acids.

1122 – **Pollination Experiments with Plums in California.** — Hendrickson, A. H., in *Agricultural Experiment Station, Berkeley, California Bulletin*, No. 310, Berkeley, July 1919.

Pollination experiments were started in 1914 with several varietes of plums under the auspices of the Division of Pomology of the University of California, in order to ascertain :

1) Varieties that are self-sterile ;

2) Varieties that are self-fertile ;

3) Varieties that although not self-sterile, may benefit by cross-pollinaton ;

4) Varieties which furnish the best pollen for the various self-sterile varieties ;

5) The relation of weather conditions to the set of fruit.

The most important conclusions may be summarised as follows :

1) The following varieties of Japanese plums were found to be self-sterile : Combination, Kelsey, Satsuma, Burbank, Wickson, Sultan, and Abundance.

2) Climax, another Japanese variety is apparently self-fertile.

3) In general the early blooming Japanese varieties, such as Combination, Kelsey, and Satsuma are scanty pollen producers and not effective pollenisers, while the later blossoming varieties such as Burbank, Wickson, Climax, Sultan and Abundance produce pollen in abundance.

4) Clyman, Tragedy and probably also Grand Duke, are self-sterile, while Yellow Egg, and Pond according to one year's data, appear self-fertile.

5) All of the 5 European varieties tested seem to be abundant pollen producers and to cross-pollinate effectively.

6) The French and Sugar prunes are self-fertile and therefore need not be interplanted wih other varieties, although, however, their yield may probably be increased, especially in certain years, if interplanting is practised.

7) Imperial and Robe de Sergeant must be considered self-sterile for practical purposes.

8) Sugar, Imperial and French prunes cross-pollinate effectively. Robe de Sergeant was found to cross-pollinate readily with Sugar and French, but no trial was made with Imperial.

9) The presence of bees in the orchard is always an advantage. Even self-fertile varieties are benefited thereby.

10) Climatic factors are probably important in the setting of plums, but investigations are not suffciently advanced as yet to throw any light upon this phase of the problem.

The following is a list of self-fertile and self-sterile plums :

a) *Self-sterile* : Combination, Kelsey, Satsuma, Burbank, Wickson, Sultan, Abundance, Clyman, Tragedy, Yellow Egg, Grand Duke, Imperial, Robe de Sergeant.

b) *Self-fertile* : Climax, French, Sugar.

c) *Doubtful* : Pond.

1123 – **The Pruning of Winter Injured Peach Trees.** — GUNDERSON, A. J., in *University of Illinois Agricultural Experiment Station, Bulletin* No. 818, pp. 388-394, Urbana, Illinois, May, 1919.

Unusually low temperatures of the winter 1917-18 caused serious injury to peach trees in southern Illinois. This included the killing of fruit buds and damage to trunks and branches. Discoloration of the inner wood, varying from light to dark brown was the principal internal symptom, but in most cases new sap wood was observed the following November, and this is therefore not an absolute indication of the inability of trees to recover from winter injury.

Trees planted only one year, and also those in high situations showed less signs of damage than older trees and those in lower localities, or those previously harmed by borers, gummosis or starvation.

Experimental work on the Elberta variety gave evidence that moderate pruning produced the best results from the standpoint of size, shape and openness of the trees, and in the number of vigorous fruit buds formed on strong wood, especially with the older tres. Nitrate of soda applied at the rate of 1 lb., per tree increased the amount and colour of the foliage only on the moderately pruned trees, and not on those pruned severely.

In the case of June-budded or small yearling trees planted recently, the usual cutting back to whips is recommended.

1124 – **The Orange; A Trial of Stocks at Peshawar.** — ROBERTSON BROWN, W. (Agricultural Officer, North Frontier Province), in the *Agricultural Research Institute, Pusa, Bulletin* No. 93. pp. 1-7, Pl. XII. Calcutta, 1920.

Investigations carried out in many gardens and nurseries throughout India, in the years 1905-11, led the writer to believe that failure has been caused by mistakes in the preparation of plants in the nurseries and unsuitability of stocks used.

Accordingly, when orchards at the Peshawar Agricultural Station were being laid out in 1911, the opportunity was taken to include a test of the orange stocks commonly used for the Malta and the Sangtara, in North-West India. Fifty plants were grafted on each of the following: *Citrus Limonum*, Osbeck var. ("rough lemon", "khatti" or "kharna"); *Aurantium*, Linn. ("sour" orange, "khatta", "narang", "Seville orange"); *C. Limonum*, var. ("sweet like", "sharbete" or "mitha"); *C. Medica*, Linn. ("galgal"). An analysis of two samples of soils from the Malta (*C. chinensis*) grove, and two samples from the Sangtara (*C. nobilis* Lour.) grove, were made by the Imperial Agricultural Chemist at Pusa, and show a notable deficiency in available phosphoric acid.

SUMMARY OF CONCLUSIONS. I. *The Malta.* — Of all the stocks used, *C. Limonum* Osbeck var. is the one which gives greatest vigour and fruitfulness.

The *C. Limonum* var. "sweet lime" is suitable in a small private garden only where a dwarf tree with a few oranges of high quality are desired. The stock is unsuitable for commercial groves. The other stocks are not recommended.

II. *The Sangtara.* — In almost all respects, the sweet lime, *C. Limonum* var. is the best stock. The rest are not suitable.

The stock and scion influence each other profoundly in producing vigour and fruitfulness in the orange tree, and in fruit development generally.

The writer states that tests of stocks should be made wherever the orange is grown in India.

VINE GROWING

1125 – **A Test of Commercial Fertilisers for Grapes.** — GLADWIN, F. E., in the *New York Agricultural Experiment Station, Bulletin* No. 458, pp. 27-43, tables 6. Geneva, N. Y. Jan. 1919.

Grape fertiliser experiments were carried out at the above Station from 1919-1918, the commercial fertilisers in use being :— nitrate of soda — dried blood — cottonseed meal — acid phosphate — sulphate of potash, and lime. These were applied annually in varying proportions to different plants.

The tests show that nitrogen, phosphorus and potassium had a marked beneficial effect upon wood growth, yield and quality of fruit.

The first of these three elements was the most helpful both in wood growth and in the increase of fruit with larger berries and clusters. The foliage also after the first few years showed a better colour and size.

Phosphorus and potassium ranked second and the check plat a poor third in this last respect. The two former increased the production of wood and fruit but did not influence the quality of fruit to the same extent as nitrogen. Potassium caused earlier ripening of the foliage than the other elements and gave more pronounced results than phosphorus, but the latter had a more beneficial effect on green manure crops in the vineyard. It affected distinctly as compared with other materials, the growth of rye, barley, wheat and cow-horn turnips, and it is believed that through the promotion of better growth of green manures, it will contribute in a measurable degree to the production of fruit and wood.

Even though the same number of vine canes were tied up for fruiting purposes, the data show that the fertiliser plats produced a decided gain over the unfertilised.

1126 – **Summer Cutting of Hail-stricken Vines.** — SANCINO, F. A., in the *Rivista di Ampelografia* Year I, No. 12, pp. 182. Alba-Livorno, July 15, 1920.

The author has been induced to write this brief article on account of the heavy hailstorms which swept the departments of Alba and Mondovì during the last days of May 1920.

The hail destroyed the leaves and damaged the shoots of the vine, but after 10-20 days, the remaining buds began to show new life and in a short time the vine was covered with many thin shoots which kept it alive but bore no fruit and were of little use for the next dry pruning so that no fruit was produced in the next year.

The loss of fruit over two years can be brought down to one year by suppressing the fructifying shoots and pruning to 2 buds the green spurs, or better still by cutting at the main junction where the fruit shoots

grow out, leaving 2 to 4. As the end of the season there will be a few long thick shoots that can be pruned as usual and next year will produce a normal yield.

The pruning of the shoots of hail-stricken vines is best done in May and June, with slender vines but it can be left to July. If, however, it is done later, at the end of July or in August, the results will not be as good since the new shoots have not had time to develop wood.

1127 - **Direct Bearers Recommended for Venetia.** — Marconi, P., in *L'Agricoltura vicentina*, Year LII, No. 7 pp. 97-101. Vicenza, June 15, 1920.

The author calculates that 18 000 to 20 000 quintals of copper sulphate and 20 000 to 22 000 quintals of sulphur, costing about 8 300 000 *lire* are used annually in Vicenza to combat mildew and oidium on vines.

Phylloxera spreads in this province with great rapidity and it is necessary to replace the present varieties by those able to withstand the attacks of the phylloxera and fungus diseases. After 10 years experience the author recommends direct-bearing hybrids such as Seibel No 1, Seibel No. 2044, Seibel No. 1000, Seibel No. 2000, Seibel No. 60, Couderc No. 7110, Couderc No. 4401. These have proved resistant to fungoid disease, give good yields and are well adapted to the conditions prevailing in this province. All these hybrids are better than Clinton, which formerly was extensively grown in the province of Vicenza and did great service there, but they should now be replaced by the afore-mentioned hybrids, which are more resistant and whose grapes are free from the "foxy." The author also advises that a certain amount of the local "Durella" variety should be grown, as its wine, rich in acid mixes well with that of direct hybrids which have plenty colour and alcohol, but lack acidity.

It is best to cultivate the ungrafted hybrids or to graft them on unharmed vines which have a certain amount of resistance, such as Riparia Gloire de Montpellier, Rupestris du Lot, Berlandieri, Riparia × Rupestris 3309 or Riparia × Berlandieri 420A.

The author concludes by citing the case of an ungrafted hybrid vine which has lived for 6 years in good condition in an area infested with Phylloxera, and of a good direct-bearing vine which has been growing for 10 years at Montorso.

FORESTRY

1128 - **World Rationing of Timber. Need for International Cooperation.** — Unwin, A. H. (late Senior Conservator of Forests, Nigeria), in *The Times Trade Supplement*, vol. VI, No. 92, p. 93. London, 1920.

In 1900 a warning note was struck at the first World's Foresters' Congress in Paris with regard to an impeding famine of timber throughout the world. All timber comes from two sources: (*a*) Forests or trees which have grown up untended or unplanted by man; (*b*) Trees or forests which have been planted, sown, or tended by the present or previous two generations of man. Up to the present time most timber has been obtained from the former type of forest, and only the smallest quantities from the latter.

In the original or virgin forests, timber is cut from trees which have been growing at least 500 years. In so far as such forests are not replanted or trees do not grow again in that locality, man has used the "capital growing stand" of the forests, which cannot be replaced under a minimum period of 40 or 100 years. In so far as the land on which the virgin forest stood is utilized for agriculture, it is lost for the production of timber. Thus, all through the world each year there has been an increasing diminution of the world's potential forests areas. In so far as land is reclaimed and replanted (a little annually in France, Belgium, Germany, in prewar days), there is an increase in the world's timber areas. However, it was a very small amount compared with that taken for agricultural use. Generally speaking, we are gradually using up the world's accumulated growth of trees and forests of many years; in other words, we are not planting, nor is enough forest growing again to replace that which is annually cut down; we are thus living on the world's "wood capital."

Europe's Position. — In Europe, Great Britain, France including Corsica, Portugal, Spain, Belgium, Holland, Denmark including Iceland, Spitsbergen, Germany, Switzerland, Italy including Sardinia, Greece, and Turkey, are large and increasingly timber-importing countries. The chief timber exporting countries are Norway, Sweden, Serbia including Montenegro, Dalmatia, Croatia and Slavonia, Austria, Hungary, Finland, Poland and Russia. Of these it is doubtful how long Austria and Hungary will be able to export timber. Serbia will largely require her own timber resources for her internal development. Poland, once she is organized again, will scarcely have much for export. Thus Russia, Finland, and Sweden are the countries from which greater exports of chiefly softwood timber may be expected. As the most accessible forests have been utilized already, any fresh supplies of timber will be obtained at greater cost than heretofore.

Even including Russian supplies, Europe was not self-supporting before the war, and obtained a large quantity of timber from Canada and the United States. In several countries, such as Great Britain, France, and Belgium, preparations are being made to replant devastated areas and reclaim fresh land by planting trees. However, the produce of these plantations will not be ready for the market for at least fifty years. The areas involved too are comparatively small, a few millions of acres compared with the hundreds of millions of acres from which supplies have thus far been drawn. Summarizing the European position, even with great economy (as enforced by the war) the Continent is not self-supporting, and even with the most complete development of the Russian and Swedish resources, it is doubtful whether it would have sufficient for all its requirements.

The Asiatic Countries. — In Asia we have: (*a*) Timber importing countries, Asia Minor, Arabia, Palestine, Mesopotamia, and China; and (*b*) Self-supporting countries, Afghanistan, Persia, and Java. Of these, Persia will soon be an importing country, once the trade of the country develops. The remaining forests have yet to be properly conserved

and utilised to their fullest extent. With a further increase of the population of Java, the demands for timber will increase, so that eventually she will become a timber importing country. Any industrial developments in any of these countries will cause further demands for timber. Against this contingency we can place (*c*) Timber exporting countries, India including Burma, Ceylon, Siam, Indo-China, the Malay Peninsula, Sumatra, the Celebes, Borneo, the Philippine Islands, Formosa, Japan, and Siberia. India and Ceylon export chiefly furniture woods and teak. It is doubtful whether inthe future, with the development of internal trade, there will be any exportable surplus of softwood timber. Borneo, the Celebes, and Philippine Islands export timber chiefly to China. In the Philippine Islands there are 38 000 000 acres of virgin and secondary forests capable of being used. This is one of the few of the remaining forest resources of the Far Eastern world. Japan, with further industrial development will probably cease to be a timber exporting country.

Australia. — Turning to the Continent of Australia, it is doubtful if Australia can become self-supporting for many years. Probably if the forest of the Northern Territory were exploited, that province would become an exporting country. Papua is a potential source of a great deal of forest wealth, at present largely untouched. It is estimated that there are 90 000 000 acres of forest.

Africa. — On the Continent of Africa there are as timber exporting countries at present, Madagascar, the Ivory Coast, the Gold Coast, Nigeria, the Cameroons, Spanish Guinea, French Congo, Belgian Congo In the last five named countries is the greater part of that vast forest belt which stretches nearly across Central Africa. This will provide one of the few world's reserves of timber in the future. In the Congo alone out of an area of nearly 900 000 square miles, one-half is covered with a heavy tropical forest full of most valuable trees. Cheap form of transport and labour on the River Congo are necessary to make this available for export to other parts of Africa and Europe. Estimating a yield of only 500 cubic feet per acre, and taking the area at 400 000 square miles, or 256 000 000 acres, a total stock is reached of 128 000 000 000 cubic feet of timber. Much of this amount is, at present, quite inaccessible as far as the world's chief markets are concerned. Smaller quantities are available in the British West African Colonies, as well as in the French Congo.

North and South America. — Turning to North America, there are as self-supporting countries, Mexico, Alaska, some of the West Indian Islands. Sooner or later most of these countries will become timber importing countries with the further development of mining and other subsidiary industries. The United States can be considered as only a self-supporting country. At the present time, although a great deal of timber is exported from the southern States and those of the north-east, the country imports ever increasing amounts of timber, and especially pulpwood from Canada. Forest conservation is being rapidly carried out so that from the 200 000 000 acres of forest reserved up to now only the annual increment will be cut. Even allowing for far more forest reserves and plantations,

the amounts of timber to be obtained from all these sources will be insufficient to supply the present requirements of the export trade, as well as the increasing demands of a growing population.

Timber exporting countries are Canada, Newfoundland, Guatemala, British Honduras, the Republic of Honduras, Nicaragua, Costa Rica, Salvador, Panama, Cuba and San Domingo. The Central American States export chiefly mahogany, cedar, and hardwoods, so that they are not so important in the world's economy of timber as the softwood bearing areas of the temperate zones. It should be noted that 85 per cent of all timber at present used is obtained from coniferous forests of these zones. Canada, and especially the province of British Columbia, is America's largest forest reserve of timber. It is estimated that there are 160 000 000 acres of merchantable timber lands in British Columbia : these would yield permanently 6 400 000 000 cubic feet of timber. Already supplying, to some extent, the markets of Australia, China and Japan, British Columbia will soon be called upon to export increasing amounts to the United States of America.

In South America timber importing countries are Peru, Uruguay Argentine, and the Falkland Islands. If all the forests of Argentine were exploited she might become an exporting country. At the present time, although she exports large quantities of quebracho wood and extract, she needs large quantities of softwoods. Peru might also become an exporting country if her more distant forests of the Amazon region were exploited.

Self-supporting countries are Chile, Paraguay, and Bolivia. Chile exports a certain amount of timber, but also imports a good deal. Probably, if all her forests were exploited she would become an exporting country. Owing to Bolivia's unfavourable geographical position she cannot at present export timber, the distance to the seaboard being too great.

As timber exporting countries there are Colombia, Ecuador, Venezuela, British, Dutch and French Guianas, and Brazil. Up to the present, it has been mainly mahogany, cedar rosewood, and other hardwoods which have been exported.

Brazil's Untouched Forests. — However, there are many hundred of species of soft-wooded trees in these tropical forests which are, at present, scarcely known or used. With the increasing world's demands for timber these will have to be utilized ; in fact, in Brazil the world possesses one of the largest remaining timber reserves ; there is probably at least an area of 640 000 000 acres of untouched forests, which contain at least 320 000 000 000 cubic feet of timber of various kinds. Many of these forests are, however, situated, on the banks of rivers 3 000 miles away from the ocean (1).

The World's Timber Position. — Summarizing the world's timber position, there are two big reserves, in Central Africa and South America, a smaller reserve in Canada, and still smaller reserves in the Asiatic islands

(1) See *R.*, July-Aug. 1920, No. 773. (*Ed.*)

of the Philippines, Borneo, and Papua. During the war the Allies all co-operated in their timber supplies, giving to each other what each required. The previous survey has shown that the world's requirements of timber can only adequately and economically be met by world rationing, and it is to the renewal of this co-operation that must be looked in order to find a starting point for the trading arrangements of peace.

1129 – **The Influence of Suckers on the Production and Form of Oaks in the Preserves.** — MER, E., in the *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. VI, No. 24, pp. 595-596. Paris, June 23 and 30, 1920.

The presence of suckers is harmful not only because it results in a feeble and perhaps withered crown but also because they decrease production and change the form of the tree to the great depreciation of its value. The conical form tends to increase and so shorten the rotation period. The quality of the wood is affected by the disappearance of the suckers as the presence of numerous dead knots cannot but depreciate the value of the wood.

It is therefore desirable to prune the saplings as soon and as often as possible after clearing. Long rotation periods help the suckers to persist because of the growth of shoots, and more time being given for them to disappear. Long rotations, however, increase the production and value of the coppices, besides favouring growth in length. On the other hand, the saplings disappear, as they cannot support a long covering, so that in any forest, selecting and marking becomes more and more difficult when the rotation period is 30 years or more.

This can be remeded, still keeping to fairly long rotations by freeing the saplings, sooner, more frequently and more drastically. In order to succeed in this the saplings must be completely isolated so that there is no chance of their being overcome by adjacent shoots. Done in this way the isolation also has the advantage of notably increasing their growth.

If annular decortication (taking care to preserve the sap wood) be also practised, the production of useful wood will be greatly increased and this aim should be sought after more than ever and by every available means.

LIVE STOCK AND BREEDING

1130 – ***Baccharis pteronioides* as a Poisonous Plant of the Southwest, United States.** — DWIGHT MARSH, C., CLAWSON, A. B. and EGGLESTON, W. W. in the *Journal of the American Veterinary Medical Association*, Vol. LVII, N. S., Vol. 10, No. 4, pp. 430-434, figs. 2. Washington, D. C., July, 1920. HYGIENE

Various reports have been sent to the Bureau of Animal Industry of losses of livestock apparently due to a poisonous plant in the forage. In 1918, *B. pteronioides* D. C. (*B. ramulosa* [D. C.] Gray), was found abundant in the Lincoln National Forest, New Mexico by EGGLESTON and where also, autumn and winter losses had occurred. This evidence led to some experimental feedings at the Salina Experiment Station to determine definitely whether or not the plant was poisonous. Consideration was taken into account of the fact that several members of the genus grow-

ing in Mexico and S. America have been used in medecine, and that, *B. coridifolia* is a well know cattle poisoning plant in Argentina, and also infects horses and sheep.

It was definitely demonstrated that the lethal dose for sheep is nearly 1 lb., and although not an actually toxic plant, it is of a decidedly dangerous character. The symptoms exhibited in this case were not distinctly characteristic.

The death of cattle in Southern Arizona and New Mexico can very probably be also attributed to this same trouble. A report received in 1915 describes the following indicative symptoms in cattle: — stiff and jerky action generally, and liability to fits When opened, the intestines were as if they had been burned with potash. In this particular case, the sample of weed which was considered undoubtedly the cause of this effect was identified as the plant under discussion.

The known range of altitude is from 4 000 to 7 600 feet, but is more commonly found between 5 000 and 6000 feet, and occurs from Central Mexico, through the Rocky Mountains of Western Texas, North to Central New Mexico and Eastern Central Arizona.

1131 – ***Triglochin maritima.*** **A New Stock-Poisoning Plant.** — Fleming, C. E., Peterson, N. F., Miller N. R., Wright, L. H., and Louck, R. C., in *Agricultural Experiment Station, University of Nevada, Bulletin* No. 98, pp. 6-22. Carson City, Nevada, 1920.

In the autumn of 1918 the authors were informed that cattle had died in Southern Utah from eating a plant known in that region as " goose-grass ". This plant was identified as *Triglochin maritima*, generally recognised as poisonous. It does not seem to be distasteful to animals, which instead sometimes eat it greedily. This fact led the authors to study the toxic capacity of the plant.

An analysis was made of an air-dried sample of the plant, and there was found 0.264 % hydrocyanic acid. Calculated to the original green weight of the plant, this is equivalent to 0.054 %. Poisonous plants of this type appear to have an erratic action both in feeding experiments and also when animals are grazing at will. Apparently the grazing of sheep and cattle upon such plants has not been accompanied with fatal results in every case. Amongst the possible factors which contribute to the action of these compounds should be noted the physical condition of the animal when fed, the state of its health, and whether the food in question is taken upon a partially filled or empty stomach.

Feedings made with *T. maritima* cut at different seasons indicated that the plant is toxic during the entire period of its growth. As regards the affected parts, the leaves have conclusively proved to be poisonous, but it has not yet been found whether the flowers are poisonous which, however, only make up a minor part of the total weight of the plant. The roots are so firmly held down by their fibrous growth that there is little or no chance of their being eaten.

In the autumn of 1918 and in the spring and summer of 1919, 20 animals were fed with fresh green leaves of *T. maritima* ; 7 sheep were poisoned,

5 of which died. The weight of green material required to provoke sickness varied from 1 ½ lb., to 4 ½ lb., the average fatal dose being approximately 2.4 lb. The irregular and apparently inconsistent action of plants containing hydrocyanic acid would render it difficult to state accurately just how much of the plant is required to encourage sickness.

A further series of feeding tests with cattle were made in spring, summer and autumn with varying quantities of green goose grass. The results were negative. One of the animals ate an average of 15 ¼ lb. daily for 7 days with no bad effects. These results, however, should not be taken to infer that the plant is not poisonous to cattle.

Further feeding tests were made with sheep and cattle to determine the toxic effect of various proportions of dry goose grass when put up in in hay and fed. Out of 13 sheep fed, 6 were fatal cases. The smallest amount which proved fatal to sheep was 2 ¼ oz., the average fatal dose being approximately 4.64 oz. These tests prove conclusively that small amounts of the dried plant are extremely poisonous. As regards cattle, one feeding test was made with a yearling calf; the result was fatal, in spite of the fact that only 7 oz., of *T. maritima* hay was fed

Another series of feedings was practised in order to determine whether small amounts of air-dried *Triglochin*, would be harmful when fed in small quantities and at varying intervals. One only of the animals was affected, which showed symptoms of poisoning after the fourth 1 oz., dose. Results indicated that there is little or no cumulative effect of small doses fed at short intervals.

The authors have also made a study of typical cases of animal poisoning and have made anatomical and pathological observations. The first symptom of sheep poisoning was abnormal breathing, usually very rapid, often as quickly as 150 per minute. In other cases it was, however, slow and deep. Abnormal breathing was often accompanied by trembling or jerking movements of the muscles which in severe cases would develop into spasms or convulsions. Fifty per cent. of the autopsy cases showed endocardial or epicardial hemorrhages, and 40 % a spleen that was dark and mushy. In general, the blood was darker than normal and formed a clot that was somewhat soft.

No experiments were carried out to determine whether it would be possible to cure the animals, but there is little hope in this respect, because, amongst other reasons the interval between the time when the first symptoms appear and the fatal results is too short to permit treatment.

On the contrary, a great deal can be done to prevent poisoning: — wet meadows where the goose grass is common should not be cut for hay; the largest clumps should not be cut, or if cut, should be burnt when dry; animals should not be put on pastures containing much goose grass when they are very hungry.

1132 – **The Chemical Examination of Three Species of Larkspurs.** — BEATH O. A., in *University of Wyoming Agricultural Experiment Station, Bulletin* No. 120, pp. 55-88, Pl. XI. Laramie, Wyoming, June, 1919.

The subject matter is confined to general methods employed in larkspur investigation supplemented by such data as seemed advisable to give an intelligent understanding of the facts.

The three species under consideration were *Delphinium glaucescens* Rybd, *D. Barbeyi* Huth., and *D. Geyeri* Greene which clearly represent distinctive altitudes and habitats. The distribution and poisonous effects combined with characteristic symptoms with cattle affected (1) are indicated. This is followed by preliminary tests for the determination of crude alkaloids by the volumetric method. Reference is made to the comparative toxicity of each poison, and in the case of *D. Geyeri* and *D. Barbeyi.* the amorphous product was in each case far the most poisonous, Chemically, the amorphous compounds were found to be quite stable substances. Oxidising reagents such as hydrogen peroxide, nitric acid and potassium permanganate had more destructive effect than the chemicals usually employed in plant analysis.

Remedial measures. — The most advisable recourse according to the Bureau of Animal Industry U. S. A. is the injection directly into the blood by means of an all-metal hypodermic syringe of the following remedy : — physostigmin salicylate 1 grain — pilocarpin hydrochlorid 2 grs. — strychnin sulphate ½ gr. This formula would apply to an animal weighing 500 to 600 lb. The " Quitman » syringe has so far been found the most useful. The needle is most conveniently inserted in the shoulder.

There seems little doubt that prompt treatment of animals poisoned by larkspur would result in the saving of most of the cases.

1133 – **The Weir Vine (*Ipomaea calabra*) and Reputed Poisonous Properties.** — WHITE, C. T. (Government Botanist), in the *Queensland Agricultural Journal*, Vol. XIII, Pt. 6, pp. 269-272, pl. 2. Brisbane, June, 1920.

This plant is fairly common on the hard red soil of the Maronoa District, and reports indicate that the tubers were used as food by the aborigines. According however to the information suppled by GUNN, the author states that when sheep ate the vine they developed symptoms of indigo affected animals. This account was corroborated by other practical stockmen. When the plant first comes up the stock can eat and fatten on it, but it is apparently the pod which does the harm. Horses and cattle were also attacked and the eyes dimmed. When the loins were affected, the results were disastrous.

The yam can be used as a potato and is quite a harmless substitute in this respect.

The leaves of some examples of *Ipomaea batatas* have been found to develop at times hydrocyanic acid yielding glucosides, but the symptoms of this form of poisoning are not identical to those ascribed to *I. calabra.*

(1) See *R.*, Jan. 1917, No. 54. (*Ed.*)

The latter are similar to those generally associated with species of *Swainsona* in Australia and *Astragalus* in the United States, and other leguminous genera, but has not, according to the author, been recorded for any species of *Ipomaea* or other genus of the family Convolvulaceae.

1134 – **Poisoning of Cattle by Feeding on Ergotised Paspalum.** — MITCHELL, D. T. (Veterinary Research Laboratory. Onderstepoort), in the *Journal of the Department of Agriculture South Africa*, Vol. I, No. 5, pp. 422-426. Pretoria, Aug. 1920.

Serious outbreaks were reported from various parts of the Province of Natal In the cases investigated, symptoms had appeared amongst the cattle grazing on paspalum pastures in the seeding stage, and a very large percentage of the heads of the grasses were infected with a fungus of the *Ergot* type This was identified by Dr POLE EVANS as *Claviceps Paspali* which has been noted in other parts of the world to have similar effects (1).

A series of feeding experiments were arranged, and the ergot-infected paspalum was collected from old paspalum lands at the Government Experimental Station at Cedara. The feed consisted of a mixture of seed heads and ripe *sclerotia* , supplemented by bran and chopped lucerne. With 9 to 12 lb., of infected heads, a definite and diagnostic train of symptoms was produced, starting on the second day. This varied in intensity from a slight inco-ordination of movements to complete paralysis and although in the majority of instances the natural cases were comparatively mild, the results produced experimentally were more marked. Recovery was noted to commence about the fifth or sixth day but was not completed until 2 months after the feed was given.

The condition was only observed to occur in cattle, and young stock of from 14 months to 2 years old appeared to be more susceptible than adult cattle. Horses, donkeys, sheep and goats grazed on the infected grass without developing any clinical symptoms.

The treatment found to give most rapid results after the necessary removal from the paspalum lands consisted of a saline purge followed by a few days rationing on green lucerne or barley, the idea being to prevent further ingestion and to assist in elimination of the unabsorbed toxic elements in the digestive tract. Prophylactic measures consisted in reaping and collection of the grass during the flowering season, at which time the material collected from the lands may be fed to cattle with perfect safety. Heavy stocking at the commencement of the summer before the flowering season is therefore advised.

Lowered vitality due to ergot intoxication was considered to be the cause of a number of deaths from " redwater " which occurred amongst a herd of young oxen grazing on the paspalum area previous to their removal to the " red-water veld. "

The toxic symptoms mentioned are exactly similar to those observed by the American investigators, BROWN and RANCK with guinea pigs but

(1) See *R.* 1917, No. 829, 924, 1035 and 1179 ; *R.* February 1918, No. 179. (*Ed.*)

the commercial ergot extract *C. purpurea* was found to produce no distinct ill effects.

1135 – **The Therapeutic Treatment of Sarcoptic Mange in Horses.** — CRIMI, P. in the *Annali della R. Stazione sperimentale per le malattie infettive del Bestiame, Portici*, Vol. V. No. 1, pp. 19-71. Portici, 1919.

The author recommends the following method for treating sarcoptic mange in horses as being efficacious, rapid, and economical. The animal should be shaved and then washed with a soft soap containing 4 % of creolin, and rubbed with an ointment composed of 25 parts (by weight) of flowers of sulphur + 5 parts of tobacco extract (State brand) + 100 parts of vaseline. The ointment should be applied to the animal's flanks, one side being treated one day, and the other the next. Two days after the second application, the animal ought to be washed with ordinary soap and warm water.

1136 – ***Onchocercosis* in Madagascar Cattle.** — CHRETIEN, A. in the *Bulletin économique de Madagascar*, Year XVII, Nos. 1 and 2 (First and Second Half-years, 1920), pp. 47-50. Tananarive, 1920.

Among the rare internal parasites of cattle in Madagascar, there is, in addition to the amphistomata of the rumen and the filaria of the peritoneum, a nematode, which the author, a veterinary surgeon, has found, often in large numbers, in nearly all the adult animals he has examined. so common is this parasite that the author thinks he could almost say, that careful direction and minute investigation would have revealed its pre-Sence in all the cattle submitted to him for inspection. He, however, adds that his researches (made in 1917-1918-1919) were confined to adult cattle from the north of the island which were slaughtered at the rate of 100 to 120 daily to supply the Montagne d'Ambre canning-factory, near Diego-Suarez.

The nematode in question is an *Onchocerca* that was recorded in 1912 by M. PIETTRE, who thinks it is the same as the *Onchocerca bovis* which he discovered, also in 1912, in cattle in France.

The nematodes are located in the conjunctive tissue in the neighbourhood of the ligaments and tendons, but not in them, for they seem unable to penetrate into the tissue of these latter.

No symptoms of the disease are, however, noticeable in the living animal. The author never observed any trace of stiffness of the neck and shoulders, or any difficulty in walking, even when the cattle arrived at the factory, though most of them had just been driven four successive daily stages of 36 to 40 km.

1137 – **Treatment of Retention of the Foetal Envelopes After Birth in Cows.** — PICCIONE, G. in *Il Coltivatore*, Year LXVI, No. 22, pp. 528-552. Casale-Monferrato, August, 10, 1920.

The retention of the foetal envelopes (placenta, membranes) is an accident that frequently occurs after parturition in cows. It is often observed after abortion, whether sporadic, or epizootic, and as a result of

long and difficult calving. The special arrangement of the placental cotyledons in ruminants appears to retard the expulsion of the after-birth.

The author mentions the symptoms of the retention of the after-birth and states that the various drugs usually administered to treat retention have but litte effect. He suggests new methods of treatment :— (1) Friction of the dorso-lumbar region accompanied with the alternate application of hot and cold plasters ; (2) injections of cold water into the umbelical vein of the placenta ; (3) massage of the uterus by way of the rectum ; (4) crushing the yellow bodies. Of these several methods, the first is not certain ; the second ought never to be used, but the third and fourth are efficacious because they induce contraction of the uterus which, after some hours, bring about the expulsion of the after-birth; they should be followed by uterine douches. The empiric method still employed in the country in Italy which consists in attaching a weight to the portion of the membrane that has already been evacuated is harmful, because the continual pull produces a diphtheric condition of the mucuous membrane of the vagina, or even necrosis, and may perhaps cause inversion or prolapsus; (5) repeated uterine douches are an easy and efficacious treatment ; (6) the best method, and that most used is the manual extraction of the placenta followed by a douche of hot or luke-warm water, or the introduction into the uterus of 100 to 120 gm., of animal charcoal in the form of 10 gm., capsules, followed 3 days afterwards by a douche (OPPERMANS' method).

As a rule, farmers do not consider the retenton of the after-birth as a matter of much importance because it rarely endangers the life of the cow, but this is a mistake, because this accident, although slowly, and indirectly, causes losses in stock production that are far from negligible.

The author no longer administers drugs in treating placental retention for they are quite useless ; he has recourse, however, to tonics, and to detachment by hand which, when properly executed, entails no risk but should be followed by repeated douches. To administer the douche all that is needed is an indiarubber tube 1.50 m., to 2 m., long, provided at one end with an indiarubber clyster-pipe to be inserted into the uterus, and at the other, with a funnel to receive the liquid to be injected. A vine irrigation-pump may also by used, provided it is held, so that no air is introduced into the uterus.

The liquids for injection are : 1 % creolin ; iodine water (one spoonful of tincture of iodine to 1 litre of water) ; a 1 % acqueous solution of carbolic acid ; 1 to 2 % permanganate of potassium ; etc. Weak solutions must be used, in order to prevent too violent contraction, which might cause inversion of the uterus. In some very serious cases, the author used tepid well-water which, as it contains no specific germs, is not injurious, even when not sterilised, as FABRETTI has shown.

1138 – **Reaction of Milk in Relation to the Presence of Blood Cells and of Specific Bacterial Infections of the Udder.** — BAKER, J. C., and BREED., R. S. (New York Agricultural Experiments Station, Geneva), in *The Journal of Biological Chemistry*, Vol. XLIII, No. 1, pp. 221-235, Bibliography of 18 publications, Baltimore, Md., August, 1920.

In a previous paper (*Journal of Biological Chemistry*, Vol. XL, p. 345, 1919) L. L. VAN SLYKE and J. C. BAKER have shown that decreased acidity of fresh milk is due to the direct filtration of blood serum into the milk as secreted. Because of the importance of this suggestion in explaining bacteriological and physiological problems, the biological data that have a bearing on this theory are discussed in the present paper.

In support of this view it is pointed out: 1) That this view is in harmony with the changes in composition that accompany decreased acidity; 2) that it is in agreement with the hydrogen ion concentration of normal milk (P_H values 6.50 to 6.60) and that shown by blood serum (P_H about 7.60); and 3) that it harmonizes with an increased CO_2 content of the less acid milk, normal milk containing about 10 per cent. by volume of CO_2 and blood serum, 65 per cent.

Further proof of the presence of blood serum was furnished by the presence of fibrin as shown by fibrin stains. This normal constituent of blood does not appear in normal milk.

The only observed chemical relation that was out of harmony with the view that unchanged blood serum caused the low acidity of certain samples of milk was the fact that no glucose could be demonstrated in several samples in which it should have been present in appreciable quantities if this were the case. At that time it was suggested that further investigations were desirable.

From the new data here given, and from histological and physiological considerations, it appears that a more exact statement of the case would be that the infection causes the entrance of a serous exudate derived by the gland cells directly from the lymph rather than from blood. This serous exudate is neither exactly like blood serum nor milk. When the infection has proceeded to the place that actual rupture of the vessels occurs, then unchanged lymph and blood would enter. The modifications in the secretions may be due to a weakening of the secretory activity of the cells or the exudate may have a definite protective function against the bacterial infection, or both conditions may hold simultaneously.

The processes involved are so complicated that it is little wonder that the matter is not clear even with the data at hand. It seems quite probable, however, that the increased CO_2 content of the milk samples having a lowered acidity is correlated with the entrance of bicarbonate from the blood The acidity of the milk would also be lessened by the entrance of increased amounts of basic phosphates or even of albumins. Changes in the secretion of the milk in relation to these substances could easily explain the changes in reaction actually noted without assuming the entrance of excessive amounts of unchanged blood serum or lymph. While these chemical changes are still only partially understood, the data establish

the fact that the modifications of the secretion are correlated with an increased entrance of the leucocytes into the lumina of the alveoli. Accompanying this change in the secretory processes there also seems to be an increasing amount of wastage from the glandular epithelium.

1139 – **Studies on "Debab"** (1). — SERGENT, É. and DONADIEU, A. (Institut Pasteur d'Algérie), in the *Bulletin de la Société de Pathologie Exotique*, Vol. XIII, No. 7, pp. 521-525 and 525-527. Paris, 1920.

I. — EXPERIMENTAL INFECTION OF DROMEDARIES WITH *Trypanosoma berberum* PRODUCING "DEBAB." — This experiment was carried out for 2 years on some twenty dromedaries that were not obliged to work, and were given nourishing food. The animals found to be healthy were inoculated with the blood of naturally infected dromedaries. The results show that experimental infection produces :—

(1) An acute phase of the disease lasting 3 or 4 months with the presence during at least half that time, of trypanosomes in the peripheral blood. The development of the parasites is always accompanied by a rise in temperature.

(2) A chronic phase (lasting months and years), the trypanosomes making their appearance twice a month on an average. This chronic phase passes into a period of latent infection accompanied by a relative immunity to new infection.

The only clinical symptoms characterising trypanosomiasis are :—

(*a*) Loss of flesh and debility, which reduce the dromedary's resistance to pathological influences. Death is usually due to complications.

(*b*) Abortion.

II. — HEREDITY OF INFECTION AND IMMUNITY OF DROMEDARY TRYPANOSOMIASIS. — The authors conclude that female dromedaries transmit the disease to the foetus (which succumbs to it), during the acute stage of the malady only. When in the chronic stage, they transmit neither the disease, nor immunity to it.

1140 – **Biochemical Changes in the Flesh of Beef Animals Receiving Insufficient Nourishment.** — MOULTON, C. R., in *The Journal of Biological Chemistry*, Vol. XLIII, No. 1, pp. 67-78. Baltimore, M. D., Aug. 1920.

ANATOMY AND PHYSIOLOGY

C. W. GREENE (*Journal of Biological Chemistry*, v. XXXIX, pp. 435, 1919) showed that during the period of spawning migration, besides experiencing a loss of muscular tissue, these fish exhibited an impoverishment of the muscular tissue that meant a loss of from 10 to 30 % of the protein content. The organic extractives nevertheless remained fairly constant and even increased under certain conditions.

In a second paper GREENE (*Ibid.*, pp. 457) confirmed the preceding results and showed further that the concentration of amino-nitrogen relative to the water content after an initial increase remained constant throughout the migration. He argued that the results indicate a storage of reserve protein in the salmon muscle.

(1) See *R.*, Dec. 1918, No. 1368 ; June 1919, No. 747. (*Ed.*)

The author in the present case undertook experiments with a view to the determination of: 1) Changes in the protein and other constituents of the flesh; 2) changes in the composition of the liver and blood; 3) changes in the size of the muscle fibres with the Hereford-Shorthorns which had in most cases been very fat when young These were treated as follows: 1) Allowed sufficient food to permit of a gain of ½ lb. daily (for 6 months); 2) kept at constant weight (for 6 and 12 months); fed so as to allow a loss of ½ lb. daily for 6 and 10 months) i. e. until nearly dying of hunger.

The analytical results presented in Table form indicate the following points:—

Partial starvation does not cause a watery muscular tissue. Fat is almost entirely reabsorbed, while glycogen apparently is not. The character of the protein is altered by a removal of nitrogenous substances amounting to 10 % of the total nitrogenous material, and consisting of albumin nitrogen. The phosphorus content of the flesh is reduced 13 to 15 %.

The liver has a somewhat higher water content in the starved animal and a high nitrogen content. This indicates a greater proportion of amino-acid and extractive nitrogenous substances. The glycogen content is not depleted.

The blood has more water and less total nitrogen in the starved steer: the muscle fibres become very much smaller but still capable of functioning.

The data presented indicate a storage of protein matter in the muscles of the steer.

FEEDS AND FEEDING

1141 – **Rice Straw as Cattle Fodder** (1). — CHIAPPELLI, R., in *Il Giornale di Risicoltura*, Vol. X, No. 9, pp. 131-137 + 1 fig. Vercelli, Sept. 10, 1920.

In Italy, rice straw is usually used as litter and very little as fodder. This is due to the frequent autumnal rains which make the preservation of it difficult, and also to the fact that dry rice straw causes intestinal disturbances. The author shows how these disadvantages can be eliminated.

Rice straw differs from other straw in that it is harvested whilst still green; when air-dried it has the following composition:—

Rice straw is, therefore, relatively rich in the nutrient materials, but these become very indigestible when dried. This can be almost entirely avoided by putting the hay into a silo with a movable cover, under heavy pressure, as in the "cremasco" process (2).

After harvesting and threshing the rice straw is spread in the sun for some days until partially dried, and then put into a silo. In the silo it is mixed with other herbage, also partially dried, that can be harvested at the same time (3). The fodder is ready at the end of one month or

(1) See *R.*, Jan., 1919, No. 115. (*Ed.*)
(2) See *R.*, Jan., 1919, No. 105. (*Ed.*)
(3) See R. Oct. 1920, No 886. (*Ed.*)

Composition of Italian rice straw air-dried.

	Novarese	Bertone	Japanese
	%	%	%
Moisture	14.3	15.0	15.0
Digestible glycogenic substances	17.3	14.4	14.5
Fats	1.9	1.5	1.4
Nitrogenous substances	4.4	3.7	3.1
Total nitrogen	46.3	48.4	50.8
Cellulose	15.8	17.5	15.2
Ash	0.7	0.6	0.5

less, and can be kept several months. It is best to add some concentrated food, such as rice-bran cakes (" pula vergine di riso ") when feeding rice straw to cattle.

1142 – **The Use of Some Salt Water Plants as Fodder.** — PARANJPYE, H. P., in *The Agricultural Journal of India*, Vol. XV, Pt. III., pp. 250-351. Calcutta, May, 1920.

The fodder growing areas in the Ratnagiri district, Bombay, are poor and limited, and the cultivators have to fall back upon such plants as can naturally grow on the poorest of soil and take care of themselves. In the tidal rivers and creeks along the west coast also, there are immense areas which are covered with several kinds of mangroves, with grasses, and holly-like shrubs. These plants grow in salt water, and contain a considerable quantity of salt. They are, nevertheless, fed, even in normal years as green fodder to milch cattle, and if possible, also to work animals. The following examples are given :—

I — The holly-like " *Marandi* " (*Acanthus ilicifolius*) — a spiny plant, 3 to 4 ft high, erect and unbranched The plant is generally cut before its flowers, and chopped into 3 inch bits; then beaten with a strong rod to break down all spines. This is the only necessary precaution in preparing the stuff for feeding Until the animal is accustomed to the new feed, a small quantity of " bhusa " or cotton seed or any other similar food may be added, but these additions may later be omitted.

II. — The " tivir ,, (*Avicennia officinalis*) — a large spineless shrub which covers large areas in the creeks, with peculiar roots which project in large numbers above the surface of the mud. Branches of this plant may be cut and fed to cattle.

III — The " *lavi* " (*Aeluropus villosus*), a small grass about 12-15 inches long, growing in salt water mud. After cleansing, it is immediately fed to cattle, preferably to milch cattle, 10 to 15 lbs per animal. The quantity of this grass available is, however, limited.

The first two plants are very common in all the creeks and rivers of the west coast of India. The cattle owners of the Kolaba, Thana and Surat districts are strongly recommended to use them as long as they are available, and thus increase the supply of fodder.

1143 - **Food Value of Willow Leaves.** — HALL, T. D. (Chemical Laboratory, School of Agriculture and Experiment Station, Potchefstroom), in the *Journal of the Department of Agriculture, South Africa*, Vol. I, No. 5, pp. 456-457. Pretoria, Aug., 1920.

Analyses show that willow leaves are highly nutritious. The samples were taken at intervals of more than a week apart during the feeding experiment conducted by R. BOURLAY with chickens, comparing the value of green willow leaves with green lucerne. In 6 weeks the chickens fed on the former gained 2 lb., in weight over those fed on the latter, — an average gain of 2 $^{2}/_{3}$ oz., per chick. The following Table compares the average composition of dried willow leaves with that of some important hays :—

	Moisture	Crude Protein	Crude Fat	Crude Fibre	Carbo-hydrates N. F. E.	Ash
	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.
Willow leaves (air dried)	10.09	15.37	5.35	19.50	40.4	8.94
Lucerne	8.0	15.5	2.4	34.8	30.6	8.9
Cow Pea	8.2	13.2	2.4	30.5	39.6	6.3
Teff	8.2	6.0	1.1	34.8	43.2	6.7

It should be noted that the mineral composition of the ash is excellent for growing animals or birds %:— silica 3.268 — iron oxide 3 692 — calcium oxide 31.360 — magnesium oxide 12.620 — potassium oxide 9.926 — phosphoric oxide, 5.04

1144 - **Composition and Food Value of Tobacco Oil Cake.** — See No. 1107 of thist *Review*.

1145 - **Use of Silkworm Dejecta in Stock Feeding.** — RUFFONI, in the *Bollettino del Consiglio Provinciale d'Agricultura, dei Consorzi agrari e dell'Istituto agricolo provinciale di San Michele*, Year XXXIII, No. 40, pp. 3. October, 2, 1920.

In the regions of Italy where silkworms cultivation is of most importance, it is customary to feed their dejecta to the cattle

One ounce of " seed " produces 80 kg , of dejecta, the composition of which varies according to the stage growth of the silkworm ; as can be seen from the analysis by M. GIRARD :—

Percentage composition of silkworms dejecta.

	After the 1st. moult	After the 2st. moult
Moisture	12.10	9.70
Nitrogenous matter	18.21	12.55
Fats	0.79	0.63
Carbohydrates	50.29	59.28
Inorganic matter	8.88	8.72
Cellulose	9.93	9.12

The composition of these dejecta gives them a very considerable value as a supplementary feed, but on account of their great absorbent power, they should be given with caution They are very often fed without dietetic rules, so that they sometimes occasion intestinal disturbances in the stock.

All the disturbances occurring in young animals, viz., an obstinate obstruction of the omasum, often manifest themselves when silkworm dejecta are used as a feed, for they have a strong dehydrating effect upon the mucous membrane of the stomach. The action of the dejecta is thus entirely physical, and if they are kept in good condition, no ill effects due to their composition need be apprehended.

When fed to ruminants, these excreta ought always to be mixed with other foods such as bran, beets, etc., and given in moderate quantities, preferably kneaded into a paste with water. Pigs can eat from 1000 to 1500 gm. daily, either alone or mixed with flour, but always soaked in water. Horses prefer the dejecta dry, and they can be fed to these animals mixed with barley or oats

STOCK BREEDING

1146 – **Sexual Neutralisation Obtained by Means of Orchilytic and Ovariolytic Serums.** — GIULIANI, R. (Direttore Istituto Zootecnico Laziale), in the *Annali d'Igiene*, Year XXX, No. 6, pp. 323-325. Rome, June, 1920.

After briefly examining the advantages and risks attendant upon the removal of the sexual organs, both in the case of the males and females of different species of animals, the author describes a new method by means of which the functioning of the sexual glands can be suppressed without the necessity of a surgical operation.

If cells or cellular extracts of heterogeneous species are introduced into the blood system of an animal, the organism reacts by the production of substances (cytotoxins and cytolysins) which cause the death and sometimes the actual lysis, of the cells of the type used in the injection.

As a rule, these substances only act on the cells of the species of animal from which the injected material was taken. Some, however, have a stronger or weaker action on related species, and also, in the case of animals of the same species, upon tissues other than those which produced the cytotoxins and cytolysins in question.

The experiments consisted, in the first place, in preparing an orchilytic serum from the rabbit. This serum was preferred to an ovariolytic one, the object of the experiment being, if possible, to cause atrophy of the testicles in the animal injected with the serum, since atrophy of the ovaries could only be attained by slaughtering the females.

A he-goat was selected to furnish the serum and was injected periodically with a nucleo-proteid solution of the testicle of a rabbit. Of the 5 rabbits subjected to the action of the serum, 2 died during the experiment; in another which was killed after 15 days, the testicles revealed to the touch that a considerable amount of atrophy had been induced, and microscopic examination showed that the seminal ducts, though still recognisable, contained a kind of granular detritus.

The other two rabbits were subjected to the action of the serum for 30 and 40 days, respectively. During this time, progressive atrophy of the glands of the testicles was observed. When examined, the testicles proved to be to a great extent empty, that is to say, they only consi ted of the albuginea, conjunctive tissue, and a small amount of parenchymatous substance.

Microscopic investigation showed a great alteration in the parenchyma, which was of a finely granular appearance, and in which the seminiferous ducts were difficult to distinguish.

1147 – **Researches on the Inheritance of Coat-Colour in Horses, in Denmark.** — WINGE, O., in the *Nordisk Jordbrugsforskning*, Part. 5, pp. 1-30. Copenhagen, 1920.

A study on the inheritance of coat-colour in horses based on data obtained from the pedigree register, and referring to about 1000 horses of the Jutland breed. Particular note was taken of animals with the 3 fundamental colours black, bay, and chestnut, and also of white and spotted individuals.

The facts observed confirm, to some extent, the theories of WALTHER and WENTWORTH, which however, in the author's opinion, are unnecessarily complicated.

The inheritance of the three colours can be reasonably explained by assuming a single fundamental colour for the three kinds of horses, and by postulating the presence of 2 factors, one R for chestnut, and another S for black. The simultaneous presence of R and S, both in the homozygotic and heterozygotic condition, would determine the bay colour.

There are thus 4 kinds of bay, R R S S, R R S s, R r S S, and R r S s; 3 kinds of chestnut, R R s s, R r s s, and r r s s; and finally, 2 kinds of black, r r S S and r r S s.

Thanks to the large amount of material at his disposal, and by dint of careful examination of it, WINGE was able to prove the truth of his theory, according to which, from the cross chestnut × chestnut, only chestnut foals could be obtained, as has been actually observed; with black × black, both black and chestnut but not bay offspring could be obtained; while bay × bay give foals of any of the 3 colours.

Among the descendants of the bay type, there may be some horses of the formula R R S S which, mated with mares of any colour, should give bay foals. Such horses have indeed been known; thus, Nobel No. 295, was the sire of 52 foals all of which were bays.

The fact that, in the Jutland breed, black individuals are much more numerous than bays, makes it probable that the formula for bay is usually R r S s or R R S s, rather than R r S S or R R S S.

On the other hand, the three chief colours occur in different shades; there is also a factor for white, and one for spottedness which are dominant as regards R and S.

1148 - **Contribution of Genetics to the Practical Breeding of Dairy Cattle.** — PEARL, R. (Department of Biometry and Vital Statistics, John Hopkins University), in the *Proceedings of the National Academy of Sciences of the United States of America*, Vol. 6, No. 4, pp. 225-233. Easton, Pa., April 1920.

The authors' tests with regard to the egg production in fowls, and milk production in cattle, showed that the phaenotypic performance was an exceedingly unreliable guide to real breeding worth. The real value of the measure of an animal as a breeder is the kind of progeny which it produces, and not the fact that the cow may have herself an enormous record. It has repeatedly been shown that a bull may come from ancestry of the highest performing ability in respect of milk and fat production, but this is no guarantee that his own progeny will be great producers.

Nearly 10 years ago the author began the intensive study of the practical problems of scientifically measuring the breeding worth or value of bulls of the dairy breeds, at the Maine Experiment Station (1) and inaugurated the project of determining the transmitting power of every bull in the Jersey breed recorded up to 1916, as having two or more daughters whose milk producing qualities were known, as well as the producing abilities of the dam.

This article gives a brief account of the scope of the work and some of its chief results. The author notes that, stated specifically if $D\,d$ represents the milk production of a daughter of a given bull, and $D\,n$ the milk production of the dam of this daughter, then the measure of this bull's transmitting qualities for milk production in respect of this pair would be:

$$\textit{Sire's transmitting power} = D\,d - Dm.$$

A Table gives in detail the net average change in butter fat production of daughters as compared with dams, and enables the breeder to form a real judgment of the worth of various bulls which appear in the pedigree of Jersey Cattle. Reference is made to the complete paper which also discusses the relation of inbreeding, and the amount of Island bred stock, etc., to production and a summary is then given of the chief results of the whole study:—

There are 224 Jersey Registry of Merit sires which meet the requirements of this performance test for their transmitting qualities in milk production. Less than one half raise the milk production of their daughters over that of their latter's dams. The largest number of the daughter-dam pairs is 39 for one particular sire Hood Farm Pogis 9th.

Out of the 225 sires which met the requirements of the daughter dam performance test for transmitting qualities of butter-fat percentage, 101 raised the latter of their daughter's milk compared with the percentage of that of the dams of these daughters.

The leading sire in this test raised his daughters on the average 1.338 % of butter fat, and had two daughter-dam pairs. Hood Farm

(1) See *Maine Agr. Exp. Sta Ann. Report for* 1919, pp. 89-204. (*Ed.*).

Pogis 9th leads in the number of daughter dam pairs with 42, and raised the butter fat percentage of his daughter on the average of 0.243 % over that of the latter's dams. Out of the 224 sires, only 99 were found to raise the butter fat production of their daughter's over that of their dams, and only 69 out of 159 sires had sons which showed similar results.

The sires are classified into two groups: 1) inferior sires, when they lower the milk production and butter fat percentage of their daughters as compared with the same variables in their dams, and 2) superior when showing the opposite results. The fact that 47 sires are included in Group I compared with 28 in Group II emphasises the need of exact knowledge of the transmitting qualities for the above mentioned percentages.

Inbreeding coefficients show that the sires of superior merit have 7.08 % of the greatest possible inbreeding up to the fifth generation. The inferior sires are inbred 9.65 % of the greatest possible amount (continued brother and sister mating). An analysis of pedigrees shows that there is little or no difference in the amount of relationship between the sire and dam of the individual bulls in the two groups. Amongst the Island bred Jerseys and the American bred Jerseys, the mean number of Island males and females in the pedigree of the superior sire's group were shown to be 6.94 and 6.55 respectively. The animals which appeared in the pedigrees in the first case more than 4 times, or in the second case more than 3 times, had appearances in the pedigrees of the sires inferior in their transmitting qualities. This fact alone makes it clear that the appearance of certain famous animals in the pedigree of a given bull is no guarantee of that particular bull's worth.

1149 – **The Relative Importance of Heredity and Environment in Determining the Piebald Pattern of Guinea Pigs.** — WRIGHT, S. (Bureau of Animal Industry, United States Department of Agriculture), in *Proceedings of the National Academy of Sciences*, Vol. 6, No. 6, pp. 320-332, figs. 6, Easton, Pa., June, 1920.

The Bureau of Animal Industry has been carrying on an experiment on the effects of inbreeding on guinea pigs since 1906. Twenty-three families were started successfully from as many pairs and were maintained wholly by matings of brother and sister. Another stock from the same source has been maintained as a control, without mating even second cousins.

A number of colour variations were present in the original stock, although these consisted largely of tricolours, and most of them kept appearing during the early history of each family as a result of Mendelian segregation. After a number of generations, however, a certain colour became fixed automatically within each inbred line, and the families became broken into a number of sub-families each characterised by a particular colour.

As a supplement to more direct attempts to determine the cause of these variations in the pattern, it seemed desirable to find the relative importance of heredity and environmental factors.

In this paper, only variations in the piebald pattern are considered, and the sexes dealt with separately. Only the dorsal areas are taken into

account. As the correlation between the amount of white on the back and belly is 0.86, and the back contains the most persistent centre of colour (the ear region), and almost the most persistent white (the nose), the grades, based on the dorsal part only, are believed to be practically as satisfactory as grades based on the entire coat.

Figures illustrate the distribution of grades of white in three of the inbred families, and in the control stock 1916 to 1918 curves represent the distribution of colour potentialities among areas in the skins.

Two stocks were chosen for special study. One was the control stock, with random matings, (except that even the mating of second cousins was avoided). The other had since 1915 been descended entirely from a single mating in the twelfth generation.

Inspection of the Tables given shows that sex makes no significant difference in the correlations. This is in agreement with the results of direct experiments. Reciprocal crosses between inbred families at the opposite extremes, produced practically the same result, the progeny being in both cases, almost exactly intermediate. Sex also makes no significant difference in variability. In the case of the means, there is, however, a sex difference. The mean and standard deviations are measured on a scale in which unity is the standard deviation of colour potentialities for areas within the skin of a single average guinea pig. Even the random bred types differ less among themselvs in this respect than the spearate skin areas of a single animal.

The correlations between parents, between parents, and offspring, and between litter mates in random bred stock and a single inbred family (No. 35) 1916-1918 are tabulated, and also illustrated diagrammatically. There is evidently very little genetic variability left in family 35, but a good deal in the control stock. The main differences which are not genetic must be due to irregularities in development due to the intangible sort of causes to which the word chance is applied. Variations which are due to inaccuracy in grading, and are therefore, merely apparent, cannot, however, be distinguished from those of this class. Checks have been made which indicate that apparent variability due to this cause is small in comparison with the large amount of variability which is found to be due neither to heredity, nor to tangible environmental conditions.

In a forthcoming paper, a method of estimating the degree to which a given effect is determined by each of a number of causes will be discussed at some length.

The progeny of a cross between two grades of piebald are almost exactly intermediate on the average, and the second generation is only slightly more variable then the first. These results might be due to to groups of dominant factors with opposed effects. The most probable explanation is that dominance is lacking, and the author adopts this view provisionally.

In the control stock, variations in pattern are determined, about 42 % by heredity and 58 % by irregularity in development, leaving no-

thing for tangible environmental factors. In the inbred family, the corresponding figures are 3 % heredity, 5 % for tangible environment and 92 % for irregularity in development. The mean squared deviation due to each kind of factor can be found by applying these percentages to the total squared standard deviation of each stock.

HORSES

1150 – **The Indices of the Horse.** — ROUARD, M. (Remount Dépôt at St. Jean-d'Angely), in the *Revue vétérinaire*, Vol. LXXII, Series 3, No. 1, pp. 539-548. Toulouse, Sept, 1920.

The index of compactness, and the dactylo-thoracic index have recently become of great practical importance.

Index of Compactness. — This is obtained by dividing the weight of the horse by its height in centimetres: $IC = \frac{P}{T}$. A better definition would be the following: the index of compactness expresses the weight of 1 cm., of height. Thus, if a horse weighing 620 kg.), measures 1.62 m., its index would be 3.80, that is to say, each cm., of height weights 3.80 kg.

It has long been allowed that this index was the ratio of the weight to the number of centimetres exceeding the metre. Thus, in the prexceding example, we should have $IC = \frac{620}{62} = 10$. Whereas stud stations, and racing clubs 62 use the formula $IC = \frac{P}{T}$, the Remount Service uses $IC = \frac{P}{T-100}$, because the commissions which studied the artillery-horse type before the war were of opinion that this index was the more mathematical.

In the following table, obtained with the formula $IC = \frac{P}{T}$, it can easily be seen that instead of varying between 2.50 and 3.08, IC varies between 7 ½ in the case of light cavalry types, and between 8½ and 9 ½ in that of artillery horses.

Type	Height metres	Weight kg.	Index of Compactness	Observation
Light horse	1.51	380	2.50	Young remounts
Dragoon	1.56	416	2.60	id.
id.	1.57	431	2.70	Adult horses
Cuirassier	1.64	500	3.04	id.
Artillery	1.50	450	3.00	Height between 1.50 m. and 1.55 m.
id.	1.57	480	3.07	Height between and 1.66 m. 1.61 m.
id.	1.62	500	3.08	Height above 1.61 m.
Draught	1.60	480	3.00	—

The index of compactness gives information principally regarding size and volumetry; given equal height, it is larger in proportion as the

weight is greater, and inversely; in the same way, the weight being equal, it will be larger in proportion as the height is less, and inversely. When this is high, this denotes great density of the tissues, the mass, and the frame, all very important factors in judging a horse.

The author basing his calculations on numerous weighings and measurements made in the cavalry and artillery regiments, and in the remount stations, has endeavoured to determine the average value of this index of compactness in the different classes of Army horses.

The limits within which the value of the index of capacity varies seem to be as follows:— 2.50 for light horses, 3.00 for medium horses, and 3.08 for heavy horses.

In some cases, the index is as much at 3.50, and not infrequently it rises to 3.70 and 3.80 in some large half-blood or draught stallions.

Examination of the Table shows that the value of IC rises from that of the light category to that of the artillery horses, by way of the dragoon and cuiraissier mounts, and reaches its maximum in the heavy draught horses. This is natural, for the compactness of a horse depends upon the development of its muscular masses. The lower compactness index of the pure-bred horse, whether a light mount or a dragoon charger, is, however, not simply due to insufficient muscular development, but is a proof of the physiological fact that the strength and intensity of muscular contraction do not solely depend upon the number of the muscle fibre but also upon their quality and the richness of their nerve supply.

The knowledge of IC does not serve only in judging an isolated individual, but very useful information can be obtained by observing the changes that take place in this index in the same lot of young horses during one year. The extent of the increase and the rapidity of the change, show the value of the rations, the amount of work to be required from the animal, and the suitability of the district for horse-breeding.

DACTYLO-THORACIX INDEX (Idt.). — This is given by the proportion between the circumference of the cannon-bone and the perimeter of the thorax. The measurement of the circumference of the cannon-bone does not merely give us information as regards the region that is measured but tells us much about the general development of the bones and tendons.

The results obtained by the author from his examination of numerous horses are as follows:—

Type	Circumference of cannon-bone	Perimeter of Chest	Idt.	Ratio	Observation
	cm.	cm.			
Light horse	18	1 72	0.104	1/9.5	—
Dragoon	19	1 78	0.106	1/9.5	—
Cuirassier	21	1 85	0.108	1/8.8	—
Artillery	19.7	1 78	0.110	1/9	Small: 1.50 m.
id.	21	1 82	0.110	1/8.7	Tall: 1.62 m.
Draught	20	0 11	0.112	1/8.8	—

These figures confirm the data already accepted.

The tenth part of the circumference of the chest should always be less than the total circumference of the cannon-bone, and never exceed it by 5 cm.; if it is more, the animal may be considered as deficient in chest development.

CATTLE

1910 - Cattle Breeding and Milk Production in Austria. — *Communicated by M. E. Blumenthal, Assistant Expert, Austrian Department of Agriculture, Vienna.*

In the territory now belonging to Austria, the number of cattle continued to increase, although slowly, until 1910, after that year it decreased gradually until the commencement of the war since when it has rapidly fallen. The following data of the official census were taken from the "Wirtschaftsstatistische Materialien über Deutschösterreich 1919", published in the *Statistisches Handbuch* Vienna, 1883, 1884, 1911, 1913):—

Table I. — *Head of cattle in the Austrian Empire 1880-1913.*

Region	1880	1890	1900	1910	1913	Decrease between 1910 and 1913
Lower Austria	904 281	834 833	806 838	840 899	803 800	15 %
Upper Austria	833 003	851 074	888 980	880 811	876 491	4
Salzburg	248 880	241 481	240 240	238 808	230 002	3
Styria before the Peace Treaty	961 073	980 802	998 802	982 443	—	—
Styria after the Peace Treaty	—	—	—	476 499	458 208	15
Carinthia	258 253	247 827	256 000	262 282	250 000	14
Tyrol before the Peace Treaty	400 849	402 869	403 403	420 000	—	—
Tyrol after the Peace Treaty	—	—	—	269 927	251 998	6
Vorarlberg	80 202	88 810	92 832	98 898	92 827	6

As is shown by Table II, the decrease in milch cows is still more serious than that in other cattle.

Table II. — *Head of milch cows in the Austrian Empire in 1910 and 1913.*

Region	1910	1913	Decrease between 1910 and 1913
Lower Austria	548 964	534 009	27 %
Upper Austria	576 599	557 041	27
Salzburg	90 134	89 598	20
Styria (reduced)	305 625	270 692	27
Carinthia	84 321	76 980	9
Tyrol (reduced)	89 980	88 889	1
Vorarlberg	51 896	49 478	10

This decrease in the number of cattle is due to different causes. Before the war, cattle-breeding was hindered by frequent epidemics of epizootic aphthic fever and by the spread of contagious abortion. The high price of cereals caused these crops to be more extensively cultivated, whereas the low price of milk discouraged milk production. The increasing use of fertilisers made cattle-rearing appear superfluous from the point of view of manure-supply, and caused horses to be substituted for draught-cattle. In many farms, the cattle were replaced by pigs, the latter being thriftier and more prolific. A large number of high mountain pastures were bought by hunters who replanted them with trees and kept them for hunting-preserves. (See H. KALLBRUNNER: The Decrease of Small Rural Holdings and the Legislation for the Control of this Phenomenon in Austria. *International Institute of Agriculture. Monthly Bulletin of Economic and Social Intelligence*, April 1920).

As a rule, however, it was only the number of cattle that decreased, and not their quality. There was, indeed, an increase in live-weight and milk production; therefore, the diminution in the number of head would not in itself have been sufficient to render it difficult to supply Austria with milk. On comparing Austria with Switzerland, it can be seen how little the number of head of cattle had to do with the matter. Even when the number of cattle was at its lowest (in 1918), there were more of cattle per 1000 inhabitants in Austria than in Switzerland, viz. 333 as against 326 (See DURIG: "Zum Ernährungsproblem Oesterreichs" in *Wiener Klinische Wochenschrift*, Parts 17 et seq., 1920).

The conditions created by the war which influenced the number of cattle in a decisive manner, as well as those indirect influences we have just mentioned, were of totally different character. In the first place, the scarcity of food due to the increasingly severe blockade, drove cattle-owners to slaughter a much larger number of animals for their own consumption. Further, large quantities of hay and forage-straw were requisitioned for military purposes, and bran could only be bought in small quantities and that was of inferior quality. Other concentrated foods that had formerly been used in all the farms often in considerable quantities, were not do be found, or only to be obtained in very limited amounts; in fact, the breweries that formerly furnished malt and brewer's grains were themselves without barley while no raw material from abroad arrived at the oil-factories. The cultivation of sugar-beets diminished rapidly and this entailed the decrease of pulp and molasses, both of which had previously formed an excellent and much appreciated feed for milch cows. The diminished and ill-nourished stock produced less manure, and the small quantity obtainable was employed solely for the fields, none remaining for the meadows and pastures. Again, as the scanty store of fertilisers was also reserved for the fields, the forage crops suffered from the lack of nutritive substances, and their yields were very low. In addition, bad weather prevailed throughout the war. As a rule, the weather was dry during the vegetation period of forage crops, which prevented them from developing properly and when the time for cutting

arrived, the rain damaged the hay, often entirely spoiling it. As most of the men between 17 and 50 had joined the colours, labour was lacking everywhere; this was all the more serious because milking-machines and many other machines used in the dairy industry were almost unknown in Austria, and the old-fashioned construction of the cattle-sheds permitted of no labour saving devices. In a large part of Austria, the cattle are all stall-fed, so that labourers are required to cut, load, transport and distribute all the forage used. Ensilage so common in North America, is hardly known in Austria. Beetroot pulp and crowns, which are the only feeds preserved in heaps, are not ensilaged, but put into pits, which is perhaps less practical from the labour point of view. Lack of labour also prevented the regular supervision of the meadows and forage crops, and of the drainage ditches, so that the forage suffered both in quality, and quantity.

All these circumstances rendered cattle rearing very difficult in every respect. The great hindrance in the development of this industry was, however, the military requisition of beef cattle. When the stock of these animals was exhausted, it became necessary to fall back upon young animals, and later even upon milch cows. The cattle owners sacrificed their cows in order to fulfil their obligations, though this was contrary to the orders of the military authorities.

Before the war, Vienna was almost entirely supplied with meat by Hungary, only a small quantity coming from Galicia, while the amount furnished by regions which constitute the present Austria, was very little. In 1913, Austria and Galicia only provided 45 896 animals towards the consumption of Vienna which amounted to between 4200 and 5000 head of cattle weekly (see "Statistik der Gemeinde Wien, für das Jahr 1913" Vienna, 1915, and Dr. MESSNER, "Die Viehproduktion und die Fleischversorgung in Oesterreich-Ungarn", Munich, 1915). During the war, Hungary almost entirely suspended her consignments of cattle. None could be supplied by Galicia, which for years was the theatre of the war. It therefore devolved upon the Alpine districts (in addition to their other obligations towards the military authorities) to supply Vienna with the necessary quantity of meat. This could only be done by greatly lowering the quality of the beef cattle, and by cutting down the meat ration per inhabitant to a considerable extent. According to the *Wirtschaftsgeographische Karten und Abhandlung zur Wirtschaftskunde der Länder der ehemaligen osterreichisch-ungarischen Monarchie*, Vienna, 1919, the average weight of beef cattle in 1919 was 120 kg., as against 250 kg., before the war, and the weekly meat consumption per head was 0.125 kg., instead of 1.54 kg. In the three summer months of 1920, the cattle sent to Vienna amounted to only 8918 animals from Lower Austria. Many animals slaughtered scarcely weighed 80 kg.

All these consignments of cattle had consequences that were all the more serious seeing that, owing to agricultural conditions, it was impossible to raise calves to make up the depleted herds. In Lower Austria, out of 100 stock owners 35.8 possessed but one or two head of

cattle, and had neither the land nor the means necessary for rearing calves.

The handing over of the milch cows, in accordance with the provisions of the Treaty of St. Germains, was a particularly serious blow to agriculture.

The feeding conditions had become worse, *pari passu* with the decrease in the number of cows, which had fallen a little more since the census of 1918 ; this can easily be understood after all that has been said regarding forage production, and consequently the milk yield was affected, although the farmers tried to consign the inferior animals and retain the good milkers.

To the author's knowledge, the milk production has fallen to at least half the usual amount in all dairy-farms.

The following, data, taken from the books of a large and well-managed establishment, may serve as an instance :—

1913-1914	2 880	litres of milk
1914-1915	2 686	» »
1915-1916	2 188	» »
1916-1917	2 393	» »
1917-1918	1 878	» »
1918-1919	1 324	» »

(These data refer to all the cows, and therefore include cows not in milk and young heifers).

This decrease in milk production is observable even where the most scientific and modern methods of cattle breeding are adopted, and where only pedigree cows are kept, the inferior animals being rejected. According to the *Jahresbericht für das Jahr* 1918, the average annual milk yield of the cows under the supervision of the " Verband der Murbodner-Murztaler Viehzuchtgenossenschaften in Steiermark " from 1910-1918 was as follows :

Years	Milk	Fat content of milk	Butter
	kg.	Per cent.	kg.
1910	1897	4.04	83.66
1911	1957	3.95	84.75
1912	2053	4.02	90.16
1913	2097	4.05	92.80
1914	2215	4.03	97.56
1915	2238	4.03	98.50
1916	2232	3.94	95.98
1917	2152	4.01	94.26
1918	2181	3.93	93.56

The highest milk yield of any cow under the supervision of the above-mentioned association was :—

In 1914	. . . . .	5 356 kg.
» 1916	. . . . .	4 615 »
» 1917	. . . . .	4 580 »
» 1918	. . . . .	4 487 »

This shows the bad effect of poor feeding upon the milk production, even of the best milch cows. M. Stockler, Secretary of State for Agriculture, considers that the average milk yield of a cow has fallen from 15 to 6 litres ("Sitzung des österreichischen Nationalrates vom Mai, 1920"). M. Löwenfeld-Russ, Secretary of State for Food (see also his work entitled *Ernährungswirtschaftliche Gegenwartsprobleme*, Vienna, 1920), estimates that the total milk production of the 915 327 cows possessed by Austria is only 11 487 000 quintals per annum, a miserable amount when compared with the Swiss milk yield in the same year. In fact, in M. Schneider's work *Darstellung über Erzeugung und Verbrauch von Nahrwerten in der Schweiz*, published in 1917, the annual milk yield of the 739 922 cows possessed by Switzerland is estimated at 24 705 000 quintals; this high figure is primarily due to the excellent system of breeding and cattle-management that has been practised for centuries.

To sum up. it can be said that the farmer obtains much less milk from his reduced number of cows, of which the yield has considerably diminished, than he could count upon if the sheds were full of animals. At the same time, his household consumption of milk has risen, owing to the difficulty, and sometimes even the impossibility of procuring other food. The stock-owner also eats much more butter than formerly, when his pigs were fed on good concentrated food and produced more fat than they do to-day. Owing to the scarcity of other suitable food, the calves and other young stock are given more milk than before, so that there is much less milk on the market, and the dairies receive scarcely $^1/_{10}$ of the amount sent to them previous to 1914.

It should further be added that neighbouring countries, which formerly sent their surplus milk (about 300 000 litres per day) to Vienna, have prohibited the export of this commodity, which shows how serious a problem the milk supply of that city has now become. Whereas, before 1914, Vienna, with 2 million inhabitants received on an average 900 000 litres of milk daily, during the winter 1919-1920, it only received 60 000, and in April, 1920, before green forage was used, only 30 000 litres (according to information furnished by the "Milchwirtschaftstelle der Stadt Wien". Similar or even worse conditions also exist in some provincial towns and industrial centres.

In spite of the reduced amount of milk, the expenses of the industry have not diminished but increased, owing to the higher salaries and wages of the employees and labourers, and the greater cost of the upkeep of buildings and of the feeding of draught animals. This increased

outlay, together with the high prices of food-stuffs and raw material, has contributed to the extraordinary rise in the price of milk.

1152 – **A Comparison Between Sheep-Breeding and Cattle-Breeding.** — Govin, R., in the *Journal d'Agriculture pratique*, Year LXXXIV, No. 42, pp. 309-310. Paris, October, 14, 1920. SHEEP

The author proposes to see, when sheep or cattle are kept under similar conditions, which of them pays best for the forage consumed, He leaves out of the question sheep living under conditions suited to them alone such as on waste land, stubble, the poor pastures of arid regions, or on steep slopes.

Whereas in the case of other animals their wants increase as their bodies grow, the sheep needs less as its body surface becomes larger. An ox 500 kg., in weight, requires when doing no work, sufficient food to supply 11 500 calories ; the surface of its body being about 6 sq. m., this means 1916 calories per sq. m. ; 10 sheep of 50 kg., also representing 500 kg., of live weight, only need 15 000 calories, or 1153 per sq.m.; which is about 60 % less per surface unit than the ox.

The maintenance of 500 kg. of sheep requires food producing 3 500 calories more than is needed for the support of 500 kg. of ox.

Thus, the cost price of mutton is very considerably higher than that of beef. What is necessary is, that it should fetch a higher price that is in proportion to its cost ; this proportion is :—

$$\frac{\text{cattle}}{\text{sheep}} = \frac{11\,500}{15\,000} = \frac{77}{100}$$

Before the war, the current prices per kg., of live weight were :

$$\frac{\text{cattle } 0.75 \text{ fr}}{\text{sheep } 1.20 \text{ fr.}} = \frac{62.5}{100}$$

It paid better to feed cattle. The extreme and average prices at the markets of La Villette in October, 1920, were :—

$$\frac{2.75}{4.40} = \frac{62.3}{100} \qquad \frac{4.10}{5.70} = \frac{74}{100} \qquad \frac{5.43}{6.96} = \frac{78}{100}$$

To this must be added the profit from the sale of the wool.

It appears from these figures that it is quality that pays, and this is found in the ox, which was produced on the pasture or on the farm with the same food as fed to sheep. In this comparison, the lowest prices need not be taken into consideration, for these are only paid for sheep to be exported, or for those that eat forage which is of no use to cattle.

1153 – **The Decline in Sheep Breeding**— Rew, Sir H. in *The Journal of the Ministry of Agriculture*, Vol. XXVII, No. 5, pp. 450-455. London, August 1920.

The author deals with this subject from the point of view of statistical facts and economic tendencies and not from the practical standpoint.

The annual returns summarised in quinquennial periods show that the total stock of sheep in Great Britain has varied as follows, the numbers representing millions :— 1870-74, 28.6 ; 1875-79, 28.4 ; 1880-84, 25.3 ; 1885-89, 25.8 ; 1890-94, 27.6 ; 1895-99, 26.6 ; 1900-04, 25.9 ; 1905-09, 26 3 ; 1910-14, 25.4 ; 1915-19, 23.7. This indicates the substantial fall during the present century, quite apart from the war period which is considered later. It should however be noted that the age at which sheep are slaughtered is on the average now considerably less than it was fifty years ago and it is evident that with the progressive adoption of this principle the number of sheep returned each year would decrease even though the actual number bred were maintained. This is obvious from the records of the average numbers of ewes returned during the past 25 years, in millions : 1895-99, 10.0 ; 1900-04, 10.1 ; 1905-09, 10.3 ; 1910-14, 10.1 ; and 1915-19, 9.6.

A comparison is then made between the pre-war position and the succeeding years up to 1919 of the total number of ewes and other sheep, the figures again representing millions : 1914, 24.3 ; 1915, 24.6 ; 1916, 25.0 ; 1917, 24.0 ; 1918, 23.4 ; 1919, 21.5.

There are three factors to which the recent decline of sheep breeding has been attributed : 1) Special economic conditions ; 2) control of prices, distribution and sale by the State ; 3) extension of arable cultivation.

With regard to the first, this naturally ensued owing to shortage of labour and increased cost of feeding stuffs, but it was in 1917 that the other factors were intoduced. The author states that if the State chose to take over the management of all the flocks, with all that this implies it could then determine regardless of economic considerations, how many ewes should be put to the ram each year, and thus control production. Otherwise the control of prices and of distribution must finally reduce the number of sheep kept.

While the cost of production increased on arable land to a much greater extent than on grass land, the arable sheep farmer was prevented from obtaining the higher prices for the lamb and mutton produced which would have been fetched in a free market. But, if the importance of extending the arable area and increasing the production of cereals is recognised, it should also be recognised that one of the means which will assist in securing that end is to ensure that confidence be restored to the sheep breeding interest which has for so long been the mainstay of British agriculture

1154 – **Sheep in Tunisia.**— *Comptes Rendus de l'Académie d'Agriculture de France*, Vol. VI, No. 29, pp. 710-711. Paris, October, 13, 1920.

The Minister of Foreign Affairs communicates a report made by the Resident-General in Tunisia upon the measures adopted in the Protectorate for the encouragement of sheep-breeding.

On various occasions, Shows have been organised, with prizes in kind for the exhibitors of the best flocks of sheep for breeding purposes. In addition a model sheep-farm has been established at the Sidi-Tabet Stud

Station, for rearing pure-bred sheep of the Chatillonnais Merino, the Arles or Crau Merinos, and thin-tailed Algerian breeds. These animals will be ceded to French or native breeders, with a view to propagating the breeds of sheep most adapted to the soil and climate of the different regions. The General Directorate of Agriculture likewise proposes to establish sheep-breeding stations in the best sheep-rearing districts, and when necessary to make an appeal for assistance to private owners of large estates.

Finally, grants of land have been made in Tunisia to persons undertaking to keep sheep upon it. They are also required to construct shelters for their flocks, and to dig wells, in order to ensure a sufficient supply of water.

1155 – **Sheep Raising in Ontario, Canada.** — TOOLE, W., and SACKVILLE, J. P., in *Ontario Department of Agriculture, Ontario Agricultural College, Bulletin* 274, pp. 1-56. Toronto November, 1919.

The number of sheep in the Province of Ontario in 1911 amounted to 1 046 456 ; in 1911 the number was reduced to 742 188. During the War period, owing to the enhanced prices for wool and mutton, the number increased to 972 341. A general classification of the breeds is made according to fleece, the two classes being known as the *medium wool* and the *coarse* or *long wool* breeds. In Class I is included : Shropshire, Southdown, Oxford Down, Hampshire, Suffolk, Dorset Horn and Cheviot ; in Class II : Leicester, Lincoln, Cotswold and Romney Marsh.

It is absolutely essential to maintain a good pure-bred sire which should possess all the best characteristics combined with proper type and conformation. In addition to this the ram should possess abundance of vigour and vitality. The fleece will depend on the particular breed to which he belongs, but in all breeds, the density, and quality and length should be taken into consideration. In selecting a ram preference is often given to a twin, hoping by this means to obtain further twins. There is considerable difference regarding the age at which a ram should start breeding. In any case, flocks ranging from 6 to 20 will give satisfactory results provided they are judiciously handled, but a mature ram will care for a flock of from 40 to 50 ewes.

The rams should be kept in good vigorous condition at all times of year. A short time before the breeding season, it is advisable to give a light feed of grain once per day, and a supplement of ration consisting of 2 parts oats + 1 part bran can safely be fed at the rate of 1 to 3 lb., per day per ram. The rams may mix with the ewes during the day time, but must be separated at night.

The ewes should also be selected with care, and should show all the desirable characteristics, of fulness of form, strength and vigour, combined with feminine character. Those with broken mouths, defective udders should be discarded, and those retained should receive good care, so that when the breeding season comes they are in good condition and will give birth to lambs in a vigorous way.

The feeds will consist in concentrates, roughage and silage, roots and pasture grass. The concentrates which give the best results are: maize, gluten feed, wheat (not often used owing to high cost), wheat bran, oats, oat hulls, bran etc., the following are also equally useful, but are given in smaller quantities :— barley, brewer's grains, malt sprouts, rye, millet, buckwheat, cottonseed meal, linseed meal, peas, beans, tankage, etc. ; alfalfa and red clover are the two best roughage feeds. Maize silage is quite commonly fed. Pastures containing red clover, alfalfa and rape are the most satisfactory.

The main feature in housing sheep during the winter is that their quarters should be dry, and free from draught. As the ewes must have plenty of exercise, a large yard should surround the pen. It is good policy to make as much use as possible of the cheaper, more bulky feeds. Dry roughage in the winter, green forage in the spring and summer, prove satisfactory. For a regular summer pasture, it is advisable that sheep should be kept on land that is comparatively high and dry. Rape has always been regarded as an excellent pasture. When the pasture becomes very short and dry, lambs will doubtless make good use of a light grain ration. The lambs should be separated from the ewes when between 4 and 5 months old. A rape pasture makes an ideal pasture for lambs after weaning.

Spring dipping is practised as a general rule immediately after shearing, and again in the autumn. In order to keep the flock in healthy vigorous condition, and obtain good quality wool, it is important that they should be kept free from ticks and lice.

In order to obtain quantity and quality as regards wool, it is essential that the flock be maintained throughout the year in good condition. A good growth of wool depends entirely on adequate nourishment and management in general. Wool produced during a period of sickness or low condition of the sheep is bound to be weak in fibre.

1156 - **Bureau of Animal Industry Range Sheep Experiments.** — MARSHALL, F. R. in the *National Wool Grower*, Vol. VII, No. 1, pp. 35-36, 1917 ; Vol. VIII, No. 1, pp. 35-37, 1918 ; Vol. X, No. 1, pp. 17-19, 1920 ; abstract in *Experiment Station Record*, Vol. XLII, No. 9, pp. 868-869. Washington, D. C., 1920.

I. — BUREAU OF ANIMAL INDUSTRY RANGE SHEEP EXPERIMENT. — A brief summary of some records of the experimental work with range sheep conducted by the U. S. Department of Agriculture at Laramie, Wyoming.

During the years 1910 to 1915, 72.8 % of the yearling ewes lambed, and of these 86.5 lambed again as two-year-olds. Of the ewes which did not lamb as yearlings 88.8 % had lambs the following year.

For three successive years a lot of 17 ewes were hand-shorn and a similar lot machine-shorn, and for two years another lot of 12 were hand-shorn and a similar lot machine-shorn. The records indicated that after two years, fleeces of sheep shorn by machine had increased in weight over the hand-shorn fleeces to an extent, which, in the author's opinion, can not be attributed entirely to closer shearing. Two years' records also

showed heavier fleeces from folded than from plain-wool sheep, but the wool was longer in the latter fleeces.

II. — SOME EXPERIENCES IN BREEDING RANGE SHEEP. — Tables are presented showing the relation of fineness of wool in Rambouillet ewes to grease weight of fleece and length of wool, based on records secured by the Bureau of Animal Industry of the U. S. Department of Agriculture at Laramie, Wyo., in 1915 and 1916. It is also noted that the percentage of lambs produced was higher and the proportion stillborn or dead within a week was lower in the case of the Lincoln × Merino crossbreds than in the case of pure bred Rambouillets and Corriedales.

RESULTS OF EXPERIMENTS WITH CROSSBRED RANGE SHEEP. — Results secured by the Bureau of Animal Industry of the U. S. Department of Agriculture since the transfer of the sheep experiments to Dubois, Idaho, in 1917, are summarized.

The F_3 generation of the Lincoln × Rambouillet cross form a desirable and fairly uniform strain for which the name Columbia is proposed. Each generation is mated inter se. It is thought that after a few more generations the Columbias will be entitled to consideration as a distinct breed.

1157 – **Open air Pig-Keeping.** — *The Journal of the Ministry of Agriculture*, Vol. XXVII No. 5, pp. 456-457, figs. 2 London, August, 1920. PIGS

Open air pig keeping has been successfully carried out in England on poor London clay which had been allowed to fall into bad condition, and was not capable of raising good crops. The animals are penned with iron hurdles or chestnut pales and it is found that 1 acre will carry 10 pigs for 6 months. These are treated like sheep and after the necessary preliminaries, are allowed to fallow unattended. Breeding is arranged to suit the weather and so that the sows farrow in January and July. For sows with a litter, 7lb., per day of concentrated food is the maximum allowance. The ration consists of the following mixture %: — fish meal 10; barley meal 28; middlings 20; palm kernel meal 40; maize germ meal 10.

No ringing is practised and the pigs are not fed before being turned out. Pigs born in midsummer 1919 were wintered on rape and given 4 lb., per head daily of the mixed meal and a fresh fold of rape every third day. In February they were put into an orchard and given an extra ration of 2 lb., of beans every week and in March, run wild over young wheat and winter peas and fed at midday with the 4 lb., ration as above. In April and May they were folded on rye, with possible necessary additions of peas or beans, but never exceeding the 7 lb., limit.

Catch crops are raised throughout the year, and rape, kale and clover are found the most useful in preference to rye and tares. It is claimed that pigs graze more closely than sheep. Many 5 months old gilts folded on rape and clover with a 3 lb., daily ration, are fat enough to kill. The early January gilts farrow when 13 months old. There have been no cases of tubercle, and no deaths in farrowing. Ordinary winter weather has had no bad effects.

One of the most important effects is the beneficial effect on the land. In this particular case the whole of the agricultural position has greatly improved and heavy crops of corn are grown where it was before impossible.

1158 – **Winter Rations for Brood Sows.** — Robison, W. L., in *Monthly Bulletin of the Ohio Agricultural Experiment Station*, Vol. IV, No. 12, pp. 363-368, figs. 2. Wooster, Ohio, 1919.

Three experiments are reported involving comparisons of supplements to maize and legume hay as winter rations for pregnant sows. They were begun in December, 1915, January, 1918, and January, 1919, respectively, and each sow was continued on the experimental rations until she farrowed. The combined result (including those from 3 lots, one fed on tankage, another linseed meal, the third skin milk and the last oats) are summarized as follows :—

Comparison of supplements to rations for brood sows.

Supplement	Number of sows	Daily ration			Weight per sow		Daily gain per sow	Pigs per litter	Average birth weight per pig	Daily cost of rations	
		Ground corn	Supplement	Legume hay	Initial	Final				Gross	Net *
		lb.	lb.	lb.	lb.	lb.	lb.		lb.	cents.	cents
Bone	14	4.02	—	2.55	398.7	450.0	0.60	12.6	2.27	12.6	9.2
Tankage	37	3.75	0.31	2.55	391.9	457.4	0.84	11.9	2.24	13.6	7.3
Linseed Meal	7	5.24	0.37	1.53	398.9	479.8	0.87	10.2	2.45	16.1	8.4
Skim milk	15	4.23	10.14	1.87	405.6	496.2	1.22	11.0	2.31	18.5	7.3
Oats	7	2.47	2.47	1.54	437.7	504.7	0.85	11.6	2.29	13.3	7.0

* Gross cost less value of daily gains at 12 cts a pound.

Maize was charged at 2.5 cents a lb., oats at 2.25 cents a lb., skim milk at 60 cents per 100 lb., linseed meal at $80 a ton, tankage at $110 a ton, and hay at $ 20 a ton.

The author holds that sows should gain in body weight during gestation, and points out that seemingly expensive rations may in reality be cheap if credit is given for gains. It is also noted that oats when low in price with respect to maize may be used as a partial substitute for the latter.

POULTRY

1159 – **The Economic Position of the Poultry Industry.** — Brown, E., in *The Journal of the Ministry of Agriculture*, Vol. XXVII, No. 5, pp. 458-462. London, August, 1920.

The main factors in the increased prices of eggs and poultry in England, especially the former, are the great decrease of imported supplies. The following Table prepared from figures given in the Trade and Navigation Returns of the Board of Trade, demonstrates this fact :—

Country	Eggs in Thousands of Gt. Hundreds *		Poultry, dead. cwt.	
	1913	1919	1913	1919
Russia	11 453	—	119 944	8
Denmark	4 265	1 638	—	—
Germany	514	—	—	—
Netherlands	977	—	—	—
France	702	6	31 175	3 083
Italy	846	—	—	—
Austria–Hungary	884	—	26 674	—
U. S. A.	6	1 409	54 242	100 512
Egypt	1 096	759	—	—
Canada	2	1 477	—	—
Other Countries	835	355	46 430	43 964
Total	21 580	5 644	278 465	147 567
Decrease per cent.	73.8		47.0	

* Great hundred of eggs.

The three countries which have sent the greatest volume of supplies since 1914 are Egypt, Canada, and the United States. As far as can be anticipated, imports from the two first will continue unless prices fall very heavily but it is unlikely that the same quantity will be received from America. As the imports from all three in 1919 only represented 17 % of the total imports of 1913, they do not present a serious factor in competition with the home market. Before the war 56 eggs per head of the population were imported, while in 1918 and 1919 the imports were respectively 7 and 14 eggs per head. This indicates not only the imperative need for production to meet the shortage of imported supplies, but also to provide for an anticipated increased demand. In the opinion of the author, an increase of about one and one-third of the total number of adult fowls would make up for the reduction in imports. Extension of production is advocated on an open range where the costs of feeding and equipment are comparatively low One of the effects of the war has been to stabilise commercial poultry farming for egg production and economically this aspect of the industry is one of the most promising and has encouraged the idea also of domestic poultry keeping. The high prices obtainable for stock may be held to have considerably strengthened the position of breeding farms.

There is, however, a comparative lack of knowledge and a need for extension and development of scientific experimental work and inquiry into the causes of and prevention of diseases. Efficient training and instruction among the rural population is very much needed, and the proposed National Poultry Institute should be worked on these lines.

1160 – **The Bourbonnais Fowl.** — BRECHEMIN, L., in the *Journal d'Agriculture pratique*, Year LXXXIV, No. 42, pp. 314-315, plate, 1. Paris, October 14, 1920.

This hardy breed, which is well suited to the country, does not thrive in small runs, but does well if it has a fairly extensive range. It made a tentative appearance at poultry-shows previous to the war, but attracted little attention. At the last Show of the Central Society of Aviculture in Paris (held at the Grand Palais), it was awarded the prize of honour.

The Bourbonnais fowl, as met with in very widely separated districts of France, is a white bird with ermine mantle. The Bourbourg race in the North and many of the Gâtinais fowls also have this plumage, but the actual type in question at present is especially common in the valleys of the Allier and the Loire, whence its appellation of Bourbonnais.

The Bourbonnais Club has recently fixed a standard, of which the most characteristic points are given below.

The cock should be strong, but elegant and active, not heavy ; *head* average size ; *beak* strong, white, striped or marked with black ; *eyes* lively, orange-red ; *comb* not over-developed, simple, of fine texture, very straight and detached from the beak, having 5 to 6 very regular and distinct notches ; *ear lobes* medium-sized and red ; *wattles* average, fine in texture ; *neck* is well-proportioned to the back, which is long and broad ; *chest* broad and deep ; *wings* not over-developed, but strong ; *legs* powerful, free from the body ; lower part of leg rather long of pinkish-white colour ; *tail* of average length forming a good continuation of the line of the back ; *toes* 4 in number and *claws* of same colours as beak.

The hen has the same characters as the cock, with the usual sexual differences, i. e., rather smaller size, comb smaller and often hanging down during the laying season.

In both sexes, the *plumage* is entirely white, except the feathers of the mantle, which are barred in the centre ; in the cock, the tail is black, with a white border on the edge of the large and median feathers. The mantle of the hen seems darker, the feathers being striped with black rather than barred ; the tail is black with some white stripes.

1161 – **Feeding Fowls on Groundnut and Palm-Oil Cakes.** — GOUIN, A., in *Journal d'Agriculture pratique*, Year 84, No. 41, pp. 296-298. Paris, October 7, 1920.

For 25 years, the author has been giving his fowls (which he keeps in a pen), cakes with a high nitrogen content, and for the last 4 years, he has fed them exclusively on this fare, consisting of $\frac{1}{3}$ groundnut cake, and $\frac{2}{3}$ palm-oil cake. The birds never get grain of any sort, the only addition ever made to the cakes being a little bone-meal. Each fowl consumes daily just under 100 gm., of the mixture, the daily ration costing 6 centimes. As 25 fowls lay on an average, 10 eggs a day, the net cost of the eggs is 15 centimes each. The quality of the eggs leaves nothing to be desired.

Further, these nitrogenous cakes make the birds grow more quickly than the other, dearer foods usually given to poultry (wheat, buckwheat, rice, bran, potatoes).

Ducks also greedily eat groundnut and palm-oil cakes, and grow very rapidly when fed on them.

1162 – **Extraordinary Early Laying of a Black Bresse Hen.** — *La Revue avicole*, Year XXX, No. 11, p. 6. Paris, November 1, 1920.

M.me M. L. BRUN, member of the Central Avicultural Society of France, mentions a case of extraordinarily early laying on the part of one of her pullets. The bird, which belonged to the black Bresse breed and was hatched on April 12, laid its first egg on July 8, that is to say, when less than 3 months old. This egg weighed 35 gm., and those the bird laid afterwards weighed as much as 37 gm. At the end of October, the fowl had already laid 52 eggs.

1163 – **Experiments in Crossing Pea-Fowl.** — BLAAUW, T. E., in the *Revue d'Histoire naturelle appliquée*, Part. II, *Ornithologie-Aviculture*, No. 2, pp. 46-48. Paris, February, 1920.

After having bred black pea-fowl (*Pavo-cristatus* var. *nigripennis* for twenty years, the author obtained a black and white male. The latter, on being mated with females of the same variety and of the usual colour, produced perfectly white peacocks and pea-hens.

When mated with a white *cristatus* female (from another brood), it produced 2 male and 2 female *cristatus* chicks. These being mated together, their offspring were nearly all ordinary *cristatus* individuals, but there was one normal *nigripennis*.

The hybrids resulting from crossing a Javan male (*P. muticus*) with a *cristatus* pea-hen showed intermediate characters. These hybrids were perfectly fertile when mated together, or with individuals of the original species. The offspring of the hybrids that had been mated together resembled their hybrid parents, and did not revert to either of the two original types.

The mating of one of these hybrid males with a white *nigripennis* female produced :—

(1) A male resembling a male *cristatus* or *nigripennis* with a small zone of brown feathers barred with black on its back similar to that found in the centre on the back of the pure Javan male, or in the young of that species.

(2) A female resembling a *cristatus* female, with the lower part of its body imperfectly pencilled. The yellow skin on the head of the Javan pea-fowl, which persists in the hybrids, had disappeared in the case of the last two birds.

The results of these experiments is, in the author's opinion, that *nigripennis* is a variety of *cristatus* due to melanism about to turn into albinism.

A cross between *cristatus* and *nigripennis* does not give any intermediate forms, but reproduces one or other of the parent forms, as occurs in crossing the white Arctic goose (*Chen hyperboreus*) with the blue species (*Chen coerulescens*).

It is however, curious that the white bird produced by *nigripennis* parents, and the white offspring produced directly by *cristatus* are not the same, judging by their descendants. The white offspring of *nigripennis*, on being crossed with *nigripennis* birds, produces white *nigripennis*, or black and white *nigripennis* individuals (the latter occur rarely). The white offspring of *cristatus*, crossed with *nigripennis* produces *cristatus* birds that, in their turn, produce *cristatus* and *nigripennis* descendants.

As the Javan pea-cock and the *cristatus* (or *nigripennis*) are two very distinct varieties, their products are intermediate, but these varieties must be very nearly related as they mate together and their offspring in all degrees are fertile.

The *muticus* and the *cristatus* (or *nigripennis*), varieties behave like the Golden Pheasant and the Amherst Pheasant.

The following table summarises the crosses made by the author :—

N ♂ . . . N ♀ . . .	N ♂ ♀	N^P ♂ N ♂ ♀
N^P ♂ . . . N ♀ . . .	N^B ♂ ♀	
N^P ♂ . . C^B ♀ . . .	C ♂ ♀	C N
S ♂ . . . C ♀ . . .	H ♂ ♀ hybrids inter-fertile and fertile with 6 and C or N	
H ♂ . . . N^B ♀ . . .	C, variety without yellow skin present in first cross H	
N^B ♂ . . N ♀ . .	B + N + N^P	
C^B ♂ . . N ♀ . . .	C	C N

Abbreviations : N = *nigripennis* — C = ordinary (*Cristatus*) — P = black and white — B = White — S = Javan pea fowl — H =hybrids.

1164 – **Cross Between a Peacock and a Fowl.** — Trouessart, E. (Professeur de Mammalogie et d'Ornithologie au Muséum d'Histoire naturelle, Paris), in the *Revue d'Histoire naturelle appliquée*, Part. II, *Ornithologie-Aviculture*, Nos. 4-5, pp. 100-102. Paris, April-May, 1920.

In 1907, the Author together with M. Pays-Mellier, presented to the Académie des Sciences, two birds, the offspring of a cross between a peacock (*P. nigripennis*) and a buff Cochin-China hen (*Pavo cristatus* var. *nigripennis* × *Gallus* var. *sinensis*). They inherited the proportion of the peacock, and like it could fly, whereas the wings of the mother were

quite useless for purposes of flight. Both the hybrids were males, and had well-developed spurs. On the whole they resembled a pea-hen, however, the only character these birds seemed to have inherited from their mother was the number of their tail-feathers, which was 14, as in the hen instead of 18, as in the case of the peacock.

1165 – **Sericulture in France and in the French Colonies** (1). — I. RANC, A., La sériculture française, in *La Nature*, No. 2411, pp. 241-344. Paris, June 19, 1920. — II. IDEM. L'industrie française de la soie et de la sériculture coloniale. *Ibid.*, No. 2422, pp. 155-159 September 4, 1920. SERICULTURE

I — According to the General Report on French Industries drawn up by the Ministry of Industry and Commerce in 1919, the condition of the French trade in silk fabrics, and articles of silk, was as follows:

Normal production	600	million	francs
Total exports	400	»	»
Imports	49	»	»
Home consumption	250	»	»

From 1750 to 1852, silk production in France was continually increasing. Starting from an average annual production of 6 600 000 kg., of cocoons during the period 1750-1780, it rose to 24 000 000 in 1846-1852 and to 26 000 000 in 1853, a date which also coincides with the great development of the spinning industry when the production attained 2 000 000 kg. of raw silk. But with the appearance on the market of Asiatic silk and the breaking out of silk-worm diseases, an irregular, but constant decrease in cocoon production set in, and this reached its lowest in 1876, when only 2 000 000 kg., was produced. A slight increase was observable in 1858-6 the figures rising to 11 000 000 kg., and this favourable turn of affairs continued in 1862-73. The first increase was due to the introduction of silk-worms from Bulgaria, Wallachia, Georgia, Armenia and the Caucasus, and the second was brought about by the practical application of measures for the control of silk-worm disease, which were based on the investigations begun by PASTEUR, in 1855, and coincided with the use of Japanese eggs, these being more resistant to pebrine.

However, although the production of resistant "seed" had developed to a considerable extent, so that in 1900, 30 000 kg., of "seed", worth 6 880 000 francs, was exported, and in spite of the importation of foreign silkworm eggs, the silk industry continued to decline. During the decade 1891-1900, the annual average was 8 458 175 kg., with a maximum of 10 584 491 kg., and a minimum of 6 883 587 kg. From 1900 to 1910, the average sank to 7 million kg., and from 1914 to 1919, the decrease was always noticeable, as is shown by the following Table:—

(1) See: *R.*, Sept. 1912, No. 1330; *R.*, Sept. 1914, No. 839; *R.*, Dec. 1914, No. 1157; *R.*, June, 1918, No. 676; *R.*, Nov. 1918, No. 1264; *R.*, Feb., 1919, No. 234; *R.*, July Sept. 1919, No. 966; *R.*, Oct.-Dec. 1919, No. 1212; *R.*, March, 1920, No. 353. (*Ed.*).

Years	Production in kg.	Value in francs
1914	5 067 000	19 908 000
1916	2 820 000	12 024 000
1918	3 010 000	22 257 000
1919	2 671 000	20 121 000

The value of the cocoons, however, has greatly increased, although there has been a great diminution in the number produced.

During the first half of the nineteenth century, cocoons only fetched from 3 fr. to 4.50 fr. per kg. The scanty supply in 1858 raised the price to 8 fr., and it remained at this level for ten years, to sink again, in recent years, to 4.25 fr., per kg., in 1916, 7.38 fr., in 1918, and 7.53 fr. in 1919.

The decrease in the number of cocoons produced of late years may be attributed to the war, but how can it be explained in times of peace? In 1913, France produced 500 000 kg., of raw silk, and consumed 5 109 000 out of the 7 545 000 kg., imported. The large demand and the small supply should have increased the price of cocoons. The latter, on the contrary, fell, owing to the introduction of Asiatic silk on the market. This Eastern influence was especially manifested by the importation of raw silk produced in the Far East by factories that employed European methods. To such a large extent was this foreign silk used that, whereas in 1875 there were 27 250 reeling basins, in 1888 there were only 10 300. Further, the following figures, giving the amount of cocoons imported, show the decrease in the work:—

Years	Weights of imported cocoons
	kg.
1897	1 201 541
1901	366 582
1905	182 502
1906	685 114

In 1913, the import of cocoons rose to 464 900 kg., supplied by Turkey, Russia, Spain and the French Colonies. If, however, hopes may be entertained that the spinning industry will improve, there is little chance of improvement in sericulture.

The following Table shows that the latter continues to decline.

The high prices (107 to 110 fr.) paid last April at Marseilles for picked cocoons from the East suggest that the industry will recover, for it is anticipated that the native cocoons of next season will fetch 15 to 20 fr., per kg.

It must not be forgotten that sericulture is an industry that is only possible where labour is cheap. For this reason, it ought to form one of the occupations of the colonies, which would send the raw material to Paris.

Years	Number of silk-worm rearers	silk-worm eggs put to incubate (ounces of 25 grammes)
1902	128 000	—
1904	125 244	—
1908	123 804	187 073
1912	99 000	—
1914	83 525	108 943
1916	52 758	61 765
1918	60 057	67 136
1919	52 041	—

II. — The condition of the French silk industry at the present time is characterised by :— (1) The decadence of national sericulture ; this seems irremediable, given the great cost of labour ; (2) the stagnation at the reeling-basins, which threatens to stop the importation of colonial cocoons ; (3) the important position assumed by Japan and the United States on the world's silk markets ; (4) the decrease in raw materials.

The statistics of raw-silk production show how greatly it has increased in the Far East.

Four year averages of raw silk production in kg.

Years	Western Europe	East and central Asia	Far-East	Total
1871–1875	3 676 000	676 000	5 194 000	9 546 000
1876–1880	2 475 000	639 000	5 740 000	8 854 000
1881–1885	3 630 000	700 000	5 108 000	9 438 000
1886–1890	4 340 000	738 000	6 522 000	11 600 000
1891–1895	5 518 000	1 107 000	8 670 000	15 295 000
1896–1900	5 220 000	1 552 000	10 281 000	17 053 000
1901–1905	5 312 000	2 304 000	11 476 000	19 092 000
1906–1910	5 459 000	2 836 000	15 917 000	23 212 000
1911–1914	4 619 000	2 419 000	18 076 000	25 114 000

In 1913, production reached its maximum with 27 320 000 kg., but at once began to decrease, being only 23 665 000 kg., in 1915. The following Table, which gives the production of the various countries for the last 3 years clearly shows the great superiority of Japan.

Buyers in the United States are considerably increasing their purchases on the markets of Japan, Shanghai and Canton, which has the effect of continually raising the prices.

Country	1917 kg.	1918 kg.	1919 kg.
France	205 000	240 000	185 000
Italy	2 820 000	2 695 000	1 185 000
Spain	70 000	75 000	70 000
Austria	85 000	85 000	75 000
Hungary	65 000	65 000	50 000
Europe	**3 245 000**	**3 160 000**	**2 230 000**
East and Central Asia	**1 040 000**	**1 040 000**	**800 000**
China (Shanghai)	4 580 000	4 871 000	3 900 000
China (Canton)	2 345 000	1 650 000	2 300 000
Japan	15 445 000	14 655 000	14 600 000
India	105 000	110 000	100 000
Indo-China	5 000	5 000	5 000
Far East	**22 480 000**	**21 291 000**	**20 905 000**
GENERAL TOTAL	**26 765 000**	**25 431 000**	**23 935 000**

The following statistics show the decrease in the amount of raw silk imported into France from China and Japan from 1913 to 1919 :

	1913	1917	1918	1919
China	3 623 000	2 893 900	1 952 400	2 822 600
Japan	1 577 000	1 444 900	2 145 500	1 081 000

In addition, the amount of silk purchased by America from France in 1918 was reduced by 40 500 000 fr.

Both these facts indicate that France should endeavour to obtain the raw material from her colonies, especially from Morocco and Indo-China.

In Morocco, the silk-industry was in a flourishing condition from the tenth to the thirteenth century, but the competition of European products and silkworm diseases (especially pebrine, which made its appearance in 1850) greatly reduced it. Nevertheless, ten thousand workers are still employed in the industry, which is of considerable importance even now. They are engaged in working up Spanish-Morocco products. The factories use imported raw material ; from 1910 to 1916, the amount of raw silk imported reached 114 600 kg., of which $^4/_5$ came from France.

The propaganda for the encouragement of silkworm rearing dates from

1914, and includes: The distribution ofdifferent varieties of silk-worm eggs; supervising and popularising silkworm breeding; the purchase of the products obtained, and in addition, the plantation of mulberry trees, of which there are large numbers at Meknès and Rabat.

The following Table gives the results obtained for the first 4 years :—

Years	Number of breeders	Quantity of silkworm eggs, in ounces	Weight of cocoons in kg.	Average yield % per ounce	Observations
1914. . . .	—	—	402	—	Trial brood
1915. . . .	12	50	1349	27	—
1916. . . .	38	44	815	18.5	Disease (Pebrine)
1917. . . .	108	51	1149	22.5	Disease (Muscardine, flacherie)

From the experience of these 4 years, it was found that selected; "seed" should always be imported in the autumn; by the use of incubators, the silkworms hatch out quickly, making their appearance in April just when the mulberry leaves began to unfold.

It was also discovered that there was a great lack of hygiene on the part of the natives. Therefore, the best plan is to produce cocoons in Morocco and send the finest to supply the French factories, reserving the remainder for the native industry.

The problem is simplest in Indo-China, where it is not a question of resuscitating a dead industry, but of improving and organising one that already exists. Tonkin, Annam, Cochin-China and Cambodia could supply France with large quantities of raw material, specially Cambodia, where the climate is warm and sufficiently dry, the soil is fertile, and the inhabitants' skill in silkworm-rearing is well-known.

In 1905, the French Administration furnished silkworm eggs selected according to Pasteur's method. At Phu-lang-Thuong, an establishment for the production of eggs was founded and popular leaflets were distributed. The excellent results of this propaganda led to the foundation of new types of silkworm-breeding establishments and the founding of 2 silk-worm egg-supplying centres at Bach-hat and Kienau (Tonkin) which were chiefly engaged in the selection of native breeds while a sericultural research station was added at Phu-lang-Thuong.

Cochin-China, Annam and Cambodia followed the example of Tonkin.

The reeling-basins were also altered in order to obtain silk of a better quality, and steam spinning mills were established. Owing to the private initiative of French companies, the matter has been taken up successfully, with a great advantage to France, as can easily be imagined.

The following data give the exports of silk from Indo-China:

		France Metric tons	Foreign countries Metric tons	Total Metric tons
1912	Raw silk	16	86	102
	Waste »	83	4	90
	Floss	2	3	2
		101	**93**	**194**
1911	Raw silk	40	59	99
	Waste »	69	—	69
	Floss	2	—	2
		111	**59**	**170**
1913	Raw silk	17	76	93
	Waste »	71	—	71
	Floss	3	—	3
		91	**76**	**167**
1914	Raw silk	11	37	48
	Waste »	42	—	42
	Floss	—	—	—
		53	**37**	**90**
1915	Raw silk	20	35	53
1916	Raw silk	7	25	32

1166 – **The Results of Experiments in Breeding Japanese Bivoltins in Italy.** — CAMPBELL, C., in *Il Coltivatore*, Year LXVI, No. 25, pp. 616-618. Casale Monferrato September 10, 1920.

During the silkworm season of 1919, the author carried out, at Cassino (Province of Caserta), the first experiments with Japanese bivoltins introduced into Italy by the Sericultural Institute of the " R. Scuola Superiore di Agricoltura " at Portici (Naples), using the " Nipponnishiki " breed.

Most of the eggs hatched out quite regularly, but as is characteristic with bivoltin races, some of the eggs did not hatch at all. In the first stages, the larvae proved very strong and moulted at the right times. They differed greatly both in their development and the pigmentation of their skin as well as in the distinctness of the crescent-shaped marks on the 5th and 6th segments, which were scarcely visible in some of the insects, and very clear in others. Further, some of the larvae were more or less gibbous. The latter, which according to QUAJAT, belonged to the Chinese breed " Pai-pi-lung-chiao-tsan ," were isolated, in order to study their offspring.

The pupation of the larvae was not very regular, for after the second moult, there was a certain difference in size between the caterpillars of each

brood. The cocoons also were not very uniform, either in size, or shape; some of them were very much constricted, in others the constriction was scarcely noticeable, while in a certain number, it was entirely absent. Though most of the cocoons were white, others were of a golden yellow of different shades; they also varied in shape; these last were kept apart for isolated breeding.

During the season of 1920, two small rearing experiments were made with the eggs of moths from the gibbous caterpillars and those laid by moths from the yellow cocoon.

Not all the eggs of these two lots hatched out. Sometimes the larva developed completely within the egg, but it never emerged, and why it did not do so, the author is unable to say with any certainty. He reared two lots of the silkworms that did hatch out; they developed quite regularly until pupation, without any visible sign of disease.

In the group of gibbous larvae, this character did not occur in all the individuals, and when present was not always equally distinct. The cocoons of this group were all white and fairly uniform as to shape and size.

The lot of caterpillars from the yellow cocoons all produced yellow cocoons varying in shape and size, like the cocoons from which they originated.

None of the eggs laid by the two groups in 1920 hatched out. They were yellow when laid, but quickly changed to the ashen colour characteristic of annual breeds. The bivoltin character was evidently lost, or was not natural to the isolated forms.

The observation of the Japanese bivoltins reared in the district of Caserta, and especially his investigations on a special brood, enabled the author to state that the character of gibbosity, which is so clear in the last stages, only occurred in a minimum proportion of the larvae, and was little accentuated. There was greater uniformity in the characters of the silk worms than that he had found in the brood reared the preceding year. On the other hand, there were many larvae that moulted 5 times. In the case of these individuals, although they had hatched out at the right time, the moulting periods were so very irregular, that some moths emerged from the cocoons after 40 days, while there were also larvae that had not yet pupated.

The author concludes that it is most important to encourage summer breeding as much as possible, but that the scientific and technical side of the question is by no means solved. In the meantime, it is evident that the Japanese bivoltin " Nipponnishiki " breed is not pure, but is the result of many crosses, and it would be useful to know how it has been obtained. The types that have been isolated from it have not the characteristic of bivoltins and the larvae and cocoons are very variable.

1167 – **Bee-Keeping in the Grand Duchy of Luxemburg.** — KUNNEN, N. P. in *L'Apiculteur*, Year LXIV, No. 10, pp. 239-241. Paris, October, 1920. BEE-KEEPING

Bee-keeping was very general in the Grand Duchy of Luxemburg as early as the end of the eighteenth century. In 1775, while the country-

was still under the dominion of Austria, the Empress Maria-Theresa promulgated an edict conferring great liberty and many favours upon bee-keepers. A book on the industry published in 1756, by Joseph Collignon at the "Bible d'Or" in Metz, and written by Abbé Perillat of that town, under the title of "Nouvelle construction de ruches de bois avec la façon d'y gouverner les abeilles, inventée par M. Palteau, premier Commis du Bureau des Vivres de la Généralité de Metz" was fairly widely read in the Grand Duchy, as was also a book by M. Duchet, published at Fribourg in 1771 viz., "Culture des abeilles, ou methodes sur les moyen de tirer meilleur parti des abeilles par une construction de ruches mieux assorties à leur instinct." A pamphlet published in German in 1786, and of which a second revised edition was brought out in 1918 by M. Beffort, 3 Place d'armes, Luxemburg, served as a guide to a certain number of bee-keepers of the period who already were using hives with partitions. Bee-keeping was, however, not regarded as a means of gaining a livelihood, but rather as a little subsidiary industry in the hands of the labourer, workman, and small employee.

In Year IX, when the Duchy, as the "Département des Forêts" formed part of France, an official communication recommended bee-keeping in the following terms :— "If the bees were more numerous and better cared for,we should no longer be dependent upon foreign countries for our wax supply the value of which exceeds 30 million fr., per annum." In 1811, the Director General of the Waters and Forests addressed a circular to the officials of his Department. His concluding phrase was :— "I urge you to spread these ideas among your foresters and such of your agents as have facilities for bee-keeping and to assure them that this industry would in no wise interfere with their duties. By so doing, you would further the interests of your subordinates and carry out the wishes of the Government."

Thus, apiculture was already flourishing in the Grand Duchy, where, in 1853, the Abbé Dr. Dzierzon, of Karlsmarkt (Silesia), invented or improved the movable hive-frame in Germany. Very soon, hives with movable frames found their way into the Grand Duchy. In 1862, M. Klein, a magistrate at Esch on the Alzette, published a translation of a French hand-book by Menuisier on the movable system. However, the Menuisier hive which opened above, like the composite hives in use at the present time, found no partisans.

The Italian bee, which was introduced into Germany by Dr. Dzierson, was first imported into the Grand Duchy in 1860, by Koltz, Inspector of Waters and Forests, and again, in 1864, by Buch, a schoolmaster at Belvaulx. In the south of the country, there was a certain predilection of the Italian bee, until towards the end of the nineteenth century. In the north, the Carnolian variety was frequently imported. During the last twenty years, the black native bee has been reared by preference.

At the Agricultural and Horticultural Show held at Luxemburg in 1875, on the occasion of the 25th. anniversary of the Lord-Lieutenant-ship of Prince Henry of the Netherlands, two Luxemburg bee-keepers ex-

hibited 2 kinds of hives with movable frames, which were then in use in the country. One of the exhibitors, Abbé Sax, and his friend Graf, showed a hive of the Oettl horizontal type, the other (the author) showed Berlepsch's vertical type.

The first of these systems is still met with in some of the hives of the country, the second (the Stander with 3 storeys) has held its own until the present time, and can be found beside others of more recent design.

Since 1875, apiculture has taken a new impetus. A certain number of bee-keepers, who had been on friendly terms since the Exhibition of 1875, joined together in 1876 to found a Cantonal Bee-keeping Association.

Bee-keeping courses have been held since 1883 at the Ettelbruck-State Agricultural College, these were followed some years later by special bee-keeping courses for schoolmasters, with practical demonstrations at the hive. Finally, in January, 1886, the cantonal Societies founded in the preceding years, united to form a Federation of the Apicultural Societies of the Grand Duchy. The apiculturists who were elected to discharge the duties of President and Secretary in 1896 are still in office. For 34 years, the Federation sent, first every 4 years, and afterwards every 2 years, lecturers to each Cantonal section, It publishes a paper on beekeeping, the *Bienenzeitung* which is sent gratuitously to the members of the Association. This paper relies largely on experiments made in other countries, and reprints from the agricultural review of neighbouring lands, extracts adapted to the requirements of Luxemburg.

Thanks to these efforts, movable frames are now the rule throughout the Grand Duchy, and rational methods are widely practised there. Nevertheless, there are still some 3000 hives constructed on the fixed system among the 13000 hives (in round number now existing in Luxemburg).

The Apiculture of the Grand Duchy has not failed to take part in international organization and has sent exhibits to the various international exhibitions. The Luxemburg Apicultural Federation won the gold medal at the Paris World Exhibition in 1889 for its model hive, and in 1900, its collection of honey from the different States of Luxemburg was awarded the first prize. At the World Exhibition at Antwerp in 1894, and at Brussels in 1897, the Luxemburg apicultural products enjoyed well-earned success.

At the 4 first International Apicultural Congresses (at Paris, Brussels, and at Bois-le-Duc (Holland), in which France, Belgium, Holland, Italy, Russia, Austria, the United States, and Luxemburg took part, the Federation of the Apicultural Societies of Luxemburg was represented by M. Ed. Hemmer and by the author, both members of the Permanent Committee of the International Congresses of Apiculture. At the festivities held at Paris in 1906 on the occasion of the fiftieth anniversary of of the central Society of Agriculture, the Secretary General of the Grand-Ducal Federation conveyed the congratulations and good wishes of the Luxemburg bee-keepers (see the *Apiculteur*, Paris, 1906, Year 5, pp. 168-169). Two Luxemburg bee-keepers sent reports to the 5th International Congress which was held at Turin. Being unable to attend personally

they entrusted the reading of their reports to their representatives MM. Tombu de Huy änd Menden of Cologne. The Vice President and the Secretary General of the Grand-Ducal Federation have, since 1889, attended the important Congresses known as the "Wanderversammlungen der deutschen, osterreichischen, und ungarischen Bienen-zuchter." Luxemburg apiculture has thus not held itself aloof, but has taken a large part in international life.

Nevertheless, according to the author, the Grand Duchy is still far from having reached the height of its prosperity. He, however, mentions with great satisfaction, that the Luxemburg clergy and especially the schoolmasters, are devoting themselves with much zeal to the promotion of intensified methods of apiculture.

FARM ENGINEERING

AGRICULTURAL MACHINERY AND IMPLEMENTS

1168 – **Power Farming in Spain.** — I. Concurso de tractores en Sevilla, in *Boletín de agricultura técnica y económica*, Year XII, No. 139, pp. 513-515. Madrid, July 31, 1920. — II. Concurso de aparatos para el cultivo mecánico de las tierras. *Idem*, No. 141, pp. 712-715, Sept. 30, 1920. — III. Passelègue, G. La culture mecanique en Espagne, in the *Journal d'Agriculture pratique*, Year LXXXIV, No. 42 pp. 312-314. Paris, Oct. 14, 1912.

Following upon a meeting of the Spanish Agricultural Association held in Madrid on November 25, 1916, and also in consequence of reports presented by M. Fernandez Cortès and by C. Resines Secretary of the Spanish Royal Automobile Club, a petition was presented to the Government and Parliament requesting that the customs duty on petrol should be lowered to enable mechanical farming to become economically possible and that the State should give financial and technical help to the Association in all attempts initiated or supported by it with the object of popularising power farming.

A Royal Decree dated November 30, 1919, reduced from February 1, 1920, the customs dues from 30 pesetas to 10 pesetas (1 peseta = 9½d. at par) per 100 kg. In addition an extra Government grant was given to the Machinery Experimental Station at Madrid and to the agricultural schools to enable them to study and popularise mechanical cultivation.

Power farming trials were held near Seville from May 1 to 15, 1920, under the auspices of the Seville Chamber of Agriculture, on the initiative of their President Don José Huesca y Rubio. The technical arrangements were in the hands of Don Mariano Fernandez Cortès, Director of the Machinery Experimental Station attached to the Royal Agricultural Institute at Madrid.

These were the first official trials to be held in Spain.

The sixteen machines that took part, originated as follows:—

1 British, 3 French, 8 American, 1 Italian, and 3 German.

Tractors with 2 driving wheels: — 18 HP. Chapron; 25 HP. Saunderson; 18, 25 and 40 HP. Case; 20 and 30 HP. Titan; 25 HP. Parret; 25 HP. Fiat; 30 HP. Lanz; 25 HP. Hansa Lloyd.

Caterpillar tractors : — 20 HP. CLEVELAND.
Motor ploughs : — 80 H. P. W. D.
Are carriage tractors : — 18 HP. MOLINE.
Rotary cultivators : — 5 and 35 H. P. S. O. M. O. A.

The trials include the cultivation of fields and olive groves. In the former, each machine had to plough at a depth of 18 to 25 cm., a plot of about 2 hectares using petrol as fuel ; and in the latter, spring ploughing had to be done at a depth of 12 to 15 cm.

The land chosen for large-scale ploughing was a very strong alluvial deposit, which had been a pasture for some 40 years and was full of thistle and couch-grass, whilst horse teams and pedestrians had beaten out paths in every direction. The work practically amounted to breaking up, and further, there was risk of obtaining bad results, particularly too heavy a consumption of petrol.

The ground chosen for cultivating olives was more normal and rain had left it in excellent condition for ploughing. The following table gives the most interesting results :—

Test results of mechanical cultivation of an olive grove.

Machine	H. P.	Plough	Average Depth cm.	Petrol consumption per hour litres	Petrol consumption per hect. litres
Cleveland	20	10″ 2 furrow Olive	13.81	7.97	24.07
Moline	18	10″ 2 furrow Moline	11.80	6.21	19.22

According to G. GUILLEMÉ BRULON (1), an agricultural engineer, mechanical cultivation is bound to develop considerably in Spain. The lack and irregularity of the rainfall often causes great scarcity of fodder and pasturage, and the maintenance of draught animals is very difficult. In addition, the shortness of the rainy season gives very little time favourable for ploughing. In nearly all Spain and Andalusia the rotation practised is " el tercio, " that is to say the soil is cultivated once in three years, the rotation being : — 1st year cereal ; 2nd year pasture ; and 3rd year fallow. An Andalusian agriculturistst Sanchez de IBARGÜEN who has a farm at Moron de la Frontera (Seville) has showing that with the use of mechanical cultivation results can be obtained that would not be economically possible with teams ; using a motor he has been able to work the soil in August and to replace the fallow in the rotation ly a leguminous crop. In a book entitled *Agricultura Moderna*, Andié GARIDO states that SANCHEZ DE IBARGÜEN now feeds 546 kg., live weight of cattle

(1) See G. G. BRULON, La culture mecanique en Espagne, in *La vie agricole et rurale* Year IX, Vol. XVII No. 46 pp. 302-304. Paris, Nov. 13, 1920, (*Ed.*)

per hectare ploughed instead of 40 kg. by ordinary means. His harvest averages 18 quintals of wheat per hectare, whereas according to the most recent statistics the average for this region is barely 10 quintals per hectare.

Another exhibition of power-farming machinery organized by the "Consejo de Fomento" with the co-operation of the Provincial Deputation, the "Ayuntamiento" and the scientific economic and agricultural institutions of Saragossa was held in that town from Sept. 25 to Oct. 10 and was followed by an exhibition of agricultural machinery from Oct. 12 to 20, 1920.

It will thus be seen that Spain is striving to extend the use of mechanical cultivation.

1169 – **A Tractor with the Greatest Possible Grip.** — DESSAISAIX R. in the *Journal d'Agriculture pratique*, Year 84, No. 41, pp. 1-300, figs. 1 Paris, Oct. 1920.

In order to obtain the greatest possible effort of traction from a tractor, it has been attempted to make all the wheels propulsive. For several years tractors of this kind have been suggested in Great Britain, France, America, and Italy.

A new model, the VALERE CHOCHOD, was shown during the Semaine d'Automne de Chartres, by the CARTOUCHERIE FRANÇAISE DE SURVILLIERS (Seine et-Oise). The 4 cylinder engine, running on oil 90 mm., in bore and 150 mm., stroke, develops 20 to 24 HP. at 1,100 revs. per min. A pulley below the radiator provides a belt drive for other machinery.

The four driving wheels are 40 inches in diameter, the tyres, 1 inch thick, are fitted with grips and the two wheels on each side are actuated by an enclosed chain drive.

Through the gear box the engine drives shafts which can be geared up to each wheel separately, each wheel actuating. through a chain, the corresponding wheel running loose on the other axle. Thus the two wheels correspond to the chain-tracks of a caterpillar tractor. Steering and turning is done though levers which brake the wheels on one side while the other turns. The weight of the tractor is about 2 ½ metric tons, the maximum and draw-bar pull is 1300 kg.; the ratio of these two figures gives a coefficient of 0.52.

The tractor is provided with two driving seats facing each other, so that there is no need to turn the machine round at the end of each furrow. The two speeds are 3500 and 4500 metres per hour and there is a reverse.

The track is 1.25 m. × 1.75 m. overall length, 2.98 m. breadth 1.87 m., height 1.85 m., the ground clearance being 30 cm.

1170 – **The A. R. A. Vineyard tractor.** —, FERROUILLAT P. in *Le Progrès agricole et viticole*, Year XLI, No. 43, pp. 394-397, figs. 3 Villefranche (Rhône), Oct. 24, 1920.

The problem of the mechanical cultivation of vines planted at intervals of 1.5 metres as is the case with most of the vineyards of southern France and Algeria, has according, to the author, not yet been satisfactorily solved. A motor is required that is powerful enough to work the whole width between each row in a single journey, narrow enough to travel

without touching the vines and able to turn in a very small radius ; such a motor, must have a narrow, short frame..

Until now the tractors shown at trials are either too weak to draw an implement for earthing-up etc., at a depth of 10 to 12 cm., and cover whole width between the vines, or powerful tractors whose width constitutes a danger to the vines and, moreover, only suit vines planted 1.8 to 2 metres apart.

The new A. R. A. tractor for road and field work is made under the patents of A. DE VIREL and M. E. CAHEN at the DELAUNAY WORKS, Belleville.

It has a patented pliable chain track mounted on four bogeys, its overall length is 2.25 m., breadth 0.70 m., and height 1.50 m., The centre of gravity has been placed as low as possible, 50 cm. from the ground.

Without risk of overturning, the tractor thus can work across ground at a slope of 35° (7 in 10), and is thus excellent for hillside vineyards. The 4-cylinder (70 × 130 mm.) engine runs on paraffin, developing 21 H.P. at 1500 revs per min, 25 H.P. at 1800 revs. per min., and 30 H.P. at 2000 revs. Ignition is by high-tension magneto, there is pressure-fed oiling and thermosiphon water-cooling through a fan and a CHARDARD radiator which has movable parts, and is easy to repair. A metal plate clutch is provided.

The two speeds give 2.5 and 3.6 km., per hour and there is a reverse. The weight is about 1 ½ tons, giving a pressure about 5.7 lb., per sq m. of bearing surface of the track. On the starting handle axle is a driving pulley about 12 in., in diameter by 6 in., broad geared at the ratio of 1 : 2 to the engine. By this means threshers, forage presses, pumps, trussing machines etc., may be driven. As the pulley is keyed to the axle the transmission belt easily keeps taut, the tracks being sufficient anchorage. During ordinary work the pulley is out of gear. A small windlass is also mounted on the tractor for lifting up the implement hauled. The plough made by GUICHARD, at Lieusaint (Seine-et-Marne), can be used either. for earthing-up or uncovering. On a triangular frame, carried on 3 wheels, are 4 plough-bodies, two turning to the right and two to the left, and behind a small double drill plough. These five cover the whole space between the lines. The height of the wheels can be regulated to increase or decrease the ground clearance, and the depth of ploughing. The frame can also be extended to carry plough bodies (one being a drill plough) for use when the inter-lines are 1.50 m., wide. For uncovering, the frame is turned round, with the apex of the triangle in front and the plough bodies are reversed as regards direction and side. The shares are lozenge-shaped and are tightly held by grooves in the frame. The plough is attached to the tractor by a ring or some other pliable coupling. At the back of the plough is the lifting cable which passes over two pulleys on two iron bars fixed on the back of the tractor behind the driver's seat and thence to the windlass.

The plough lifts almost vertically and the tractor can turn within a headland 3 metres wide at the most. The plough can be replaced by

other agricultural implements such as hoe tines, vibrators, etc. About 3 3/4 hours are necessary to plough one hectare.

1171 – **The Dubois Polyculteur.** — DESSAISAIX in the *Journal d'Agriculture pratique*, Year VI, No. 47, pp. 414-415, figs 1. Paris, Nov. 18, 1920.

The tillage machine known as the " Polyculteur Dubois " (29, rue de l'Avenir, Asnières, Seine,) and which was shown at the " Semaine de Motoculture de Chartres ", is driven by a 20 H. P. engine and weighs about 2 metric tons.

The machine is a motor-plough rather than a tractor. The two driving wheels have separate clutches and steering is effected by disengaging one or the other. The back of the chassis receives the front portion of a double-brabant 3-furrow plough fitted with the ordinary lock. Underneath and in front of the chassis, at a certain height from the ground is a loose wheel, placed horizontally, on which the machine only leans when turning.

The method of turning is as follows: — On reaching the end of the furrow, the plough is unlocked by pressing a pedal. The tractor is stopped, and backed, tipping round the axle of the driving wheels and pressing on the loose wheel in front; the ploughs are then disengaged and lifted up. The land wheel is locked and the whole outfit turns on it. The friction of the mouldboards ensures that the ploughbeam will swing over in the transverse plane until the locking pin engages again and the tractor is ready for the next journey.

The head of the plough-beam, which takes all the pull and supports most of the weight of the double-brabant whilst turning, can be regulated vertically according to the depth of ploughing desired. The Polyculteur can be used for hauling other farm implements as well as a cart.

1172 – **Method for Sealing Bottles Hermetically with Unground Glass Stoppers.** — CUSMANO, G. in *L'Italia vinicola ed agraria*, Year X, No. 40, pp. 458-459, figs 4. Casale Monferrato, Oct 3, 1920.

The author has thought out a new method of hermetically sealing, of which the consistent parts are: —

(*a*) A glass stopper with a hemispherical head having 8 grooves.

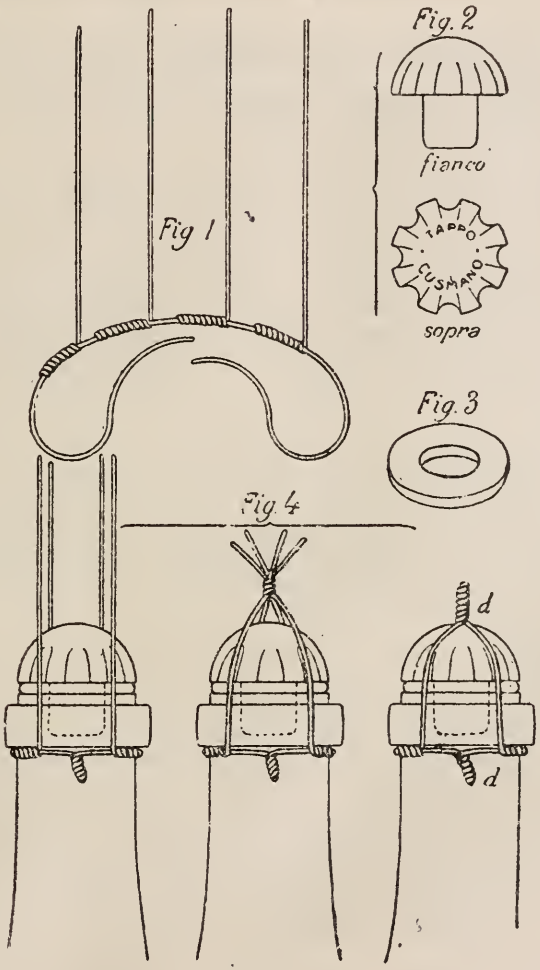
(*b*) A flat rubber ring previously dipped in paraffin wax. This ring can be used continuously, all that is necessary being to wash the ring in water and potash and re-dip it in wax.

(*c*) A length of galvanised iron wire, having 3,4 or 5 lengths of thinner wire wound on it, and sticking out at right angles for about 4 inches.

The stem of the stopper (fig. 2) is passed through the rubber ring and placed in the mouth of the bottle (fig. 3), the iron wire is bent round the lip, secured, then the lengths of thinner wire are passed over the grooves of the stopper and securely twisted ; the bottle is thus hermetically sealed The following illustration shows clearly the method.

To open the bottle, any of the binding wires are cut. As a guarantee of the contents of the bottle, a lead wafer can be fixed to the twisted ends of the wires, marked *d* in fig 4.

Another apparatus invented by the author is an "otturatore rapido" a rapid corking machine, which will cork bottles in twenties up to one hundred One man can deal with 1000 per hour.



Method of hermetically sealing bottles with unground glass stoppers.

1176 - **The Rancidity of Philippine Coconut Oil.** — PERKINS, GRANVILLE A. (Chemist. Bureau of Science), in *The Philippine Journal of Science*, Vol. XV. No. 5, pp. 463-474 tables 3. Manila, November, 1919.

The purposes of this article are to present evidence as to the relative effect of various factors in the development of rancidity in edible coconut oil, and to point out wherein this evidence leads to a confirmation, modification, or extension of the former conceptions of rancidity. The rancidity factors and their relative effect were: Initial acidity, air, light, moisture, enzymes and non-fatty material, i. e. the substances, largely protein and carbohydrate, that, together with moisture, give the cloudy appearance to freshly expressed oil and which are removed by filtration using trough fuller's earth.

Two year storage tests were made on thirty samples of edible coconut oil, prepared by PARKER H. O. of the Bureau of Science. The results were in general agreement with the accepted views of rancidity and its causes. The action of light was found to be a powerful, but not necessary factor in the production of rancidity. Enzymes from the fresh coconut meat had some effect on the keeping qualities of the oil, but sterilisation was of doubtful benefit.

An oil of low initial acidity remained sweet during two years exposure to air and light.

The author outlines the conclusions formed by previous experimentors, and submits the following conclusions as a result of the above mentioned experiment: — In the type of rancidity of coconut oil studied the first stage is a hydrolysis, the rapidity of which varies with the initial acidity, and the amount of moisture present. Exclusive of any mould action, this hydrolysis may be somewhat accelerated by the action of air, light and a fat soluble enzyme. The second stage is an oxidation of the free fatty acids. Possibly this involves also the oxidation of unhydrolised olein, but the amount of oxidation s dependent on the amount of hydrolysis.

Oxidation is hastened by light and moisture, but light is not a necessary condition.

Though this appears to be the common type of rancidity in coconut oil, the possibility of others is not excluded. Previous tests with peculiar types indicate that a single chemical test is not sufficient to enable a distinction to be made between edible and non edible oils.

For the ordinary types, it appears that the decrease in iodine value, the fuchsine aldehyde test, and the oxidisability number give good indi-

cations of the amount of deterioration. The iodine number alone without some data on the original number has no value. The acidity is a measure of the first stage in the rancidity process.

1177 – **Oil from Tobacco Seed.** — See No. 1107 of this *Review*.

1178 – **Experiments on the Biological Control of Concentrated Extracts of Tomato by the American Method. Proposed New Method of Control and Observations on the Mycological and Bacteriological Content of these Extracts** (1). — BERTARELLI, F. and MARCHELLI, M. (Istituto d'Igiene, University of Parma), in the *Annali d'Igiene*, Year XXX, No. 6, pp. 309-322, bibliogr. of 8 publications. Rome, June 9, 1920.

The HOWARD method for controlling tomato extracts consists in: — (1) Counting the moulds, and determination of a degree tolerance based on a certain % of optical fields containing hyphae; (2) counting the hyphae and spores, according to a conventional cubic unit of measure; (3) counting the Bacteriaceae directly under an average magnification without staining, but with fixed limits of tolerance and in such a way as to avoid counting cocci, which are less easy to distinguish.

When counting, magnifications of 90, 180 and 500 diameters are used, and in measuring, the THOMA-ZEISS cell is used to count the red globules. The various concentrations of the extract are not taken into account. As regards the moulds, a good concentrated extract should not contain more than about 150 hyphae per cc.: the spores and the ferments should not exceed 25 per $^1/_{60}$ cub. mm., and the bacteria should not exceed 100 millions per cc. As the Italians protested, the United States Government is reported to have extended these limits to: 250 spores or ferments per $^1/_{60}$ cub. mm., 100 million bacteria per cc., and 66 % of the optical fields with moulds.

G. ROSSI remarks that the method is not logical if the characteristics of the tomato and its derivatives are considered, and that the sole guide is constituted by the organoleptic characteristics. He draws attention also to the fact that in the first place the technical proceedings are too inexact. One of the authors, and also ROVESTI and PEASE express similar opinions as regards the technique. CH. VINCENT has modified the method by replacing counting in the THOMA-ZEISS cell by counts effected in preparations fixed and stained on glass. After having diluted the liquid with 2 parts of sterilised water, 1 cc. of the material is placed on a sheet of glass 1 cc., in size; this is left to dry, then fixed in alcohol, stained with LOEFFLER methylene blue and examined with an oil-immersion objective.

The germs in fields of 0.205 mm. diameter are counted; the average is of the total found multiplied by 300 000, which gives the number of germs per cc.

The authors attempted to ascertain: — (1) If the HOWARD method, modified according to VINCENT, is worthy of adoption; (2) if the concen-

(1) See *R.* Jan. 1912, No. 216; June, 1917, No. 674; May 1919, No. 650. (*Ed.*)

tration of the product has an influence on the microfloral content, and, in consequence, if the limits of tolerance as regards moulds and bacteria should be modified each time ; (3) if the test deserves to be modified and rendered more accurate and simple ; (4) if the cultural tests, really offer possibilities of judgment different from those afforded by a simple optical examination, and, in any case, if the number of active bacteria is low or negligible in comparison with that of inactive bacteria ; (5) if being given the actual nature of the Italian concentrates, there is reason to fear a considerable increase in the number of bacteria during transport over a long distance ; (6) if, consequently, the practical corollary would ensue that indicates the necessity of sterilising the concentrate destined for the United States, by employing practical methods, with which there is the least possible alteration in the organoleptic qualities of the extract, especially as regards colour and perfume.

As regards the enumeration of the moulds, the authors consider that it is not advisable to treat materials naturally poor in extracts in the same way as others which are richer ; also, that despite the care utilised in the preparations, these remain with much the same density as in the THOMA-ZEISS cell. In respect of many points, well defined and clear vision is a difficult matter ; and it is still more difficult to estimate the moulds, which sometimes show only a thread of hypha in the field of vision and at others a felted mass of mycelium.

The counting of the spores and ferments is still less accurate ; they are almost impossible to discern, and identification is uncertain, admitting infinite personal errors. The authors consider, therefore, that it is wiser to omit enumeration, being completely of negative importance, since the hyphae and bacteria are already counted, and the method is full of errors of unlimited magnitude. It is not easy to understand why the estimation of the spores belonging to the hyphomycetes can have any particular value ; the invasion is more logically applied to the number of hyphae than that of the detached spores, and the Blastomycetes always represent, in ordinary pratice, a modest figure that is negligible in comparison with the Bacteriaceae.

As regards the examination of the bacteria, the authors' criticisms are directed towards the fact that no account is taken of the active and inactive bacteria, and that the bacterial content is not estimated in relation to the true residue of the liquid. What is more, in the enumerations that are made, it may be noted that even in the same preparation, the modifications of the figures are considerable and these increase still more when large fragments are present in the field which hide some of the bacteria ; this last drawback is also present in the VINCENT method, which, although it has its advantages, presents nevertheless the disadvantage of having too much density and possibilities of notable personal errors.

The method adopted by the authors may be summarised as follows : — 2 cc. of concentrated extract taken from the tin are put into a test-tube and shaken down by tapping the base gently with a spatula. The content is poured into a glass (after washing with distilled water that is reckoned in

the mass), and still further distilled water added to make up a total of 50 cc. After mixing well, the whole is filtered through a quadruple filter of gauze, carefully washing the precipitate with another 50 cc. of distilled water. The filtrate contains practically all the bacteria in the material and repeated tests have shown that not more than 16 to 20 % of the total bacteria remain on the filter or attached to the glass. A small amount of the of filtrate is removed by means of a pipette graduated to $^1/_{200}$ cc., and $^1/_{200}$ cc. of filtrate is spread over glass slides (washed with alcohol and ether), by holding horizontally; alcohol-ether is used as a fixative and the material is stained with LOEFFLER'S methylene blue.

Counting can be done with the help of an oil-immersion; the authors employed a KORISTKA No. 7 objective with ocular No. 7 fitted with a small glass disc similar to an ocular micrometer with a scale of 1 sq. cm., divided into 100 small squares.

An examination of the data presented shows that the concentrated extracts from Parma correspond as a whole to the requirements of the North-American legislation. There exist, however, in the various types, notable differences as regards the microbial purity and the presence of moulds and ferments. By fixing the limits of tolerance, it should be made clear that the figures fixed by the American regulation apply only to simple concentrated extracts, not exceeding 20 to 22 % of residue, and that, for double and triple concentrated extracts the figures should be increased by at least $^1/_5$ or $^1/_4$, especially as regards the mould content, owing to the fact the maximum oscillations noticeable in the products from the microbial point of view chiefly concern the moulds.

The authors, however, put this questions:— Being given that complete sterilisaton is not possible without changing the organoleptic qualities of the product, is it possible for the living bacteria which remain to multiply in such a way as to make the product inacceptable in America? They therefore proceded to ascertain the number of living bacteria; they perforated the tin with a red hot iron and took samples at various points with a FRAENKEL spoon; the surface was levelled with a sterilised spatula end, the spoon was placed in a small glass dish previously tared while containing an empty spoon. On weighing, the exact weight of the sample would be ascertained. The full spoon was placed in a test tube with 2 cc., of broth and small sterilised glass balls. This was well shaken, rendered uniform, 0.01 cc., was extracted and placed in a second tube containing 9 cc. of broth. After well shaking, another 0.01 cc., was extracted from this second tube and placed in a third tube containing 1.9. cc., of sterilised broth. Samples were then taken from the last-mentioned tube for gelatin plates, from which readings were taken after 10 to 20 days. The removal of samples was repeated, and the examination was completed by counting the moulds. In addition, the tins were kept for 12 to 19 days at a temperature of 37°C., in order to ascertain whether a considerable increase in the number of Bacteriaceae is possible during transport over a long distance.

The authors present a Table showing the results obtained, from which the following points of practical interest have been deduced:—

The active bacteria exist in insignificant numbers compared with the total living and dead Bacteriaceae counted by means of the readings taken under the direct optical examination.

Even after about 3 weeks at 37° C., the number of active bacteria increase but slightly (maximum ratio 1 to 1.5), and in such a way as to be of no value as regards the limits of tolerance. The increase is only marked in the case of moulds, and the danger as regards these should be considered more serious than in the case of Bacteriaceae. In no case, however, was the preliminary conclusions drawn altered, at least as regards the samples examined by the authors. It would be advisable, however, to employ very clean tomatoes especially for goods intended for export. In addition, as there are no reasons that require the radical sterilisation of a product which will keep in practically the same condition for several months, it is useless to insist upon still more rigorous measures.

1180 – **Sausage Yeasts.** — CESARI, E. and GUILLERMOND, A., in the *Annales de l'Institut Pasteur*, Vol. XXXIV, No. 4, pp. 229-247, figs 4. Paris, April, 1920.

All the yeasts isolated from sausages by the authors belonged to the genus *Debaryomyces*, but together with yeasts of this type, salted and pickled meat were found to contain yeasts which could not be made to produce spores. It is very probable, according to the authors, that a systematic investigation of all the yeasts used in salted meats would reveal further new species (1).

1181 – **The Patting of Honey.** — *L'Indépendant de Seine-et-Oise*, quoted in *L'Apiculteur*, Year LXIV, No. 9, pp. 220-221. Paris, Sept., 1920.

Freshly extracted honey is transparent and liquid, then it becomes opalescent, opaque, very hard, i. e. granulated.

Before potting, the impurities should be allowed to rise and then skimmed off. Bad tasting and fermented honey are treated thus :— Boil for 2 minutes in a copper vessel 3 kg., of honey, 850 gm., of water, 75 gm., of chalk ; then add 150 gm., of washed and dried powdered carbon and boil for another 2 minutes. Add 3 whites of egg beaten in 90 gm., of water. and boil for another 2 minutes. Leave to cool and then filter. The honey may also be melted over a water-bath and a red hot iron plunged into it ; then pot as a preserve.

Scum on the honey indicates that it is obtained from sainfoin and is of good quality. If liquid honey is preferred, it can be liquefied in the following way :— Heat over a water-bath until nearly completely melted without boiling or stirring, and allow to cool slowly ; or pasteurise the honey at 90° C. for 15 minutes, but for a longer time at 50 to 55° C, is preferable ; or heat over a water-bath at 77° to 83° C., and draw off into pots while hot.

(1) M. CESARI attributes to the yeast, described in the above note, a part in the ripening of the sausage. See *R.*, Oct.-Dec., 1910, No. 1254. (*Ed.*)

Granulated honey becomes very hard and can be made into briquettes squares, and cubes, which should be wrapped in waxed paper.

1182 – **Grape Storage Tests.** — BONHAM, C. N., in *The Agricultural Gazette of Canada*, Vol. Vol. 7, No. 6, pp. 476-478. Ottawa, June, 1920.

AGRICULTURAL PRODUCTS; PRESERVING, PACKING, TRANSPORT, TRADE

Commercial grape storage tests were started at the Grimsby Precooling and Experimental Fruit Storage Warehouse during the grape picking season of 1919, in order to determine the varieties most suitable for storage for the Christmas market, and the general commercial value therefrom. The 5 varieties included were Niagara, Agawam, Lindley, Vergennes and Black Rogers. The following types of package were employed: 1) Six quart climax basket packed as for immediate shipment: storage temperature 32°F. Removal of all crushed or spoiled grapes was the only special preparation. This method cannot be recommended for long time storage owing to consequent stem mould damage; 2) keg similar to that in which foreign grapes are imported. Layers of granulated cork intermixed between the berries. The condition of the fruit was practically the same on removal as when put in storage. For small lots this method is preferable to any other but is not economical on a large scale; 3) storage "flats," i. e. shallow trays 18 × 24 in., and 4 in., deep, with spaces for ventilation; found decidedly suitable for long time storage of the varieties tested; Niagara proved worthless for commercial purposes owing to the persistant falling off of berries. Taking all the others into consideration the loss from stem mould was small enough to be overlooked as a cause of serious waste except in a very late season when the grapes have to be picked before they can be properly matured. The Agawam var. was slightly more susceptible than the rest, and the Lindley vars. were almost immune.

General results indicate that if the fruit is stored and packed correctly, a market may be developed which will enable the Canadian grower to dispose of a considerable quantity of grapes on the Christmas market at a satisfactory margin over the prices received at picking time.

MEANS OF PREVENTION AND CONTROL

1186 – **Destruction of Zoospores of Plant Disease Organism by Natural Enemies.** — Harvey R. B., in *Science*, New Series, Vol. LII, No. 1334, pp. 84 Lancaster, Pa, July 23, 1920.

In making some motion-picture photomicrographs of the liberation of zoospores from the sporangia of *Physoderma Zeae-Maydis* (1), the author observed that the zoospores had been destroyed by certain animalcules which are commonly found in decaying vegetable material. No reference has ever been made regarding the importance of these natural enemies of plant diseases which are disseminated by zoospores.

The number of zoospores swallowed by one rotifer (*Proales* sp.) is remarkable. When the animalcules are abundant, the zoospores disappear rapidly. One infusorian (*Keronia* sp.) was observed to devour a perfect stream of the zoospores, at the same time increasing in size until it became almost unrecognisable.

In active cultures, a field may be seen by means of the microsope filled with millions of zoospores swimming about. In a few hours, large numbers of these have been devoured by the animalcules, which rapidly increase in numbers. A few hours later the same protoplasm constituents are seen swimming about not as zoospores but as animalcules. The process of change is so rapid that it raises the question as to whether there is always a cleavage of the proteins and a re-synthesis, or whether there may not be some quicker method of assimilation especially in the unicellular organism in which the cytoplasms of the infusorian and the zoospore ingested are in such intimate contact.

Starting with dry material collected from maize stalks infested with

(1) See *R.* Oct.-Dec.-1919, No. 1269. (*Ed.*)

Physoderma, the animalcules appear first and are present for each batch of zoospores.

It would be interesting to determine just how important these animalcules are as natural enemies of the plant disease which are disseminated by zoospores. Also it would be desirable to collect data to determine if the destruction of the soil microfauna by excessive liming may not be correlated with certain epidemics.

1191 - ***Phytophthora erythroseptica*, a Peronosporaceae Injurious to Belladonna (*Atropa Belladonna*) in Holland.** — WESTERDIJK, J. and VAN LUIJK, A., in the *Mededeelingen uit het Phytopatholo,isch Laboratorium "Willie Commelin Scholten,"* Amsterdam, IV, pp. 31-32, figs. Amsterdam, 1920.

Phytophthora erythroseptica Pethybridge, already described as a parasite of potato tubers (1), was found by the authors during the summer of 1918, to be the cause of root-rot in one of the Solanaceae, *Atropa Belladonna*. The host-plants examined were suffering from a typical form of wilt due to the fact that the roots and lower part of the stem had been attacked by the fungus. A brown discoloration extended downwards from the collar, by way of the fascicular bundles of the root. The lower part of the fascicular bundles of the stem were also brown and occasionally even the surrounding parenchymatous tissues.

In the discoloured fascicular bundles, the authors discovered a phycomycete which was easily cultivated on artificial media. These cultures soon produced characteristic fructifications which proved the parasite of the belladonna to be identical with *Phyt. erythroseptica*.

Potato tubers inoculated with pure cultures of the fungus isolated from belladonna and from the potato, showed the characteristic reddening of the pulp, which gave place to a blackish-brown after two days. The authors were unable to make infection experiments on the root of belladonna, but they consider it certain that *Phyt. erythroseptica* is the cause of a form of root-rot affecting *Atropa Belladonna*.

1192 - ***Macrosporium Solani*' Hyphomycete Injurious to Tomato in Delaware.** — ROSENBAUM, T., in *Phytopathology*, Vol. X, No. 9, pp. 415-422, figs. 4. Baltimore M. D., Sept. 1920.

Numerous specimens of tomato plants were received in June and July, 1919, from Delaware, showing a disease, the symptoms of which differed markedly from those of any known disease of tomatoes.

(1) See *R.* Sept. 1919, No. 1105. (*Ed.*)

The stems, at the point where they emerge from the ground first turns dark brown. This brown rot or canker penetrates deeply into the tissues and extends above and below the surface soil. With age, the infected portion of the stem becomes even darker in colour, the tissues shrivel up and may break, and the stem falls over at the original point of infection. Occasionally similar brown to black spots are found on other parts of the stem above ground. In such cases, it often spreads a considerable distance from the point of infection and in many cases the rot at the base of the plants produces a girdling effect. If this occurs when the tomato plants are still young, they throw out new roots above this point. In addition to these effects, the plants show varying degrees of wilting and discoloration of the leaves. The disease has been found on tomato plants of all ages, both in the seed bed and in the field. The symptoms mentioned suggested the possible designation of this disease as "foot rot."

This disease was found doing considerable damage in Delaware.

A microscopic examination of diseased stems showed fungus mycelium within the affected tissues.

Numerous isolations from infected plants and from artificial inoculations in the field and greenhouse, establish the fact that a fungus belonging to the genus *Macrosporium* is the organism responsible for the disease in question.

Comparisons of this *Macrosporium* were made with *M. Solani* from potatoes; with *Macrosporium* cultures isolated from a tomato fruit rot from New Jersey, and with typical "nail-head" spots on tomatoes in Florida. These comparisons show that the *Macrosporium* here discussed differs from the one isolated in Florida, and resembles, on the other hand, *M. Solani* and the *Macrosporium* isolated in New Jersey. It should then be referred to in future as *Macrosporium Solani* Ell and Mart.

1193 – **Fungi Isolated from "Spotted" Apples in Great Britain.** — Horne, A. S. (Dept. of Plant Physiology and Pathology, Imperial College of Science and Technology), in the *Journal of Botany, British and Foreign*, Vol. LVIII, No. 694., pp. 238-242. London, Oct. 1920.

During an investigation into the spotting of apples, which commenced at Wisley in 1915, several fungi were isolated from the diseased tissue underlying the surface spots occuring on apples of many different varieties cultivated in Great Britain. These fungi do not usually form fertile reproductive bodies *in situ*; they sporulate, however, when grown in potato mush agar.

Besides *Leptospharia vagabunda, Coryneum foliicolum, Fusarium Mali, Alternaria Grossularieae,* and other readily identified species, the fungi obtained included a number of forms which could not be determined at the time. The latter are now regarded as new species, and technical descriptions are given for the first time using the following names:

Pleospora Pomorum, n. sp., *Polyopeus*, n. gen., *P. purpureus*, n. sp., (and vars. *verus, incoloratus, latirostratus, nigrirostratus*), and *P. Pomi,*

n. sp. (and var. *verus* and *torpidus*), *P. recurvatus*, n. sp., (and vars. *verus* and *curvatus*), *P. aureus*, n. sp., *Fuckelia botryoidea*, n. sp., *Coniothyrium Cydoniae* var. *Mali*, n. var., *C convolutum* n. sp., *Alternaria pomicola* n. sp. *Sclerotium stellatum* n. sp.

1194 – ***Sporotrichum Persicae* n. sp., a Mucedineae Injurious to the Peach in Liguria (Italy).** — POLLACCI G. in the *Atti dell'Istituto botanico dell'Università di Pavia*, Series II, Vol. XVII, Part 5, pp. 203-208, plate. 1 Milan, 1920.

In June, 1920, the Cryptogamic Laboratory at Pavia received from Albenga some peaches in different stages of development for examination. On the pericarps of all the fruits, there were white incrustations or patches; these were usually very clearly marked out, the edges being seldom irregular. Many of the peaches were covered with a numerous small spots, whereas on others the patches were few, but very extensive, sometimes invading the greater part of the pericarp. The colour of these incrustation was nearly always pure white, but in some cases there were blackish nuclei present.

From information received from Albenga, and from a visit paid there by the author, it appeared that this disease, which had never before been seen by the horticulturists of the district, was both serious and wide-spread. The author himself observed it on all the peaches he examined in the region of Loano.

The varieties most attacked were "Trionfo," "Amsden" and "Sneed."

The pericarp beneath the patch does not rot, but thin white incrustations form which spoil the fruit, and often render it unfit for sale. On cutting the peach, the tissue under the skin seems to be unaltered Among the innumerable hairs of the pericarp, and only where the patches are present, there appears, however, a quantity of hyphae, often accompanied by the conidia of a mucidinea described by the author as a species new to science, under the name of *Sporotrichum Persicae*, and which he considers to be the cause of the disease. The author suggest the name of "peach sporotrichosis" for the disease.

Artificial cultures of the micromycete were obtained by introducing portions of *Sporotrichum* taken from the characteristic patches of "sporotrichosis" into a medium composed of boiled peach pulp and agar. After two or three transplantations, pure cultures with the characters peculiar to the fungus are obtained. If a small piece of the fungus is removed with fine forceps from the patches of "sporotrichosis," or taken from the artificial cultures and placed on green peaches which are still growing on the tree, alterations of the pericarp very similar to these previously described make their appearance after a fortnight. Needle-inoculations gave no positive results.

Bordeaux mixture applied to the diseased peaches has had no good, practical effect. The author believes that it is necessary to treat the fruit with copper salts while they are still very young, and to use mixtures containing some adhesive substance, because, otherwise, the long hairs

covering the pericarp and forming a refuge for the mycete, prevent the drops of the spray from remaining on the peach.

Practical experiments carried out with a view to determining the effect of copper sulphate upon the germination of the conidia of *Spor. Persicae* taken from artificial cultures, have shown that very small quantities of a solution of copper sulphate are enough to kill the conidia, and thus prevent their germination.

1195 – **Disease and Pests of Pine-apple in Cuba.** — See No. 1119 of this *Review*.

WEEDS AND PARASITIC FLOWERING PLANTS

WEEDS AND PARASITIC FLOWERING PLANTS

1196 – **The Prickly Pear in Australia.** — ALEXANDRA, W. B. (Science Abstractor in *Institute of Science and Industry, Bulletin No.* 12, pp. 5-48 Melbourne, 1919; II. CAMPBELL W. S., *Queensland Agricultural Journal*, Vol. VIX, Pt. 2. pp. 73. Brisbane, Aug. 1920.

Although the tree pear has become naturalised in all Australian States, it is at present only in Queensland and New South Wales that prickly pears have become a pest. The area infested contracts with the areas under the principal crops 1916-17, as follows:

Crop	Area in Acres
Prickly Pear	**22 208 000**
Wheat	11 532 828
Hay	2 671 862
Oats	844 130
Green Forage	390 867
Maize	360 072
Orchards and Fruit Gardens	257 687
Total under Crops	**16 806 380**

The rapidity at which the prickly pear spreads can perhaps be sufficiently gauged by the fact that it has overspread some 23 000 000 acres in less than 50 years. There is little doubt that cattle and horses are more important agents in spreading the pear, than birds.

UTILISATION: *Food for Man.* — Reference is made only to use in other countries, of the Barbary Fig., *Opuntia Ficus-indica*, *O decumana*, and *O. streptacantha.*

Fodder for Cattle (1). — The Pest Pear (*Opuntia inermis*) has proved of considerable value as a fodder reserve in case of drought, but four experiments carried out with the feeding of this pear to steers, dairy cattle, calves, and sheep, point to the following conclusions: (1) Preliminary treatment is necessary prior to the feeding of stock. It may be harvested, sliced by hand or machine and fed in troughs, or singed, roasted or boiled. The last was found to be the least satisfactory. (2) This pear is not highly palatable to any of these animals, its chief utility is as an emergency drought feed. (3) For full maintenantce of stock, a

(2) See *R.* March 1915, No. 209; Nov. 1915, No. 1180, Feb. 1917, No. 169. (*Ed.*).

supplementary protein supplying feed is required, i. e. linseed meal, cocoa nut oil cake, maize oil meal, lucerne or cowpea (hay or chaff). (4) The inclusion of apreciable quantities of prickly pear in rations for milch cows lowers the percentage of butter fat, and reduces the total fat yield, but may slightly increase the flow of milk. The milk is suitable for cheese making purposes. For milch cows it is more advantageous to use only part and not the whole as roughage ration. 5) *O. inermis* is a suitable feed for cows in calf if the deficiency of protein is added, also for weaned calves, during drought. (6) For dry sheep, the ration must also include some kind of rough chaff, and in any case is unsuitable for ewes rearing lambs, or for lambs. Blood-meal can be used instead of linseed or other meals to provide the necessary protein. (7) Cattle must have access also to edible scrub or herbage supplying protein. (8) In hot weather all stock fed with prickly pear require water.

Green Manure. — Potash is added to soil by this means (1) as well as its value as humus. In Ceylon, India, South Africa and Mediterranean Countries, and occasionally in Australia, it has been tried with success.

The products obtained from the prickly pear by the process of destructive distillation were investigated in 1913 (Cambpbell). The liquid distillate, crude tar and charcoal were constituted as follows ; Water, 88.4 %. — Acid (as acetic) 0.154 % — ammonia, primary and secondary amines (as ammonia) 0.005 % — tertiary amines (as pyridine) — crude Tar. 1 % — Charcoal 4 %.

As a source of alcohol and the utilisation of the fibre for conversion into paper pulp or board have not proved economical proceedings in Australia.

Eradication. — 1. *By Mechanical Means.* — The only adequate method suggested at present is the rolling down of the infested area, followed by collecting and burning or ploughing it in as green manure.

2. *Poisoning.* — The materials found more or less injurious to prickly pear were :— antimony chloride — arsenic mixtures — barium chlorate, — cadodylic acid — chlorine — chloroform — copper sulphate — ferrous sulphate — formaldehyde — lysol — mercuric chloride — mercuric oxycyanate — phenol — phosphorus — potassium compounds — sodium compounds — sulphuric acid — zinc chloride and zinc sulphate. Four methods were employed : Solid injection — liquid or solution injection, — spraying — gas or vapour charges.

The compounds of arsenic were found undoubtedly the most efficacions and ecomical poisons, and during the last year of experiments only the three following specifics were given further trials viz : Arsenic acid (crude arsenic pentoxide) — arsenious chloride (arsenic trichloride) — arsenite of soda and salt (arsenic trioxide, caustic soda and common salt)

The first is the most poisonous specific, but is unobtainable in Australia ; arsenious chloride is the only specific available where the pear is so dense that it can only be gassed ; arsenious acid " white arsenic " used in

(1) See *R.* Nov. 1915, No. 1131. (*Ed.*)

solution together with caustic soda is cheaper, but not so efficient. It is less dangerous to use but involves the use of large quantities of water and two spraying operations.

The cost under present circumstances amounts from £2.10s to £4 per acre.

3. *Employment of Natural Enemies* (1). — In many localities the Tree Pear (*Opuntia monacantha*) has been almost or quite exterminated by a cochineal insect (*Coccus indicus*, Green.). The author suggests that it is possible that a hybrid might be produced between the Pest Pear and the Tree Pear, and that the cochineal insect might be induced to feed on this, and after a time be transferred successfully to the other parent. A common snail (*Helix aspersa*) is adicted to prickly pears at Sydney and it is also suggested that a very large snail (*Achatina fulico*) from Africa should be introduced into infested areas.

The Travelling Commission of the Queensland Government prepared a list of number of other insects which live entirely on prickly pear in America, are not known to feed on any other type of vegetation, and which can be recommended to be introduced into Australia with proper safeguards, and also recommended that two fungi (*Gloeosporium lunatum* and *Sclerotium* or *Sclerotinia Opuntiarum*) which cause diseases of prickly pear in South America should also be introduced. The Government Advisory Council has received a grant for research work on the prickly pear problem. The author adds a list of the recommendations of the executive committee for this work, and also an appendix giving the sources of information and bibliography employed in this article, and the advised precautions which should be taken if arsenious chloride is used on infested areas.

II. — Apparently the only effective method of eradication in the infested area in New South Wales was found to be by burning, but in most cases this was inpracticable. The author considers that the only method which will keep the pear in check and ultimately eradicate it is the application if intense heat.

The heat formed by the combustion of 1.7 volumes of oxygen, and 1 volume of acetylene (3482° C) applied by specially constructed blowpipe, or even a heat of 1000° C would entirely melt the pear like wax. Although perhaps an expensive process, the results would prove exceptionally beneficial to Queensland.

1197 - **Efficiency of Indigenous Insect Pests as a Check on the Spread of *Lantana aculeata* (= *L. Camara*) Verbenaceae in India.** — Ramachandro Rao., in *Memoirs of the Department of Agriculture in India. Entomological Series*, Vol. V. No. 6. pp. 239-314, figs. 3, pl. 14. Calcutta, June 1920.

The author undertook the study of the indigenous insects parasitic on *Lantana aculeata* L. (= *L. Camara* L.), in India, with a view to ascertaining the existence of species which serve as an efficient check on the spread of this Verbenaceae, which was first introduced into the country as an ornamental plant, and has since become distributed at random

(1) See *R. March*, 1916, No. 365. (*Ed.*)

and is now a troublesome weed throughout India and Burma The shrub is really a denizen of the Tropical American Region and the distribution extends to Ceylon, Hong-Kong, Singapore, Mauritius, Seychelles, and in fact to the whole of Tropical Asia and Africa.

In Hawaii, successful results have been achieved by the introduction of Mexican insects by KOEBELE selected and set free by Dr. PERKINS; but conditions are unfavourable to importing foreign insects into India. A shipment of the seedfly (*Agromyza* sp.) was reported to have been made from Hawaii to New Caledonia, Fiji Isles, and Australia. But as the flora of India includes a number of other useful Verbenaceae spp., and seeing that the seed-fly is liable to attack these also, it is not considered prudent to introduce the said fly into India.

The author has discovered that in India and Burma, *L. aculeata* is subject to the attacks of numerous insects (he has enumerated 148 species), to two fungus diseases and to the attack of dodder (*Cuscuta* sp). Few of these are however really important.

The most efficient undoubtedly is the Plume-moth (*Platyptilia pusillidactyla* Wlk.), Which is found throughout India, except perhaps in Punjab. It breeds also in *L. indica* and *Lippia germinata*; but is itself kept in check by parasites.

The various microlepidopterous caterpillars such as *Lobesia aeolopa* Meyr., *L. genialis* Meyr., *Cacoecia epicyrta* Meyr., are not found in sufficient numbers to prove efficient checks.

The Lymantriads, such as *Euproctis* spp. and *Olene mendosa* Hb. would be efficient, if they occurred in sufficient numbers, but as they also attack cultivated plants, they cannot be encouraged

The caterpillars of other lepidoptera *Hypena* sp., *Diacrisia obliqua* Wlk. var. *confusa* and *todara*, *D. flavens* Moore, *D. indica* Guer., *D. lubricipeda* (?), *Pericallia ricini* Fb., *Amsacta albistriga* Wlk., *Creatonotus gangis* L., *Celama internella* Wlk., *C. fasciata* Wlk., *Chionaema peregrina* Wlk., *Asura rubricosa* Moore are chiefly leaf-feeders and are not so useful as those that feed only on the flowers and thus directly control seed formation.

The dipteron *Asphondylia* sp., which feeds on the pollen masses and causes the formation of a gall, even when it occurs in abundance, is of low efficiency, and as it is very probably identical with *A. sesami* Felt., which is fairly serious on sesame in Coimbatore and Nagpur, it ought not to be introduced into new districts

Amongst the rhynchota, the bugs *Plautia* and *Nezara*, etc., are found feeding on fruits, whilst others attack flowers e. g. *Campylomma* sp., but it is doubtful if the bugs on the whole, are really efficacious. *Orthezia insignis* Doug., which has been unconsciously introduced into the Wynaad, is on the other hand an effective check on *Lantana*, as it is known to kill the bushes outright; but owing to its well known polyphagous nature, it is an insect which ought not to be tolerated.

The result of these investigations appears unmistakeably to indicate the absence at present of any indigenous insect capable of checking the

spread of *Lantana* in India. However, at least in parts of India, some insects are sufficiently numerous to serve as auxiliaries if an efficient insect of the nature of the *Agromyza* sp., were to be introduced.

1198 – **Eradication of Silver Fern in New Zealand.** — DEEM, J. W., in *The New Zealand Journal of Agriculture*, Vol. XX No. 6, pp. 358. Wellington, June, 21 1920.

From the experience of settlers, and according to the writer's own observations in North Island there appear to be only two effective methods of treatment where silver fern (*Pteris scaberula*) is prevalent. First, to subdivide the area and stock heavily with sheep or cattle, according to the conformation of the land. As the patches of fern are crushed out they should be surface sown with a heavy seeding of grass suitable to the district. If the land is steep, the mixture should contain a large percentage of *Danthonia pilosnia*. Secondly, to fire the patches of fern, preferably about the end of March, but this should not be undertaken unless the fern is in a very dry condition. As soon as the ashes are cool, a heavy seeding of grass is recommended and this to be sown before rain has fallen.

Pteris scaberula is also known as carpet fern, creeping fern, hard fern and pig fern.

INJURIOUS INSECTS AND OTHER LOWER ANIMALS

GENERAL

1199 – **The Selection of Food Plants by Insects with Special Reference to Lepidopterous Larvae.** — BRUES, C. T. (Bussey Institute, Harvard University), in *The American Naturalist*, Vol. LIV No. 633, pp. 313-332. Lancaster, Pa. July-Aug. 1920.

Nearly all the larvae of the Lepidoptera are phytophagous at the present time and according to the author there can be no question that since the order has existed, this condition has prevailed. Owing to the change in the form of the trophi during metamorphosis by which the adults develop haustellate or sucking mouthparts, the food of the imagines is entirely different from that of the larvae, and they subsist on liquids, mainly the nectar of flowers.

Although nearly all the species feed on plant food, a few isolated cases feed on other living insects or on material of animal origin ; wool, horn, beeswax, etc. The prey in the second case almost always consists of Coccids or Aphids where predatory caterpillars are concerned. Other interesting examples are the *Feniseca tarquinius* which feed on plant lice on the alder and the *Lycaena arion*. The larva is herbivorous in its early stages, but enters the nest of ants to prey upon the anti-larvae during its final period of growth. No less than 75 species of European Lepidopterous caterpillars are known to be occasionally predatory through temporary aberrations of their trophic instincts. Such plasticity of behaviour leads to the conclusion that the origin of sarcophagy in Lepidoptera is due to independant changes which have become firmly fixed in individual species or genera.

The use of Phanerogams as food plants is very general, but it is noti-

ceable that in a former tabulation (SCUDDER) of the food plants of butterflies of eastern N. America, the following families are entirely omitted:— Iridaceae, Orchidaceae, Caryophyllaceae, Euphorbiaceae, Vitaceae, Primulaceae, and Rubiaceae. Observations as to the habits of special species seems, however, to indicate that the selection of food plants must be considered as dependent upon one or several of a number of factors namely:

1) The odour of the plant and also its taste; for example, the oligophanous species occuring on Cruciferae, Umbelliferae and various Compositae, and the selection by the same insect of several plants in a family like the Solanaceae where a more or less similar odour does not become a family characteristic.

2) Some attribute of the plant.

3) A similarity in the immediate environment or general form of the food plant. Certain oligophanous and polygaphagous caterpillars feeding mainly on trees or shrubs, e. g., as the gipsy moth, *Cercropia* moth, etc. and some of the Arctiid moths that feed upon a great variety of low plants.

4) Apparently chance associations that have become fixed, which seem to be analogous to structural mutations.

The food habits are tabulated as follows:

Melitaeids	Various plants
Limenitids	» »
Apaturids	» »
Ruralids	» »
Urbicolids	» »
Papilionids	» » (Several groups with particular food plants)
Vanessids	Urticaceae, Compositae, etc.
Argynnids	Violaceae exclusively
Brenthids	Violaceae generally
Pierids	Cruciferae essentially
Anthocarids	» »
Satyrids	Graminae mainly
Sub Group Thymelicines	» »
Urbicolines	» »
Cyclopidines	» »
Hesperiines	Leguminosae and various other plants
Coliads	» almost entirely
Gonepterygids	Rhamnaceae
Lycaenids	Diverse food habits
Chrysophanids	Polygonaceae almost exclusively

MEANS OF PREVENTION AND CONTROL

INSECTS ETC., INJURIOUS TO VARIOUS CROPS

1203 – **On *Bruchophagus funebris* Clover and Alfalfa Seed Chalcis Fly.** — URBAHNS, T. D. (Entomological Assistant, Cereal and Forage Insect Investigations), in the *United States Department of Agriculture, Bulletin* No. 812, pp. 1-19, tables 2, figs. 2, pl. 8, Bibliogr. of 11 publications. Washington, D. C., May 31, 1920.

Seed pods of alfalfa examined in California in April 1915 showed 39 % of the seeds to be infested. Periodical examination indicated that attacks increased until mid May, but from then until mid July the average dropt to 28 %, this being the time when pods were forming in great abundance. The average from then until the end of September was 49,5 %, and seed pods collected in mid October gave 85 % infected seed. After the harvesting of the latest seed crops, and after spring irrigation which hastens emergence of adults, there was a sudden scarcity of eggs, breeding larvae and pupae in the field.

Experiment proved that the pathenogenetic habit is well established in the females of this species.

The most practical methods of prevention are mostly cultural methods such as the burning over of infested areas to destroy hibernating larvae, and the cultivation of alfalfa seed fields during the winter, and thus covering the infested seeds containing these larvae. Irrigation in early spring is advised owing to the fact that the emergence of the pest is accelerated from seeds of the newly forming crop which would otherwise become sufficiently dry to force many of the larvae into a resting period. Actual destruction by irrigation has proved unpractical. Cutting early plants on waste areas ; the careful cutting of hay crops, pasturing before growing seed after the removal of the first crop, (but avoiding the mistake made by pasturing badly infested areas not worth harvesting) ; care taken to secure a heavy setting of pods with the first bloom and removing the crop from the field as early as possible : these are all essential in order to avoid a high percentage of infested seed.

As a result of the increased abundance of chalcis flies in the summer, an attempt to grow a second crop of alfalfa seed in a single season is destined to failure.

The larvae of a predacious midge described by FELT as a *Lestodiplosis* sp., apparently destroy the larva of *B. funebris*. It seems probable that they confine themselves to cracked and broken seeds and where the larva is exposed.

In addition to the hymenopterous parasites previously mentioned by the author (1), the following are included : 1) *Tetrastichus bruchophagi* Gahan in Northern United States, especially California. This has been observed to destroy about 50 % larvae 2) ; *T. venustus* Gahan found in California and. Arizona ; 3) *Liodontomerus insuetus* Gahan, New Mexico, Kansas, Arizona ; 4) *Habrocytus medicaginis* Gahan in California, Idaho, Utah, Arizona, South Dakota, Kansas, New Mexico, Nevada and Oregon 5) *Eupelmus* sp. in California.

(1) See *R.* June, 1919, No. 797. (*Ed.*)

The life history, distribution, and means of dispersion of *B. funebris* are described in detail.

1204 – ***Bruchus quadrimaculatus*, the Cowpea Weevil in Texas.** — PADDOCK, F. B. and REINHARD H. J., in *Texas Agricultural Experiment Station, Agricultural and Mechanical College of Texas, Bulletin* No. 256, pp. 92. figs. 3, pl. 6. College Station' Brazos County, Texas Dec. 1919.

Bruchus quadrimaculatus Fabr. (Cowpea weevil) seems to be found in every locality in Texas wherever any variety of *Vigna Catjang* is grown. The climatic conditions of the State are especially favourable for the development of the weevil. All varieties of cowpeas grow in the locality are subject to attack, and no preference is shown by the weevil to any particular variety. The annual loss in Texas of the *V. Catjang* crop, resulting from this insect, is very great.

Under favourable condition, the life cycle from egg deposition to emergence of the adult may be completed in less than 3 weeks. The weevil is very prolific. An average of 106 eggs have been produced by females during the warm season. Temperature has a positive influence on the rate of oviposition and the length of the various stages of the weevil. In stored seed, breeding is practically continuous throughout the year. Most weevils undoubtedly hibernate in stored seed. Nine generations of weevils occur in a year at the College Station.

The larva of *B. quadrimaculatus* is attacked by the parasite *Bruchobius laticeps* Ashmead. The minute egg parasite *Uscana semifumipennis* Girault destroys the weevil eggs in great numbers. The weevil is, however, not sufficiently checked by its natural enemies.

Proper harvesting will greatly reduce the initial infestation of the field. To prevent seed from becoming reinfested, it must be stored in tight bins or containers and not in sacks. The weevil can be destroyed in any stage by heating the infested seed to a temperature of 146°F for an exposure of 15 minutes which will not affect the germination of the seed. Fumigation with carbon bisulphide is an effective means of destroying the weevil, and used at the rate of 4 lb., per 1000 cub. ft., of space with a 24 hour exposure, it will kill the insect in any of its stages. It should be remembered that fumigated or heated seed is, contrary to the general belief, always subject to reinfestation by the weevil.

1205 – ***Rhyparida morosa* a Leaf Eating and Stem-Boring Beetle on Sugar Cane in Queensland.** — JARVIS. E. (Assistant State Entomologist) in the *Queensland Agricultural Journal*, Vol. XIII, Vol. 6, pp. 274-276, Pl. 1. Brisbane, June, 1920.

Report of the infestation of third "ratoons" (new shoots springing from the sugar-cane root after cropping) by the chrysomelid beetle in the Cairns district, Queensland, 1920.

The attacked leaves were edged with fragments of dead brown tissue lying between holes and thus cut off from the usual supply of moisture. Specimens were also noticed feeding with similar effects on the leaves of "blady grass" (*Imperata arundinacea*), the native food plant of this

insect. Experiments proved that three beetles in four days severely damaged a plant about 15 in., high.

The larva was found to have eaten a central tunnel about $^3/_4$ in. long at the base of the sucker, and it was also found in the succulent underground portions of the stalks of the "blady grass"; in all probability a certain percentage of young ratoon suckers growing close to the area covered with the former plant are often killed by this insect.

A description is given of the larva, pupa and the adult beetles. The last are noted to be somewhat gregarious in habit, and have often been found on the ends of young twigs of *Ficus opposita*.

1206 – **On *Prosayleus phytolymus* the Dicky Rice Weevil in Queensland.** — GALLARD, L., in *The Agricultural Gazette of New South Wales*, Vol. XXXI, Pt. 4, pp. 280-284. figs. 3. Sydney, April 3. 1920.

This has been a serious pest in orchards and nurseries for the last 15 years in Cumberland but no previous attempts had been successful in the discovery of the larvae of *Prosayleus phytolymus*. The writer, however, managed to secure both pupae and full fed larvae at various intervals in the year. The behaviour of these indicates that the pupae are not ready to emerge until the end of February, in conjunction with spring growth. The first brood takes place in October and November.

The insects live chiefly on young shoots and foliage, and young fruit is also attacked, but the question had remained unanswered as to why young trees eaten badly never made much growth. The reason can now be given owing to the discovery of larvae damaging the roots. Chafing on the bark and in many cases distinct corrugations along the roots could be traced. In this respect the habits of the larvae are almost identical with the apple root borer (*Leptops hopei*) although much smaller in appearance.

Preventive measures. — By shifting beds as the weevils appeared in any quantity an example is given of a fine plot of citrus trees almost free from any trace of attack. Where infected plots in other cases had been enclosed as poultry runs, the result was found advantageous. Reports with regard to the use of arsenate of lead sprays are contradictory but it is advised if used judiciously.

The discovery of a number of small carab beetles and Therevid fly larvae both very carnivorous, during the search for the larvae in question, suggests other possible modes of treatment and needs further investigation, especially as there has been a gradual decrease in trouble in the areas where these specimens were also found.

1207 – **Root-bark Channeller of Citrus *(Decilaus citriperda).*** — TRYON, H. (Entomologist), in the *Queensland Agricultural Journal*, Vol. XIII, Pt. 2, pp, 71-82, pl. 3. Brisbane, Feb. 1920.

The Director of Fruit culture A. H. BENSON, devised a field experiment to be conducted by J. MITCHELL in 1918 aiming at the subjugation of this pest, associating with him for the purpose a Montville Fruit Growers Experiment Plot Committee. In 1919 the author was sent to inquire into

the trouble, and gives details of the symptoms, the citrus species subject to the insect attack or immune, the factors contributory to attack, and a description of the insect and its habits with suggested remedies to combat the pest.

Results show that all varieties of citrus producing ordinary oranges, especially those of the mandarin type are favoured by the beetle. The lemon is also attacked in some instances (trees on non-lemon stocks, however, afforded the instances referred to). Not a single instance of a Seville orange tree showing injury was observed. Grafted or worked trees experienced the ill effects from attacks to a much greater extent than seedling trees. Deep rooting trees as ordinarily understood, escaped attack or injury ; shallow rooting ones the reverse. Trees that experienced most damage were those in which natural decadence had commenced or been accelerated in its progress by uncongenial soil conditions, defective treatment, soil depletion and adverse seasons, rendering the superficial soil unsuitable generally for plant growth.

Observations show that the floor and walls of the chamber at the head of the gnawed channel in which the grub resides produces constantly little droplets of gum that redden as they dry and fills its chambers not with the by-products of digestion, but with triturated fibre principally. In addition to the special gum exudation, on the sides of the channel and on its base to a less extent, issues from the active cambium and other elements of cortical tissue, a gelatinous substance that is of orange colour and hardens on exposure. This lining forms plant tissue also, and in fact is the commencement of the formation of callus, which will itself serve to protective living wood beneath from further destructive change. Circumstances do not always favour the development of this callus and then fatal injury may result.

With regard to preventives and remedies the author suggests the following : (1) As the insects evidently gain access to the roots at the base of the tree trunk or collar it would appear that they might be prevented by placing in the soil some repellant substance ; (2) at a later stage the new insect fumigant Para-chloro-benzine has been found to succed where others have failed ; (3) some fluid contact insecticide, not itself a plant tissue destroyer may be used, as the beetle is accessible in its " burrow " when the soil is dry, e. g. kyanit ; (4) judicious use of fertilisers, etc.

Further experiments are needed, however, as a guide to the best procedure, as a mode of treatment has not yet been discovered that can be relied upon for successful results.

1208 – ***Lyctus brunneus*, Powder post Beetle and its Parasite in Southern Queensland.** — Froggatt, W. W. (Government Entomologist), in *The Agricultural Gazette of New South Wales*, Vol. XXXI, Pt. 4, pp. 273-276, Sydney. April 3, 1920.

Specimens of this beetle previous to their discovery in Australia, were elsewhere identified under the following synonyms :— *L. cobydiodes* (England), *L. glycyrrhizae* (France), and *L. rugulosus* (South Sea Islands).

It is certain that the eggs or young larvae are in the sapwood when the timber is sawn up and used for building purposes, but their presence is not evident until about 12 months after the house is erected. After a series of years the infected wood is reduced to a mass of wood dust, held together by an outer thin skin of wood perforated with fine holes. The larvae may be found in timber wherever unseasoned wood (or sapwood) has been worked up in both soft or hard woods.

There has been no previous record according to the writer, of a parasite attacking or checking the spread of this harmful beetle. But, in 1919, a badly infested punctured board of " blue fig " (*Elaeocarpus grandis*) from which powdered dust was falling, was kept under observation for several months. Several adult beetles then emerged in May, identified as *L. brunneus* and at the end of this month, their hymnoptera parasite, a Braconid wasp, 4 mm., long, was first noticed proceeding from the holes in the board.

A description is given of the insects belonging to the genus *Lyctus* as a whole and also of the appearance of the parasite.

Other members of thi genus elsewhere recorded as powder-post beetles are : *L. unipunctatus*, the most common and destructive, and *L. opaculus* in stems and canes of grape vines (in the United States), and *L. striatus* in red oak (*Quercus rubra*) floors (in Michigan).

1209 – **Damage Caused by White Ants Relative to the Temperature of the Subsoil in Bihar, India.** — See No. 1053 of this *Review*.

1210 – **Formosan Termites and Methods of Preventing Their Damage.** — Oshima Masamitsu (Institute of Science. Govt. of Formosa), in *The Philippine Journal of Science*, Vol. XV, No. 4, pp. 319-383, pl. 13. figs. 5, tables 43. Manila, Oct. 1919.

In Formosa and Japan 14 species of termites are found, four of which, namely, *Coptotermes formosanus, Leucotermes speratus, Leucotermes flaviceps* and *Odontotermes formosanus* are known as pests of wooden structures. During the last ten years, investigations were made by the author, especially with regard to the first mentioned species. After a thorough study of the habits of these termites, experiments were made with 45 species of native and exotic woods.

Comparative results from two experimental areas led to the conclusion that the teak ((*Tectona grandis* L.) and the cypress pine (*Callitris glauca*) are absolutely immune timbers.

Detailed records indicate that resistance is neither due to physical properties nor to the inorganic compounds contained in the timber. It is however due to the organic compounds (oils or alkaloids) repellent or distasteful to the termites, and these are extracted by means of benzene or alcohol. The cypress pine contains about 1 % of volatile constituents according to former investigations, but nothing definite can yet be stated concerning teak. The principal ingredient of the volatile constituent is guajol 60 % which is said to be highly antiseptic. The Foochow cedar (*Cunninghamia sinensis* R. Br.) the principal building material in South China contains " cedrol " 4.6 %, another sesquiterpene alcohol but not ident-

ical to guajol. This cedar is highly resistant but not immune. The Randai cedar (*Cunninghamia Konishii*) contains 1.62 % cedrol, but its resisting powers have not yet been investigated.

PREVENTIVE MEASURES. — As the sesquiterpene alcohol seemed to be one of the chemicals effective in preventing attack, work was extended to discover some home product from which this could be obtained, for use in conferring immunity upon non resistant timbers. Camphor oil was examined and analysis proved that this contained 25 % of the required alcohol. To test its effect, a fixed quantity was injected into Japanese pine It was found that the controls were seriously attacked after five to seven days while the treated blocks remained unattacked for about one year. After numerous experiments as to the result of treatment with different percentages of camphor green oil solution from the economical standpoint, the mixture of "Niizu" neutral oil and the camphor green oil (10% solution) was found the most advantageous.

The effectiveness of other chemicals was tested in combative measures against the termites *Odontotermes formosanus*. After three years trial, the only four chemicals which proved effective were the high fraction of coal tar, mainly consisting of anthracene oil distilled at temperature above 270°C, The percentage of damage was inversely proportional to the amount of the anthracene oil. The author recommends the use of this oil in the field but not for use in houses on account of the staining of timbers.

The termite proof concrete layer has been found entirely satisfactory in preventing the entrance of termites from the ground. Lime mortar is strictly forbidden as this is readily attacked.

INTERNATIONAL INSTITUTE OF AGRICULTURE
BUREAU OF AGRICULTURAL INTELLIGENCE AND PLANT DISEASES

INTERNATIONAL REVIEW OF THE SCIENCE AND PRACTICE OF AGRICULTURE

MONTHLY BULLETIN
OF AGRICULTURAL INTELLIGENCE AND PLANT DISEASES

INDEX
Year 1920

ROME
PRINTING OFFICE OF THE INSTITUTE
1922

THE INTERNATIONAL INSTITUTE OF AGRICULTURE

Origin of the Institute and Summary of the International Treaty

The International Institute of Agriculture was established under the International Treaty of 7 June 1905, which was ratified by forty governments. Twenty-two other governments have since adhered to the Institute.

It is a Government institution in which each country is represented by delegates. The Institute is composed of a General Assembly and a Permanent Committee.

The Institute, always confining its attention to the international aspect of the various questions concerned, shall:

(*a*) collect, study and publish as promptly as possible, statistical, technical, or economic information concerning farming, vegetable and animal products, trade in agricultural produce, and the prices prevailing in the various markets;

(*b*) communicate the above information as soon as possible to those interested;

(*c*) indicate the wages paid for farm work;

(*d*) record new diseases of plants which may appear in any part of the world, showing the regions infected, the progress of the diseases, and if possible, any effective remedies;

(*e*) study questions concerning agricultural co-operation, insurance and credit from every point of view; collect and publish information which might prove of value in the various countries for the organization of agricultural co-operation, insurance and credit;

(*f*) submit for the approval of the various governments, if necessary, measures for the protection of the common interests of farmers and for the improvement of their condition, utilizing for this purpose all available sources of information, such as resolutions passed by international or other agricultural congresses and societies, or by scientific and learned bodies, etc.

PERMANENT COMMITTEE

OF THE INTERNATIONAL INSTITUTE OF AGRICULTURE. — YEAR 1920.

President : His Ex. EDOARDO PANTANO, Senator, *Delegate of Italy.*
Vice-President : M. LOUIS-DOP, *Delegate of France.*

List of the Delegates forming the Permanent Committee :

1	ARGENTINE REPUBLIC.....	I	Dr. OCTAVIO PIÑEIRO SORONDO.
2	AUSTRIA	I	. . . . .
3	HUNGARY	I	. . . . .
4	BELGIUM.....	IV	O. BOLLE.
5	BELGIAN CONGO.....	V	O. BOLLE.
6	BRAZIL	I	D. DE CAMPOS, Commercial attaché to Embassy.
7	BULGARIA.....	III	P. HADJI-MISCHET
8	CHILE	II	E. VILLEGAS, Minister Plenipotentiary.
9	CHINA	I	TCHOU YIN Legation Secretary.
10	COLOMBIA	V	Prince RUFO RUFFO.
11	COSTA-RICA	V	Prof. RODOLFO BENINI.
12	CUBA	V	Dr. F. F. FALCO.

CONTENT

PREFACE

This index though arranged alphabetically retains the grouping of the subjects used in the *International Review*.

Except in the case of the original articles, which are numbered according to their pages, the numbers of each subject refer to the paragraphs in the International Review.

The index consists of three parts: one of the original articles, one concerned with Agricultural Intelligence and the last with Plant Diseases.

In case of errors in the Bulletin with reference to scientific terms and the names of authors, it should be noted that the correct spelling can be relied upon in the Index.

The Table used for the conversion of the Weights, Measures and Money values of the various countries to the Metric System is included. A list is also given of the Periodical Publications reviewed by the Bureau.

This Index was prepared by redacteurs : Dr. Giulio Provenzal and Prof. Giulio Trinchieri, the latter compiled the Index of Plant Diseases. The whole was adapted to the English Edition by rédactrice Miss M. L. Yeo.

I. — INDEX OF ORIGINAL ARTICLES

A) INDEX OF SUBJECTS

pagation 195. On the Behaviour of Hybrids Resulting from the Crossing of a Mutant with the Original Variety, 310. Australian Varieties of Obtained by Hybridisation Wheat andSelection, 311. Experiments in Hybridisation between Certain Kinds of Wheat in New South Wales, Australia, 312. Synthetic Production, by Selection and Crossing, of Varieties of Maize Very Rich in Gluten in the United States, 313. Improvement of Potatoes through Hybridisation and Selection of Bud Mutations, 314. Investigations on the Variability and Heredity of the Characters of Certain Species of *Lolium*, 315. Crosses between the French " Chevrier " Bean with Green Seeds and Other Varieties, 316. Genetic Factors that Determine the Formation of Anthocyanin in Peas, 317. On some Attempts to Cross-Pollinate Peas and Beans, 318. On the Heredity of Red and Yellow Colours in *Beta*, 319. The Need for Extending and Intensifying the Line Breeding of Wheat in Spain, 406. Correlations between Certain Characters of the Ear and the Yield of Grain in Maize, 407. Determination of the Percentage of Cross Fertilisation between the White and Yellow Varieties of Sorghum, 408. The Improvement of Cereals, Flax and Rye-Grass in Ireland, by Selection and Crossing, 409. Determination of the Percentage of Cross-Fertilisation between *Medicago sativa* and *M. falcata*, 410. On the Need for the Selection of Turnips in New Zealand in Order to Obtain a more Uniform Product, 411. Degeneration in the Sugar-Beet and its Remedy in Selection, 412. Geographical and Taxonomic Researches undertaken in order to establish a Rational Basis for the Selection of Tea, 413. Improvement of Coffee in India, 414. Influence of Foreign Pollen on the Shape of the Fruit of the Mother Plant in Certain Crosses between *Vanilla planifolia* and " Vanillon, " 415. Possibility of an Intranuclear Cross in Homozygotes, 506. Improvement of Ligowo Oats by Crossing with Brie Oats and by Selection, 507. Heritable Characters of the Maize : Lineate Leaves, 508. Pedigree Selection of the Local Variety of Rice " Phungtien " in Indo-China, 509. Improvement of Rice by Selection and Hybridisation in Java, 510. On Variation in Tartary Buckwheat *Fagopyrum tataricum* (L.) Gaertn. in the U. S. A., 511. Selection in Soy Beans in the Philippines, 512. Improvement of Sugar Beet by Selection, in France, 513. Variation of the Coconut Tree Observed in Ceylon, 514. Probable Origin of the Dwarf Coconut Tree, 515. Fasciation and Dichotomy following the Grafting of Two Portuguese Vines, 516. Illustration of the Definite Principles of Heredity Hybrid *Catalpa bignonioides* × *C. Kaempferi*, 517. Plant Breeding and Tropical Crops, 632. Studies in the Pollination of Indian Crops, and the Possibility of Improvement by Selection, 633. Criticism on the " Crossing Over " Theory, according to the Calculation of Probabilities, 634. " Pusa No. 4", Indian Wheat Variety Imported into France because of its Early Maturity and Resistance to Scorching, 635. The Traumatic Production of a New Form of Maize: *Zea Mays* var. *polysperma*, 636. Pedigree Selection Applied to the Rice Variety " Nang-Meo," in In-

do-China, 637. Sugar-Cane Breeding in North India, 638. Studies and Observations on the Hybrids of the Genus *Citrus*, 639. A New and Improved Variety of Plum obtained from a Bud Variation of the French " Petite Prune d'Agen", in California, 640. Natural Selection of *Asphodelus luteus* produced by the Action of the Marine Climate at Côtes-du-Nord, France, 719. The " Ardito " Wheat, Obtained by Hybridisation, in Italy, 732. The Production of Wheat for the Highlands of British East Africa by Hybridisation and Selection, 733. Inheritance of Waxy Endosperm Aleurone Colour, and the Correlation between Endosperm Texture and Aleurone Colour of Maize, 734. Selection of Strains of Dent Maize, Considering both Yield and Maturity, adapted to New York State Conditions, 735. Inheritable Characters of Maize: Pistillate Flowered Maize Plants, 736. Pure Line Selections of Rice in Burma, 737. A Mutating Blackberry-Dewberry Hybrid *Rubus caesius* × *R. fruticosus*, 738. Wheat Varieties from the Rieti " Stazione di Granicoltura "; the " Varrone " Variety, 851. Improvement of Native Wheat Varieties by Selection in Bulgaria, 852. Selection of Rice Varieties at the Rice-growing Station of Cantho, Cochin-China, 853. Researches on the Genetic Composition of Certain Types of Peas, 854. The Possibility of the Transmission of Certain Characters of *Papaver somniferum*, 856. Colour Changes in Flowers Connected with Sex in Some *Dianthus Hybrids*, 857. Pollen and Pistil Development in Relation to Sterility in Pure Forms and Hybrids of the Plum, 858. Notice on the Groundnut Selection in Senegal, 870. " Riccio " Wheat, 956. Natural Wheat Rye Hybrids in the U. S. A., 957. Studies on the Heritable Characters of Maize " Brachytic Culms", 958. On the Genetics of " Rogues " Among Culinary Peas (*Pisum sativum*), 959. Selection of Sugar Cane, in Mauritius, Java and in Cochin-China, 960. Studies on the Suckering Habit of Reciprocal Tobacco Crosses: Little Dutch × Cuban, 961. Selection of Hevea at the Agricultural Experiment Station of Bêncat, Cochin-China, 962. Apple-Tree Crossing (*Malus*), 963. Bud Variation of Grape Fruit, 964. Indo-Chinese Rices: Selection, Cultivation and Hulling of Rice in Indo-China, 965. The Sterility of Hybrids from the Mendelian Standpoint, 1076. Experimental Studies on Self-Incompatibility in Hermaphrodite Plants, 1077. Selective Fertilisation in Pollen Mixture, 1078. Wheat Selection at the Cereal Growing Station of Rieti, Italy, 1079. Determination of Certain Hereditary Factors in Wild Hybrid of *Phaseolus vulgaris*, 1080. Case of Complete Dominance of a Quantitative Character in Peas, 1081. The Heredity of the " Adherent Seeds " Character in Peas, 1082. Heredity of the Colour of the Hilum of the Seed of *Vicia Faba*, 1083. " 2714 POJ " and " 2725 POJ " New Javanese Varieties of Sugar Cane Obtained by Crossing; Their Introduction into Cochin-China, 1084. Selection and Crossing Experiments with a View obtaining to New Variety of Tobacco Resistent to *Phytophthora Nicotianae* De Haan in the Dutch East Indies, 1085. Studies in the Pol-
